NATURE OF CAVITATION

By John K. Vennard,[1] Assoc. M. ASCE

Foreword

As part of the program of the Hydraulic Research Committee of the Hydraulics Division, a Subcommittee on Cavitation in Hydraulic Structures was appointed in the summer of 1942. Its first objective was to summarize the facts of cavitation which are pertinent to civil engineering problems and to bring to the attention of the profession certain experiences with the phenomenon. It was decided that this objective could best be attained by the presentation of a Symposium where there would be opportunity for others, by discussion, to report their experiences and thus bring additional facts to light. In this way the store of knowledge could be increased and assembled in convenient form for civil engineering use. The Symposium developed logically into a single paper containing a summary of facts and theories, followed by three papers on practical experiences with cavitation.

After current knowledge of cavitation has been summarized by the Symposium and ensuing discussions, the committee intends to stimulate research activity on the unanswered questions and unsolved problems with the ultimate objective of obtaining, for the designer, sufficient information for cavitation-free designs to be produced with certainty.

Introduction

Cavitation first became an engineering problem about 1900 when, with the use of the steam turbine drive for ship propulsion (which resulted in higher propeller speeds), marine engineers noticed losses of efficiency and destruction of propeller materials. Shortly afterward, mechanical engineers in the hydraulic machinery field encountered the phenomenon as speeds of turbines and pumps were increased. With the design of higher hydraulic structures and with their resulting higher velocities, the civil engineer has become increasingly involved with the cavitation problem.

The generally accepted word for the destruction and subsequent erosion of materials by cavitation action is "pitting." Although the operator frequently refers to the erosion of blades, conduits, piers, liners, etc., as "cavitation," this use of the word is to be discouraged. In brief, the cavity occurs in the liquid, the pitting in the solid boundary. Although the damaging or "pitting" of structural materials by cavitation has been variously attributed to chemical action, electrochemical action (corrosion), high tension in the water, etc., present evidence indicates conclusively that the destructive action is essentially a mechanical one, caused by the impact of liquid masses on the surface of the material. The objective of all designers is to gain sufficient knowledge of the

[1] Asst. Prof., Fluid Mechanics, New York Univ., New York, N. Y.

nature and occurrence of cavitation to prevent it or render it harmless in new designs.

Notation.—The letter symbols, used in this Symposium, conform essentially to American Standard Letter Symbols for Hydraulics (ASA—Z10.2—1942), prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1942. In each paper definitions are introduced where a symbol is first mentioned.

Occurrence of Cavitation

Because liquids encountered in engineering practice cannot expand and cannot support tension stress, cavities will form in them wherever the absolute pressure falls to (or close to) the vapor pressure of the liquid. Two of the factors contributing to pressure reductions may be seen, from the Bernoulli equation for a frictionless liquid—

$$\frac{p}{\gamma} + \frac{V^2}{2g} + Z = \text{constant} \qquad (1)$$

—to be increments of velocity, V, and of elevation, Z. (The remaining symbols in Eq. 1 are defined as follows: p is the pressure per unit area; γ is the specific weight; and g is the acceleration due to gravity.)

Considering the effect of elevation it may be concluded, for example, that (*a*) cavitation is more likely to appear at the top of a conduit than at the bottom, (*b*) higher setting of an hydraulic turbine above tailwater will increase the tendency for cavitation, and (*c*) marine propellers on surface vessels are more susceptible to cavitation than the propellers of submarines (when submerged).

The production of pressure reduction by increase of velocity is familiar to the engineer and usually results from constriction of a passage as, for example, in a venturi meter or aspirator nozzle; the tendency for cavitation to occur in regions of high velocity is obvious.

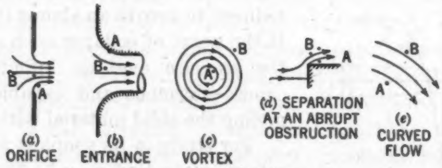

Fig. 1.—Pressure Reductions toward the Centers of Flow Curvatures

A third, and probably the most important (yet most obscure and unpredictable), factor contributing to pressure reduction and cavitation does not appear in Eq. 1. This is flow curvature, the essential facts of which are shown in Fig. 1, points A denoting the areas of low pressure and points B the areas of high pressure. (The effects of curved flow, of course, may be included in the Bernoulli equation if one continues to use the frictionless liquid as a basis for his reasoning. Since flow curvatures are invariably caused, or accompanied,

by separation, eddies, vortices, boundary layer phenomena, etc.—all of which are the result of viscous action—the assumption of a frictionless fluid is not a reasonable one.) Cavitation caused by the pressure reduction at local flow curvatures is probably more prevalent in engineering practice than any other type. These flow curvatures may exist on a boundary surface of relatively easy curvature such as a bellmouth conduit entrance, on the blades of a turbine or propeller, or at abrupt corners which produce flow separation such as gate slots, partly opened valves, or offsets in a boundary surface due to poor alinement. Furthermore, localized regions of high velocity and low pressure exist in the sharply curved flow at the centers of vortices and eddies and produce an irregular and unpredictable type of cavitation.

The relative motion of solid and liquid so necessary to the production of low pressure may be obtained by moving the solid as well as the liquid. Cavitation may be produced this way in reciprocating or vibrating devices such as plunger pumps and submarine signaling diaphragms, and in the vibratory test apparatus used by H. Peters (1).[2] This ingenious device, illustrated subsequently in Fig. 8, has proved to be an efficient means of studying cavitation under controlled conditions and producing accelerated pitting. It consists of a vertical nickel tube which is oscillated longitudinally at 6,500 cycles per sec by magnetostriction. The specimen to be tested is attached to the lower end of the rod which is immersed in a beaker of liquid. Oscillation of the rod causes cavitation in contact with the bottom of the specimen and produces pitting of the type shown subsequently in Fig. 12.

Nature of Cavitation

Cavities produced by low pressures in a flowing liquid prove to be unstable and periodically detach themselves from their point of formation. They may then be swept rapidly downstream into a region of higher pressure where they are suddenly collapsed by the surrounding liquid. As the inward rushing liquid finally fills the cavity, the momentum of the liquid is reduced to zero in an almost infinitesimal time. If the point of collapse is on a solid boundary, the pressure over an infinitesimal area becomes enormous and capable of denting or pitting the solid material within that area.

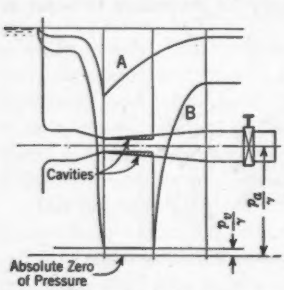

Fig. 2.—Pressure Variations in a Convergent-Divergent Passage with and without Cavitation

For study in its simplest form in the laboratory, cavitation may be produced in a convergent-divergent passage with transparent walls and the foregoing facts may be deduced from observations. In the apparatus of Fig. 2 the conventional hydraulic grade line A will be produced for a small valve opening and small flow rate. At a larger valve opening the higher velocity at the throat of the constricted passage produces an absolute pressure equal to the

[2] Numerals in parentheses, thus: (1), refer to corresponding items in the "Literature Cited," which appears as the last unit of the Symposium.

vapor pressure p_v of the liquid. Then a frothy region appears extending from the throat of the constriction into the divergent tube and the hydraulic grade line B will be obtained. Although the frothy region appears steady to the naked eye, high-speed motion pictures indicate it to be forming and reforming many times every second. The cavities form at the throat, extend themselves downstream, are torn away from the throat, and disappear near region B where the pressure gradient is high. Near B the observation window will be found after a short time to be pitted as if from delicate taps by a sharp instrument. Fig. 3

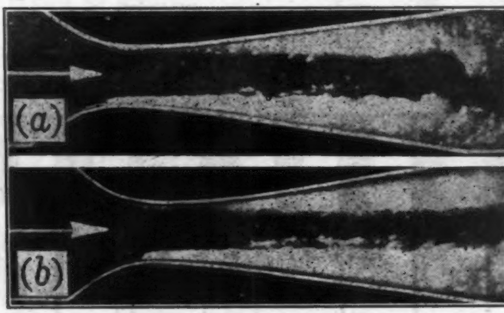

FIG. 3.—CAVITATION IN A CONVERGENT-DIVERGENT PASSAGE

shows cavitation in a divergent passage as photographed by H. Föttinger. Fig. 4(*a*) shows schematically the creation, travel, and collapse of the cavity, and Fig. 4(*b*) shows the same series of events (cavity in black), as recorded by the high-speed camera at the Massachusetts Institute of Technology, at Cambridge, Mass.

It is not implied that all cavitation assumes the form outlined in Fig. 4 but from such tests its essential nature may be deduced and the parts of the process discussed separately. Evidently the cavitation mechanism is composed of four parts: (*a*) The formation of the cavity; (*b*) its travel; (*c*) its final collapse; and (*d*) the consequences of its collapse. Since pitting of adjacent materials is one of the consequences of cavity collapse, a brief statement will be made on the pitting mechanism and on remedies that have proved successful in arresting it. In addition to the foregoing, certain luminous phenomena have been observed in the high-velocity flows on spillway aprons and in the flows downstream from the outlets of draft tubes. Since similar observations have been made on flows both with and without cavitation, it appears that these luminous phenomena are not one of the consequences of cavitation (2).

FORMATION OF THE CAVITY

Because cavities are formed at regions of low pressure and because air or other gases dissolved in liquids come out of solution in these regions it would be expected that the pressures within the cavities are larger than the vapor pressure of the liquid by the partial pressure of the air within the cavity. Measurements

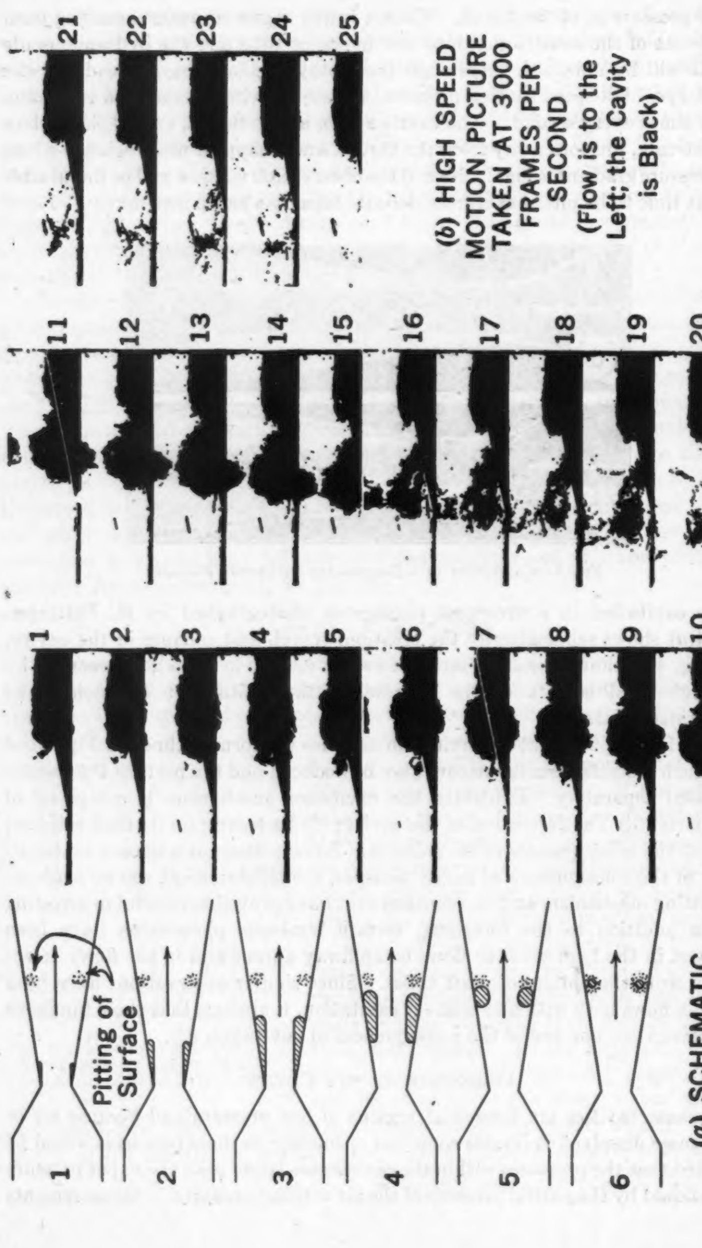

FIG. 4.—COMPLETE CYCLE OF THE FORMATION OF CAVITATION, SHOWING THE COLLAPSE OF A SINGLE CAVITY

(3) have indicated this to be the case and have also shown that the excess of cavity pressure over vapor pressure increases with the air content of the liquid.

When cavities are formed by separation from a divergent boundary, as illustrated in Fig. 4, they have a fairly regular frequency which is approximately proportional to the velocity of flow and inversely proportional to the length of the cavity (3). The detachment of a given cavity from the boundary wall is probably caused by an instantaneous rise of pressure due to the collapse of the preceding cavity.

A cavity caused by a vortex (Fig. 5) does not form and collapse in the manner demonstrated in Fig. 4. In fact, if the flow were perfectly steady it would be difficult to see how any collapse would occur. However, the turbulent

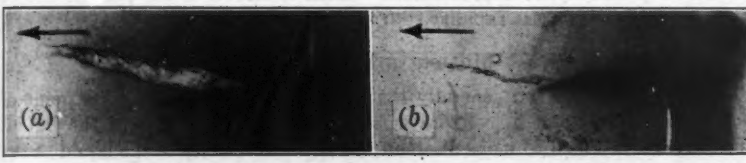

FIG. 5.—CAVITATION CAUSED BY A VORTEX (VELOCITY OF APPROACH TO BLADE, 9 FT PER SEC): (a) Gap, $\frac{1}{16}$ In.; Angle of Attack, +2.5°; and (b) Gap, $\frac{1}{4}$ In.; Angle of Attack, −2.5°

nature of the flow causes whipping of the unattached end of the vortex, which causes small portions of the major cavity to be detached and to collapse in a region of higher pressure. In Fig. 5 there is a gap between the end of the blade and the glass plate through which the pictures were taken. Upward flow occurs through the gap and produces a vortex similar to the tip vortex at the end of an airplane wing.

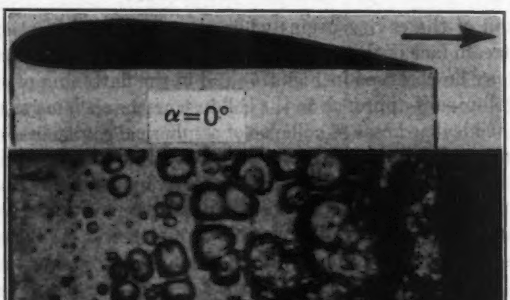

FIG. 6.—CAVITATION BUBBLES FORMING ON THE TOP OF A BLADE

When eddies that are shed from boundary irregularities, or are caused by the mixing of jets, enter a low-pressure region the pressures at their centers may be low enough to produce a cavity that will then continue to move with the flow and collapse farther downstream. Other types of cavities apparently form as small bubbles, possibly starting with a tiny air bubble as a nucleus. Such bubbles have been observed (see Fig. 6) in the flowing fluid (4), whereas

others, moving very slowly, remain in contact with solid boundaries of the flow (5). Such bubbles have been observed to expand in a region of low pressure and disappear when they enter a region of higher pressure. Evidently surface tension will affect cavitation to the extent that such small bubbles play an effective rôle in the phenomenon (6).

Although the thermodynamics of cavity formation is not known quantitatively (7), a lack of equilibrium may be safely assumed except in the case of a cavity at the center of a fixed vortex. As a cavity forms and rapidly increases in size, vaporization of the liquid will occur and gases dissolved in the liquid will come out of solution into the cavity. However, due to the turbulence that always accompanies cavitation, the speed of vaporization and of release of dissolved gases is quite unpredictable. Little is known of the process except that it occurs with great rapidity.

Motion of the Cavity

It has been observed generally that the cavity proceeds from its point of formation to its point of collapse with a speed less than that of the liquid. The cavities of Fig. 4(*b*) move at about one half the velocity of the liquid at the throat of the constriction. In Fig. 6 the cavitation bubbles, approximately spherical in shape, can be seen forming and disappearing. They are moving at approximately 15 ft per sec, whereas the stream speed is approximately 22 ft per sec. However, in the case of free small bubbles and small eddies having cavities at their centers, the speed of the cavity is probably about equal to that of the liquid. On the other hand, small bubbles attached to boundary walls have been observed to move at speeds very much less than the speed of the liquid (6).

Collapse of the Cavity

Destruction of the cavity begins when the cavity is in motion and results from the upstream face of the cavity moving more rapidly than the downstream face. This may be observed in Fig. 4(*b*) and in the flattening of the bubbles of Fig. 6. A preliminary approach to the collapse mechanism may be obtained by considering the idealized case of collapse of a spherical cavity in a mass of liquid which is at rest. By assuming that the cavity remained spherical as it collapsed, Lord Rayleigh (8) computed the pressure within the cavity to be 68 tons per sq in. and 765 tons per sq in. when its diameter had been reduced to 1/20 and 1/100, respectively, of its original diameter. C. A. Parsons and S. S. Cook (9) also showed experimentally that enormous pressures may be developed locally when water rushes into a void space containing only water vapor. At first the bubble collapse theory was accepted as a complete explanation for the production of intense local pressures and consequent destruction of materials, but further evidence indicated it to be only a partial answer. Such evidence consisted of high-speed pictures like those of Figs. 4(*b*) and 6, destruction of materials by water jets, and the realization that it was unlikely for a spherical bubble to exist in a flow and inconceivable that it would remain spherical as it collapsed. The views in Fig. 4(*b*) show the cavity to be of irregular shape and to contain droplets of liquid as well as liquid vapor. Tests

made by E. Honegger (10) and T. F. Hengstenberg (11) by moving elements of solid material through small water jets at high speed produced destruction of the material and indicated that appreciable pressures could be produced by impact of small liquid masses on solid surfaces.

From the foregoing facts it appears that the intense local pressures developed at the point of collapse are probably due to a combination of the foregoing phenomena. As collapse of the cavity occurs at a boundary, droplets may be shot at the solid surface with speeds sufficient to produce deformation and eventual destruction, or irregularities in the cavity walls may produce intense local pressures when the liquid strikes the solid material at the high speeds produced at collapse. Although the collapse of the cavity is the main cause of impact between liquid masses and solid boundaries the exact details of the impact mechanism may be quite different in successive collapses.

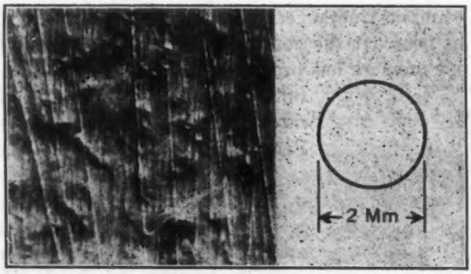

FIG. 7.—SMALL PITS (DENTS) PRODUCED ON A SMOOTH BRASS PLATE AFTER FIVE HOURS OF EXPOSURE TO CAVITATION

Experimental measurement of the pressures produced locally at cavitation collapse has proved an exceedingly difficult problem because these pressures are not produced at exactly the same point at every collapse. Even assuming a perfect measuring instrument, it is still difficult to place the instrument at the exact point where collapse occurs. J. Ackeret (12) has approached the problem by using a piezoelectric crystal 2 mm in diameter (placed in the boundary wall) and has measured local pressures of more than 200 lb per sq in. in a region where the average pressure was only 60 lb per sq in. That local pressures at the collapse point are higher than this and that they exist on a much smaller area may be inferred from Fig. 7 by comparing the size of a dent caused by cavitation on a brass plate with the 2-mm circle. The existence of high pressures in the region of collapse was also convincingly demonstrated by some tests at Massachusetts Institute of Technology (3), in which short lead tubes, having one end closed, were filled with water and placed with their open ends in the region of cavity collapse. The tubes were stretched quickly by the intermittent high pressures and soon failed in tension. The magnitude of collapse pressures cannot be deduced from such tests, of course, but the existence of high pressure is proved beyond doubt.

The thermodynamic processes in cavity collapse consist of high-speed compression of the gases (mostly air) in the cavity and the condensation of the

liquid vapor. In spite of this rapid compression and condensation, high local temperatures probably do not result because of the large water masses available to carry away heat generated by compression. Furthermore, it should be noted that the expansion and vaporization at the formation of the cavity will tend to cool the surroundings so that the heat generated during collapse will tend to restore the temperature to its original value rather than raise it appreciably above that value. Thus it appears very doubtful that thermal effects can play any appreciable part in the pitting of materials by cavitation.

Although local temperature rise appears to be of little consequence in cavity collapse, vapor pressure and air content play a significant part. Higher partial pressures of air and vapor in the collapsing cavity would be expected to offer resistance to the compression of the cavity by slowing condensation of vapor and reabsorption of air by the surrounding liquid. This in turn could be expected to produce a cushioning effect on the collapse, causing local pressures to be less intense and destruction of materials to be less rapid. Laboratory and field observations bear out the cushioning effect of increased air content but variation of vapor pressure has produced various trends. In a series of carefully controlled tests in the vibratory apparatus, using water of constant air content, H. Peters and B. G. Rightmire (13) showed that cavitation severity may increase or decrease with increments of temperature (and vapor pressure). (In Fig. 8, illustrating this apparatus, the nickel tube is oscillated longitudinally by magnetostriction.) However, J. M. Mousson, M. ASCE (14), reports swifter destruction of materials at higher temperatures in tests using a venturi type apparatus, and turbine operators have generally observed more destruction of blades and parts in the summer when temperature and vapor pressure are high and air content low than in the winter when opposite conditions exist. From the evidence available it appears that no general conclusions may be drawn as to the effect of vapor pressure on cavitation severity. Evidently the rôle that vapor pressure plays in cavity collapse is something more complicated than a cushioning effect.

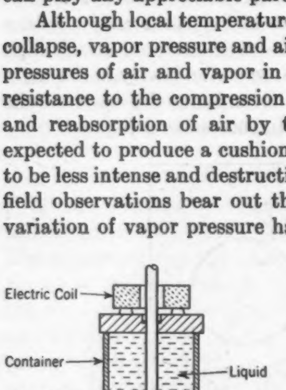

FIG. 8.—APPARATUS FOR PRODUCING CAVITATION BY THE VIBRATORY METHOD

From the random paths that cavities follow before they collapse it is evident that scattering of their points of collapse over a sometimes sizable region may be expected. Since this region is three dimensional, however, it appears likely that most cavities will collapse within the free flow and out of contact with the confining boundary surface. The question naturally arises whether cavities must contact the boundary surface as they collapse in order to damage this surface. As cavities completely surrounded by liquid collapse in the flow, compression waves will be sent out in all directions and will strike the solid boundaries confining the flow. Although it appears unlikely that such pressure waves could damage the boundary material, T. C. Poulter (15) and J. Ackeret and P. deHaller (16) report the damaging of a metal surface in a liquid by the

creation of high-frequency pressure waves in the liquid. If such pressure waves are caused by ordinary cavity collapse, destruction of material at a distance from the collapse point appears possible. Whether collapse of cavities in the flow can destroy boundary surfaces by the action of the pressure waves is still an open question but pressure waves may endanger a structure or machine by setting up forced vibrations. The pressure wave in traveling upstream into the low-pressure region also appears to be instrumental in detaching the succeeding cavity.

Damage from Cavitation, or Pitting

The harmful effects of cavitation are: (*a*) The pitting of the solid boundaries confining the flow; (*b*) the reduction in efficiency of machines and water passages; and (*c*) vibrations in the structure or machine caused by the periodic nature of cavity collapse. Thus, the designer of hydraulic structures may pay a three-fold penalty for allowing cavitation to occur, or he may reap a triple dividend by preventing the occurrence of cavitation. Since a discussion of vibrations and efficiency losses caused by cavitation would lead too far afield, pitting alone will be discussed in this paper. Figs. 9 to 12 illustrate the

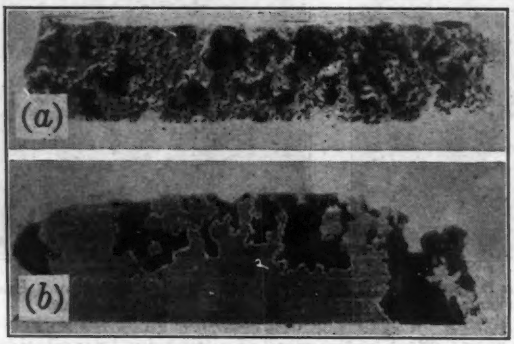

Fig. 9.—Example of Severely Pitted Cast Iron: (*a*) Surface Appearance; and (*b*) Cross Section

typical destruction of metals by cavitation. Fig. 9 was reported by Professor Ackeret (12), Fig. 10 by the Baldwin Southwark Company, Fig. 11 by the National Electric Light Association, and Fig. 12 by the Massachusetts Institute of Technology.

When a cavity collapses adjacent to a solid surface, or a droplet of liquid strikes the surface at high speed, the mechanical action is similar to striking the surface with a small ball-peen hammer. Indeed the dent that results in a malleable material appears just like the result of a hammer blow (see Fig. 7). The action of the collapsing cavity on the material is then primarily mechanical and thermodynamic or electrochemical (corrosion) effects play only a minor rôle. Although it was widely contended some time ago that pitting was primarily a corrosive action, this belief was destroyed by Professor Föttinger (18) when he obtained pitting on the glass walls of a venturi type cavitation

apparatus. However, this is not to claim that corrosive action plays no part at all, because it is well known that metals fatigue more rapidly in the presence of corrosive action.

The pitting of materials by cavitation is primarily a fatiguing action in which the surface skin of the boundary is continuously hammered by millions of tiny blows until it cracks and chips off. It has been observed generally that

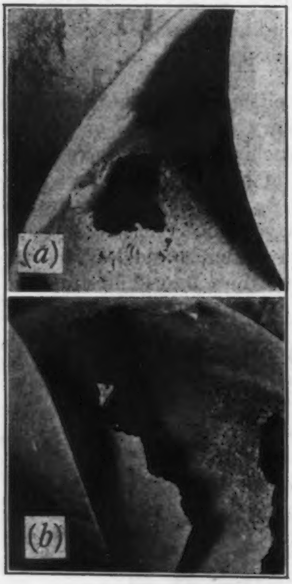

Fig. 10.—Severe Pitting of an Hydraulic Turbine Runner

Fig. 11.—Severe Pitting of a Centrifugal Pump Impeller

surface finish has an effect on the speed of pitting due to cavitation and on the rapidity of destruction of metal by water jets. Rough surfaces are invariably destroyed more rapidly than surfaces of smooth finish. Thus, as the smooth surface of any material is worn away, the pitting process accelerates and very rapid destruction usually results. In some cases, however, the pitting has stopped of itself, apparently due to a water cushion covering the eroded region and preventing direct contact of collapse point and solid material.

The precise mechanism of the accelerated destruction of rough surfaces is not known, but higher stress concentrations on irregular surfaces undoubtedly exist and should contribute decidedly to the process. Other effects may be at work in the case of very rough or cracked surfaces, however. For example, it is possible that the high pressure nucleus of the collapse cavity (possibly a tiny air bubble) is driven into fissures in the material and explodes when the pressure drops in the surrounding region. Another possibility is that the spaces at the inner ends of the cracks in the material act as cavities themselves

and collapse with destructive force when local pressures at their outer ends are increased by cavities collapsing in the flow. Still another possible explanation is the high pressure developed at the inner end of the fissure by reflection of a pressure wave entering the fissure (similar to the action of water hammer at the closed end of a pipe line). The intermolecular penetration of a high-

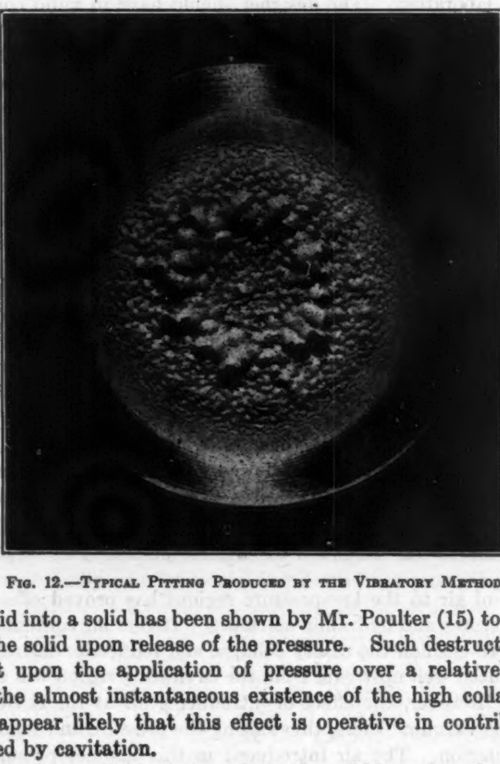

FIG. 12.—TYPICAL PITTING PRODUCED BY THE VIBRATORY METHOD

pressure liquid into a solid has been shown by Mr. Poulter (15) to be capable of destroying the solid upon release of the pressure. Such destruction, however, is dependent upon the application of pressure over a relatively long time. Because of the almost instantaneous existence of the high collapse pressure, it does not appear likely that this effect is operative in contributing to the pitting caused by cavitation.

Evidence is also available that cracks in the solid boundary do not accelerate the pitting process. Mr. Mousson (19*e*) has observed that the regions in and around the check cracks in the welding of a repaired turbine runner show no more pitting than the smooth surface material. He has also reported that destruction or weakening of the material beneath the surface is possible before cracks appear in the surface, by transmission of the effects of the blows on the surface.

Pitting of solid material suspended in a liquid, in which high-frequency pressure waves are created without cavitation, has been obtained by Mr. Poulter (15) and may be explained by the induced vibrations in the solid surfaces causing destructively high local stresses. If solid boundaries are actually destroyed in cavitation by cavities collapsing out of contact with the boundaries, this phenomenon offers an explanation of such pitting.

Remedies for Pitting

The most effective means of preventing pitting in new structures is the elimination of the cavitation that causes it. However, to "design cavitation out" of structures is not possible by design office calculations only. Cavitation can be prevented only through intelligent cooperation of the design office and the hydraulic laboratory. The designer should have in mind continually the facts that sharp curvatures, abrupt corners, or any combination of circumstances which produce flow curvature, vortices, eddies, separation, or high local velocities, are all conducive to cavitation and, like the aeronautical designer, he should make every effort to "streamline" his designs with contours of easy curvature. Even with these facts at hand, the design office cannot produce designs free from the danger of cavitation (unless such designs are so conservative that their costs are prohibitive) without the assistance of the laboratory. This results from the impossibility of using the foregoing principles quantitatively for the precise prediction of hydraulic phenomena.

In completed structures where cavitation and pitting occur and drastic modifications are not possible, various methods have been used successfully to arrest the pitting process or to prevent it after repairs have been made. Replacement of eroded parts by a tougher, more resistant material (such as the use of steel liners in conduits in the region where pitting has occurred in the concrete) has proved successful. This has its counterpart in the hydraulic turbine field where it is standard practice to chip out the damaged material and replace it with a tougher substance built up by welding. In some structures the pitting process has been allowed to continue until it arrests itself, presumably by the creation of a water cushion, as mentioned previously. Although the latter method may have little appeal, it is sometimes effective where erosion does not seriously endanger the strength of a structure or its working parts.

Admission of air to the low-pressure regions has proved effective in both hydraulic structures and hydraulic machines. Higher air content of the water has been seen to cushion the cavity collapse and reduce its destructive effects, and air introduced well upstream from the cavitation region will contribute to this process. However, the effect of introducing air at the cavitation region is to "break the vacuum" there, thus raising the pressure and tending to eliminate true cavitation. The air introduced in this manner presumably forms large bubbles which are compressed downstream in the high-pressure region but are prevented from collapsing by the cushioning effect of the large quantity of air, which cannot be absorbed by the water upon compression of the bubble.

Laboratory Testing for Cavitation

New designs may be tested for cavitation in the laboratory by suitable hydraulic measurements on a model of the new design. For cavitation testing of models there are two techniques which are commonly used: (1) The operation of the model within a vacuum tank; and (2) the operation of the model at or near atmospheric pressure conditions in the usual way. The latter method has been used successfully with water flowing in the model, and more recently with air as the fluid flowing.

The testing of models for cavitation near atmospheric conditions involves the measurement of static pressures at numerous points in the critical region so that the pressure distribution is well known. Cavitation is not produced in the model—if water is used the velocities are not high enough to cause cavitation; and, if air is used, cavitation is not possible because of the capability of the fluid to expand and fill any cavities that tend to form. However, by converting the measured model pressures to their corresponding prototype pressures by the laws of dynamic similarity, the model engineer may predict whether the prototype will have cavitation or not. The exact form of the cavitation cannot be predicted from such measurements and it is conceivable that a vortex in the flow which might produce cavitation in the prototype would be missed completely in a model that was equipped with wall piezometer openings only. In spite of this slight element of doubt, this method of testing has proved reliable in the past and it has been adapted successfully of late to the measurement of the intermittent cavitation pressures produced in highly turbulent flows, notably in the flow occurring around baffle piers. In situations like this, flow may be entirely unsteady locally, whereas the over-all flow is a perfectly steady one. At any given point, pressures may be low enough to produce cavitation at one instant and high enough to prevent cavitation at the next instant, thus producing a series of intermittent cavities or "flashes." Obviously such high-frequency pressure fluctuations could not be recorded by a piezometer column because of the inertia of the column; so the U. S. Waterways Experiment Station developed (20) an electrical recording pressure measuring device that traces the pressure fluctuations and thus may be used to predict at any point the percentage of time that cavitation pressures will occur. Assuming that all cavitation cannot be eliminated from abrupt obstructions like baffle piers (which for their very purpose must be unstreamlined), such measurements are useful in correcting designs to eliminate the cavitation pressures which exist continually over wide areas and are thus most likely to produce the regular cavitation that would be damaging to the structure.

Vacuum-tank testing of models for cavitation is much more complicated than open testing but has been shown by H. A. Thomas, M. ASCE, and E. P. Schuleen, Assoc. M. ASCE (19), to eliminate the element of doubt mentioned previously. The entire model is enclosed in a tank and the air above the model is evacuated so that the ratio of atmospheric pressure to absolute pressure imposed on the model is approximately equal to that of the model scale. By this method cavitation is produced in the model and its form and location become visible to the model operator. Photographs of expected cavitation may thus be obtained and may be supplemented by pressure measurements as well. The practical difficulties of high vacuum testing of hydraulic models are numerous but Professor Thomas has overcome these successfully and has indicated certain advantages of the vacuum-tank method. He has also developed material that will pit under the action of model cavitation and it is possible that, in the future, vacuum-tank testing will show not only the forms of the cavitation but the areas damaged by cavitation as well.

EXPERIENCES OF THE CORPS OF ENGINEERS

By John C. Harrold,[3] Assoc. M. ASCE

Synopsis

The discovery, in 1935, of severe pitting of the concrete in the conduit entrances of Madden Dam on the Chagres River in the Isthmus of Panama prompted the Corps of Engineers, U. S. Army, to undertake later that year a program of model research on the subject of cavitation. The initial purpose of this research was to develop a design of conduit entrance that would be free from cavitation. The program was later expanded to include a study of cavitation at gate slots in conduits and cavitation around baffle piers in stilling basins of high dams. The major part of this paper is devoted to a discussion of this model research and its effect on the design of structures that come under the jurisdiction of the Corps of Engineers.

The first research was conducted at Carnegie Institute of Technology, at Pittsburgh, Pa., under the direction of Harold A. Thomas, M. ASCE. Later the U. S. Waterways Experiment Station at Vicksburg, Miss., joined in the study. Since 1941 both laboratories have been engaged in cavitation research for the Corps of Engineers. At Carnegie Institute of Technology, models are tested in a vacuum tank in which the air pressure can be reduced to scale and in which actual cavitation can be made to occur. At the U. S. Waterways Experiment Station, ordinary open-air models are used and cavitation pressures are detected with especially designed electric pressure cells capable of measuring rapidly fluctuating pressures in water. These cells are attached to piezometer openings in the face of the model. Both methods have proved highly satisfactory and the results obtained at both laboratories have been correlated.

Introduction

The first high, concrete, flood control dam in the Upper Ohio River Valley—Tygart Dam—was under construction in 1935 when news reached the Pittsburgh District Office of the Corps of Engineers (under whose supervision Tygart Dam was being constructed) that severe pitting of the concrete had occurred in the entrances of the outlet conduits of Madden Dam (19*a*). Since the Tygart conduits were similar in design to the Madden conduits and were to be operated under about the same head, concern was felt lest pitting should also take place in these conduits.

The cause of the pitting in the conduits of Madden Dam appeared to be cavitation induced by the sharp entrance curve in the roof of the conduit. The curve was slightly less sharp in the case of the Tygart conduits, but it was not known whether the difference in curvature would be sufficient to prevent the formation of cavitation.

[3] Senior Hydr. Engr., Office of Chf. of Engrs., War Dept., Washington, D. C.

The possibility of conducting model tests for studying the problem was discussed with Professor Thomas of Carnegie Institute of Technology, who had already conducted model tests of the stilling basin of Tygart Dam for the Pittsburgh District Office. Professor Thomas expressed the opinion that such tests would be feasible and agreed to undertake the tests for the Pittsburgh Office. Model tests of the conduit entrances would first be made in order to determine definitely whether cavitation had been the cause of the pitting at Madden Dam and to provide a general check on the reliability of the methods of testing used. Tests of the Tygart conduits would then be made to determine whether or not cavitation could be expected to occur in these conduits. If so, further tests would be made to determine a remedy for this condition.

These tests showed definitely that cavitation had been the cause of pitting in the Madden Dam conduits. When the results of these tests were called to the attention of the Panama Canal authorities, additional tests of the Madden Dam conduits were authorized with a view to determining a remedy for this condition. Several methods of eliminating cavitation at Madden Dam were tried—reshaping the conduit entrance, constricting the downstream end of the conduit, placing fillers in the stop-log slots, and venting with air. Reshaping of the conduit entrance was finally selected as the most practicable remedy for the condition existing at Madden Dam (19*b*).

A model of the conduit entrances at Tygart Dam was then tested and found to be free from cavitation. Apparently the degree of curvature provided in the entrances of the Tygart conduits was sufficient to prevent cavitation. No change was necessary, therefore, in the design of these entrances. Although the answer was negative in this case, the experience gained from these tests proved to be very useful in subsequent testing of this type.

First Vacuum Apparatus

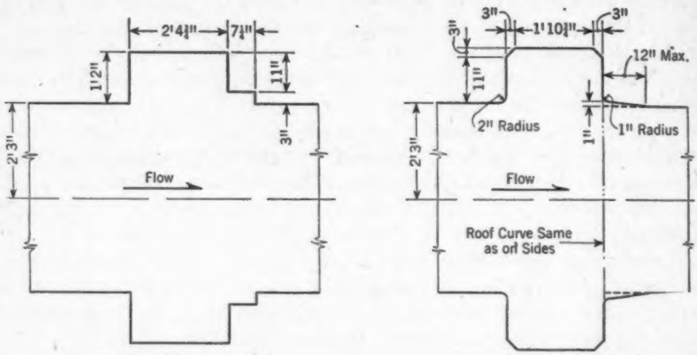
A special type of apparatus was designed by Professor Thomas and constructed for these tests—the first apparatus for testing hydraulic structures under a vacuum to be built in the United States (19*c*). It consisted of a closed, horizontal-loop, recirculation system in which the pressure could be reduced by an air exhaust pump. Water was recirculated with a centrifugal pump. A part of the system was made large enough to accommodate half-section models of conduit entrances. A glass plate was placed over the conduit on its center line so that the action of the water could be observed.

Conduit Tests

The action at the conduit entrance at Madden Dam in this apparatus has been illustrated by Professor Thomas and E. P. Schuleen, Assoc. M. ASCE (19*d*). In a similar photograph of the Tygart conduit no cavitation was visible, indicating that the conduit entrance at Tygart Dam will be free of cavitation.

A model of the conduits of another dam was tested in this apparatus in order to study cavitation phenomena in the vicinity of the gate slots. The entrance curve for this design, as a result of experience at Madden Dam, was very liberal. No cavitation was revealed either in the entrance or at the gate

slots under the conditions of maximum head for which this conduit was designed. However, a slight overspeeding of the apparatus (equivalent to increasing the head) gave rise to cavitation flashes at the downstream edges of the downstream gate slot (Fig. 13(*a*)). In order to increase the factor of safety against the occurrence of cavitation in the full-sized structure, a new design of gate slot was developed (Fig. 13(*b*)) which was found to be free from cavita-



(*a*) ORIGINAL DESIGN (*b*) IMPROVED DESIGN

FIG. 13.—IMPROVEMENT IN GATE SLOT DESIGN

tion under this increased head. A slight bevel and rounding was provided on the downstream edges of the gate slot in the improved design. This design has been used in several dams constructed by the Corps of Engineers.

BAFFLE PIER PROBLEM

In 1939, four years after the Madden Dam incident, another incident occurred which gave further impetus to the development of the technique of cavitation model testing. A very economical stilling basin design had just been developed in the hydraulic laboratory of Carnegie Institute of Technology for use below the spillway of Bluestone Dam, one of the flood control dams in the Middle Ohio River Valley (Huntington, W. Va., District). This basin consisted of a short horizontal apron at the toe of the spillway with two rows of baffle piers and an end sill on it (see Fig. 14). Fig. 15 shows the water impinging against the baffle piers of this basin. The use of baffle piers enabled a much shallower basin to be adopted than would have been possible otherwise.

After the model study had been completed and the design accepted by the Huntington Office, it occurred to Professor Thomas that there might be cavitation present around these baffle piers. Some well-known foreign engineers who visited the laboratory at that time and saw the model in operation also voiced the same opinion. Professor Thomas, therefore, undertook an analytical study of pressures around cubical blocks in high-velocity streams to determine the likelihood that cavitation would be present. Although this investigation was entirely theoretical and had to be based on certain idealistic assumptions, the results indicated quite definitely that cavitation would be present around

the Bluestone baffles. Not being satisfied with this theoretical analysis, however, Professor Thomas began to give some thought to the development of a

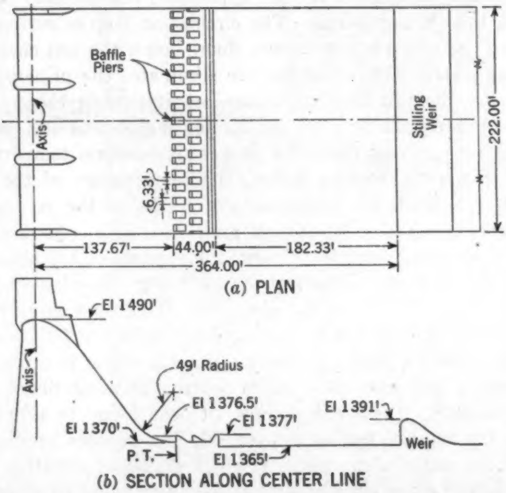


FIG. 14.—SPILLWAY AND STILLING BASIN OF BLUESTONE DAM, IN WEST VIRGINIA; SHOWING THREE BAYS

FIG. 15.—ACTION OF BLUESTONE STILLING BASIN AT MAXIMUM DISCHARGE

vacuum apparatus in which models of stilling basins could be tested. With the help of a research student he was finally able to complete the apparatus shown in Fig. 16. Fig. 16(b) is a view of the test chamber.

Improved Vacuum Apparatus

Professor Thomas' improved vacuum cavitation apparatus consists of a closed circulation system, as in the old apparatus; but in many other respects it differs from the old apparatus. The circulation loop is vertical instead of horizontal; and the pump is located two floors below the test chamber instead of on the same level. This latter feature eliminates the principal difficulties experienced with the previous apparatus—cavitation in the pump and air leakage in the pump packing. An ice cooling jacket was also placed on the vertical supply pipe to keep the water at a fairly constant temperature during the tests. Without the cooling jacket, the temperature of the water rises during the tests, making an additional correction in the results necessary. The test chamber is 8 ft long, 2.5 ft high, and 12 in. wide. Air is exhausted by a steam ejector located conveniently near the apparatus, the apparatus being constructed in the steam laboratory of the Institute. Windows were provided in the top and in one side of the test chamber. The top window is removable permitting the placing of models in the chamber. This window is sealed around the edges with modeling clay. Before testing, the water is recirculated for a short time under a high vacuum in order to draw as much dissolved air from the water as possible. Dissolved air has not been found to affect the results of this particular type of testing appreciably but it does produce a cloudy appearance of the water when released, which makes observation of the tests difficult. Dissolved air in large quantities has been found to affect the results of cavitation tests of hydraulic machinery.

Principle of Vacuum Apparatus

In a model study utilizing a vacuum tank apparatus, all features of the model are reproduced to scale, as in the case of an undistorted open-air model, except the atmospheric pressure surrounding the model. It would seem at first thought that the atmospheric pressure, being a unit force, should be reduced in the same proportion as the linear scale of the model. This would be correct, except for the fact that it is desired to simulate cavitation as well as correct pressures in the model. If the properties of water could be changed conveniently so that the water would cavitate, or vaporize, at, say, 1/20th or 1/50th of its natural vapor pressure depending upon the model scale used, it would be satisfactory to reduce the air pressure in direct proportion to the scale. However, it is inconvenient, if not impossible, to make water stay in a liquid state until it reaches such a low pressure. It would vaporize long before reaching this pressure. The temperature of the test water being practically the same as the prototype water, the test water will vaporize at practically the same pressure as the prototype water, not 1/20th or 1/50th of this pressure. A correction, therefore, must be added to the theoretical air pressure (atmospheric pressure divided by the model scale) to make up for the impracticability of changing the vaporizing properties of water.

A numerical example of the method of computing the atmospheric pressure to be used in a model study of this type is illustrated in Fig. 17. The spillway section of a dam has been chosen for the example but the analysis applies equally well to any hydraulic structure having a free water surface.

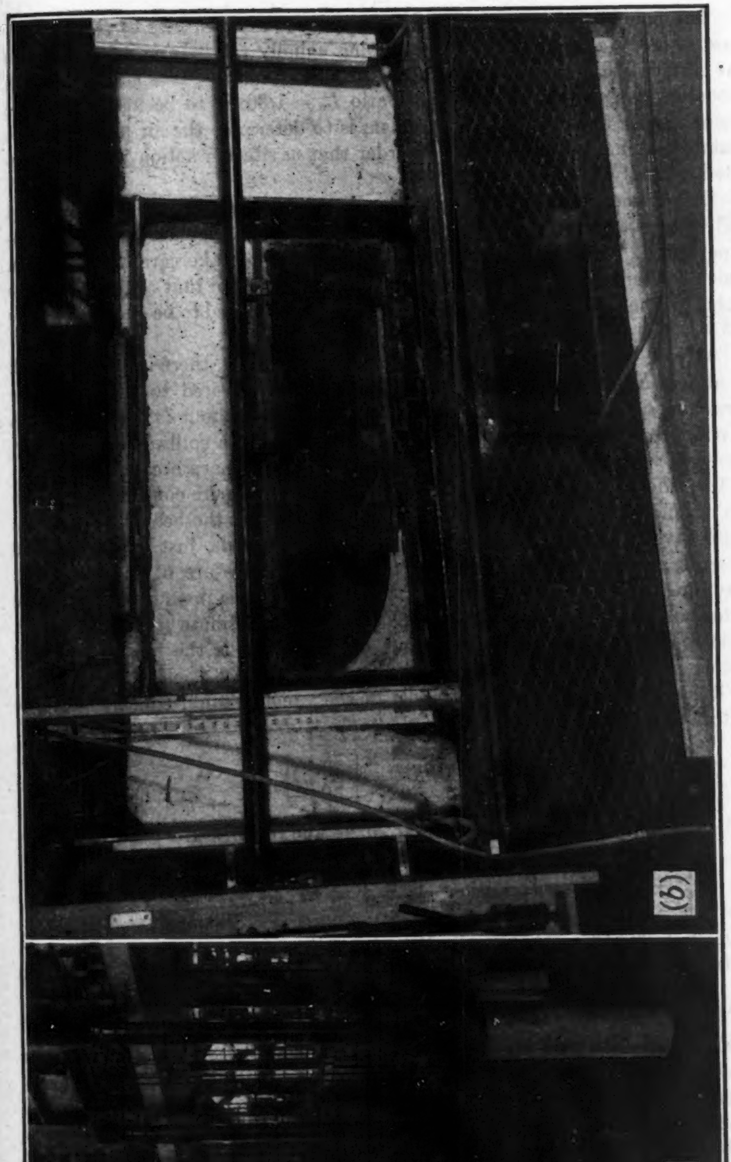

FIG. 16.—IMPROVED VACUUM APPARATUS FOR MODEL TESTS OF STILLING BASINS: (a) General View; and (b) Test Chamber

The point in question is point B on the downstream face of the spillway crest (Fig. 17(a)); but the analysis applies equally well to any other point on the surface of the structure, including the stilling basin. It is assumed that a model of this spillway (linear scale ratio $L_r = 1/30$) is to be installed in the vacuum tank for testing. The problem is to determine the air pressure to be maintained in the test chamber in order that cavitation action may be simulated correctly.

The example has been simplified by assuming that the water in the model will be kept at a constant temperature equal to the temperature of the prototype water. Later a correction will be developed to take care of the case in which the temperature of the test water is different from that of the prototype water. Atmospheric pressure in the prototype is assumed to be one atmosphere (33.9 ft of water, absolute).

Assume that at point B in the prototype, Fig. 17(a), there is a sharp break in alinement due to faulty construction and it is desired to determine the maximum head, H_p, that can be allowed on the crest without causing cavitation at point B. (The pressure on the downstream side of a spillway crest usually decreases with an increase in head on the crest, and a sharp break in alinement on this side would result in a local lowering of this pressure considerably below the normal pressure for that head.) The head, H_p, is the head that will just cause cavitation to start at point B or, in other words, just cause the local pressure at point B to be reduced to the vapor pressure of the water, p_v. Assuming the temperature of the water to be 70° F, the pressure at which the water will vaporize is $p_b = p_v = 0.838$ ft of water, absolute (obtained from a table of vapor pressures). The head, H_p, therefore, is the head which will just cause the pressure at point B to be reduced to 0.838 ft of water, absolute.

Referring to Fig. 17(b), the model in the vacuum tank, equations can be written for the air pressure, p_{am}, in the tank—

$$p_{am} = \frac{p_{ap}}{30} + \left[\frac{29}{30} p_v\right] \qquad \text{(2a)}$$

$= 1.13 + [0.81] = 1.94$ ft of water at 70° F; and the pressure, p_{bm} at point B—

$$p_{bm} = \frac{p_v}{30} + \left[\frac{29}{30} p_v\right] \qquad \text{(2b)}$$

$= 0.028 + [0.81] = 0.838$ ft of water at 70° F.

In Eqs. 2, the first term to the right of the equals sign is the pressure that would exist with the model head, $H_m \left(= \frac{H_p}{30} \right)$, if the air pressure in the tank is reduced by the direct linear scale ratio of the model, 1 : 30, and if the water would stay in a liquid state until a pressure as low as 0.028 ft of water, absolute, is reached. Since water at 70° F will vaporize when the higher pressure of 0.838 ft of water, absolute, is reached, a pressure as low as 0.028 ft cannot be realized. Therefore, to make the water just start to vaporize when the head, H_m, is reached, it will be necessary to raise the air pressure in the tank by the difference between 0.838 and 0.028, or 0.81 ft of water. This will raise all

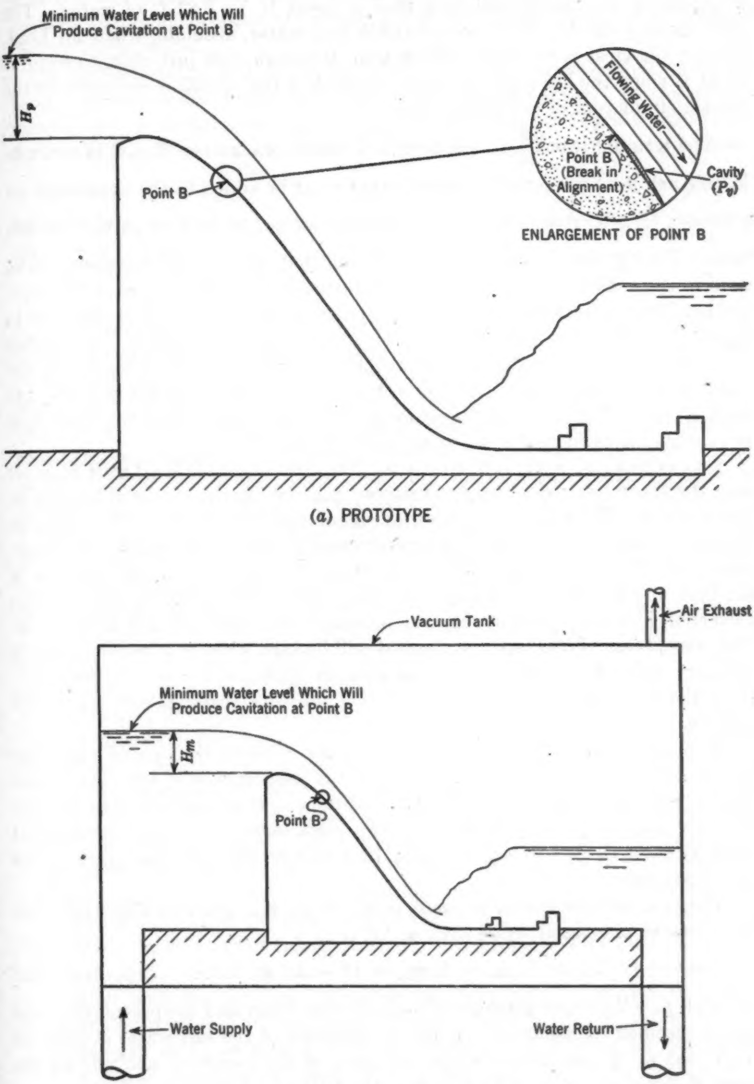

FIG. 17.—AIR PRESSURE IN THE VACUUM APPARATUS FOR A SPILLWAY MODEL (SCALE, 1 : 30)

pressures on the model, including that at point B, by 0.81 ft of water. The pressure at point B will just reach 0.838 ft of water, absolute, when the head, H_m, on the crest is reached. Cavitation, therefore, will just start to form at point B when the head, H_m, is reached, which is the condition required for the correct simulation of cavitation action.

The term 0.81, or $\frac{29}{30} p_v$, has been inclosed in brackets in Eqs. 2 in order to distinguish it as the correction factor that must be added to the theoretical air pressure, $\frac{p_{ap}}{30}$, to obtain the correct air pressure p_{am} to be used in the vacuum tank. For the case in hand, it will be noted that the correct air pressure to be used in the tank is 1.94 ft of water, absolute. With this pressure in the tank, the head on the spillway crest can be increased until cavitation is observed to begin at point B, and the head at which this occurs is recorded. When this head H_m is multiplied by the reciprocal of the linear scale ratio, 1 : 30, the result will be the head H_p in the prototype, which will just cause cavitation to start at point B and which, therefore, is the head below which the dam must be operated if cavitation is to be avoided at point B.

Since the air pressure in the tank p_{am} has been increased by 0.81 ft of water over the theoretical, all absolute pressures measured in the tank will be high by this amount. Therefore, all measurements of absolute pressure will have to be reduced by this amount before being converted to prototype values. Measurements of relative pressure (differences in pressure between the air pressure in the tank and the pressure at a given point on the model) will not need to be so corrected, however, because they are independent of the pressure in the tank. The correctness of this latter statement will be seen when it is realized that in ordinary open-air models the surrounding air pressure is considerably higher than the theoretical and yet the relative pressure readings are considered reliable.

It is also desired to call attention to the fact that, in the case of a spillway model such as that in the present example, the phenomenon of separation must also be considered, since end aeration conditions in the prototype may be such that the nappe would separate from the crest before the vapor pressure at point B is reached. It was assumed that this would not take place in the above example.

The equation for the air pressure in the tank, p_{am}, given in Fig. 17(*b*), can be expressed in general terms (21), as follows:

$$p_{am} = L_r\, p_{ap} + (1 - L_r)\, p_v \qquad \text{(3a)}$$

in which p_v is the vapor pressure of both the test water and the prototype water at the specified temperature. If the temperature of the test water is different from that of the prototype water, a review of the foregoing analysis on the basis of this assumption will show that the following formula applies:

$$p_{am} = L_r\, p_{ap} + p_{vm} - L_r\, p_{vp} \qquad \text{(3b)}$$

in which p_{vm} is the vapor pressure of test water; and p_{vp} is the vapor pressure of prototype water. Applying Eq. 3*b* to the foregoing example, it will be seen

that the correction to be added to the theoretical pressure is the difference between the vapor pressure of the test water and 1/30th the vapor pressure of the prototype water.

It will be noted in Eqs. 3 and in the accompanying example that, when the model scale L_r is small, the factor $L_r\, p_{vp}$ is extremely small. In the case of very small models, therefore, this factor may be neglected if great precision in the results is not required and the following approximate formula may be used:

$$p_{am} = L_r\, p_{ap} + p_{vm} \qquad (4)$$

The correction to be added to the theoretical pressure in Eq. 4 is only the vapor pressure of the test water.

Baffle Pier Tests

Trial runs in the vacuum tank apparatus demonstrated that this apparatus would accomplish the results desired. A preliminary model of the stilling basin of Bluestone Dam was installed in the tank and tested under the maximum discharge conditions to which the basin would be subjected. Cavitation showed up immediately around the baffle piers. This matter was then called to the attention of the Corps of Engineers and arrangements were made to have further tests of the Bluestone stilling basin conducted at both Carnegie Institute of Technology and the U. S. Waterways Experiment Station at Vicksburg, with a view to determining the severity of this cavitation condition for the complete range of discharge to which the basin would be subjected and with a view to determining a remedy for this condition, if later considered desirable and feasible. The U. S. Waterways Experiment Station, working with an open-air model, concentrated on determining a streamlined shape of baffle pier that would be relatively free from cavitation and yet be effective as a baffle pier. At Carnegie Institute of Technology tests were continued in the vacuum tank, first on a more exact model of the original basin and then on various shaped baffle piers, including the streamlined shape developed at the Experiment Station. The results obtained at the two laboratories were correlated as the tests progressed.

The tests in the vacuum tank at Carnegie Institute of Technology will be described first. A model of the original apron design with sharp-cornered baffle piers (linear scale ratio $L_r = 1/48$) was first installed in the tank and tested. Fig. 18(*a*) shows the detailed dimensions of these baffle piers. The action of this model in the vacuum tank is shown in Figs. 19(*a*) and 19(*b*). In Fig. 19(*a*), the severity of the cavitation may be judged from the fact that the upstream baffle piers (left hand in photograph) are completely enveloped in cavitation pockets. In Fig. 19(*b*) the relatively mild cavitation is revealed by a smaller pocket visible on the side of the closest upstream baffle.

Inasmuch as these tests and those at the U. S. Waterways Experiment Station (to be described subsequently) indicated that cavitation around the baffle piers of the original design would be quite severe, it was decided to investigate other shapes of baffle piers, keeping the same apron length and end sill, to see if a shape could be developed that would be relatively free from cavitation and at the same time be effective as a baffle pier and structurally rugged. Of

the many shapes tested, the most practicable shape appeared to be the streamlined shape developed by the Waterways Experiment Station and shown in Fig. 18(*b*). The same width of front face, 6.33 ft, was retained in this design, the streamlining being added to the sides.

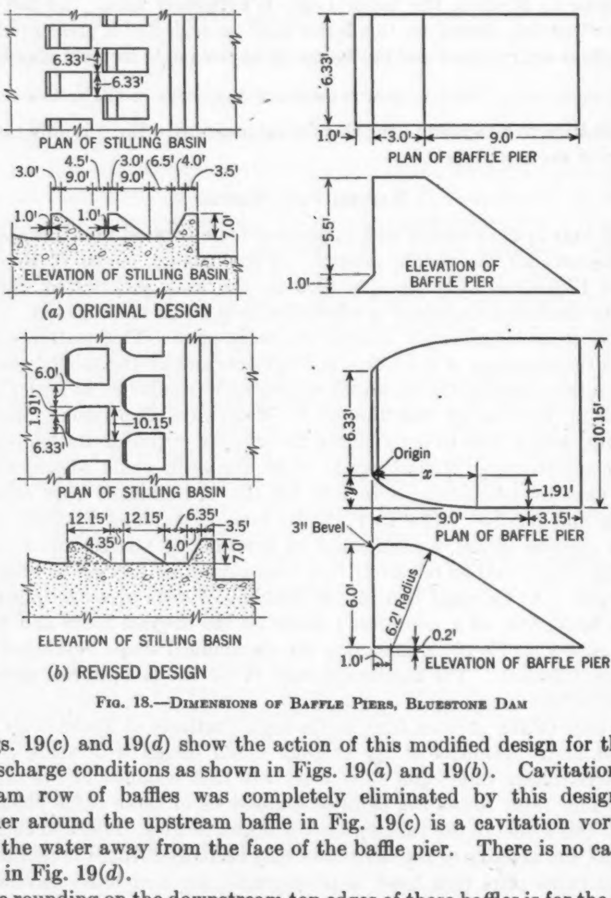

FIG. 18.—DIMENSIONS OF BAFFLE PIERS, BLUESTONE DAM

Figs. 19(*c*) and 19(*d*) show the action of this modified design for the same two discharge conditions as shown in Figs. 19(*a*) and 19(*b*). Cavitation on the upstream row of baffles was completely eliminated by this design. The streamer around the upstream baffle in Fig. 19(*c*) is a cavitation vortex well out in the water away from the face of the baffle pier. There is no cavitation visible in Fig. 19(*d*).

The rounding on the downstream top edges of these baffles is for the purpose of providing better ventilation of the jets of water shooting over the tops of the baffles. This tends to prevent a cavitation streamer from forming on the top of the baffle and causes it to leave the baffle if it does form. The reverse, rounding the upstream top edge, encourages the formation of a cavitation streamer and causes it to cling closer to the top of the baffle. A cavitation streamer that leaves the baffle is assumed to be harmless, whereas one that clings to the baffle is considered harmful.

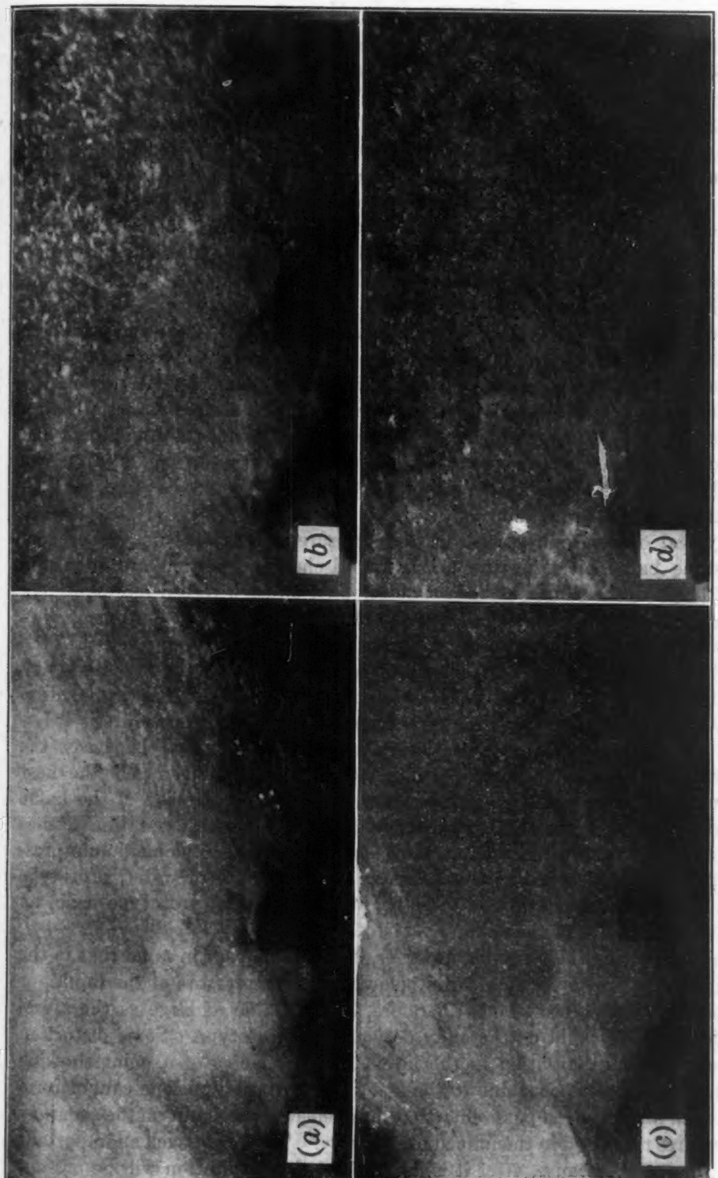

FIG. 19.—REACTION OF BAFFLE-PIER MODEL, BLUESTONE DAM, AS TESTED IN VACUUM APPARATUS: (a) Maximum Discharge with Original Design; (b) Approximately One Quarter of Maximum Discharge with Original Design; (c) Maximum Discharge with Revised Design; and (d) Approximately One Quarter of Maximum Discharge with Revised Design

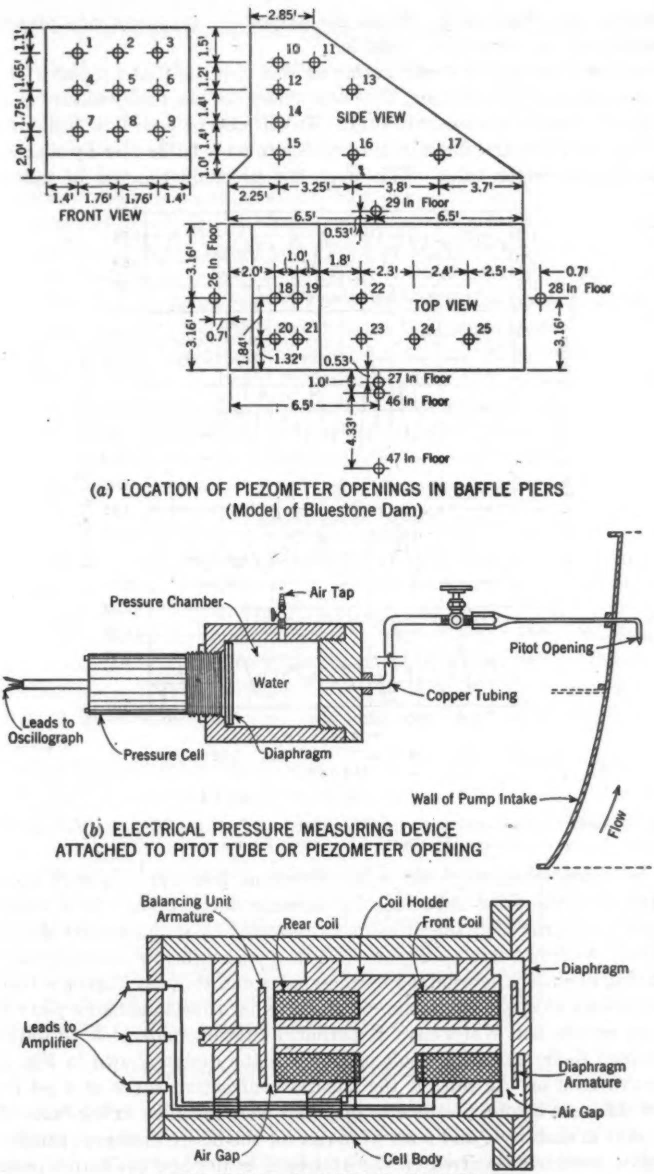
Pressure Cell Method

The tests at the U. S. Waterways Experiment Station were conducted on an open-air model for which the linear scale ratio L_r was 1/36. Two baffle piers in each row were constructed with piezometer openings in the faces as shown in Fig. 20(*a*). These piezometer openings were connected by means of copper tubing to a heavy metal pressure chamber in which was fastened an electric pressure cell, as shown in Fig. 20(*b*). (Fig. 20(*b*) shows a connection to a pitot tube but the connection to a piezometer opening is identical.) A cross section of one of the electric pressure cells is shown in Fig. 20(*c*). Several of these pressure cells can be connected to a single amplifier and oscillograph unit, and the pressure at several points recorded simultaneously.

This equipment had been developed in connection with previous tests performed at the U. S. Waterways Experiment Station (20*a*) and had been found very successful in measuring rapidly fluctuating pressures in water. The cell shown in Fig. 20(*c*) utilizes the induction principle. A pressure on the diaphragm causes it to deflect and a change in the air gap causes a change in the current in the front coil. These current variations are amplified and recorded photographically by the oscillograph. Referring to Fig. 20(*b*), it was found that a considerable length of copper tubing could be used without affecting the pressure readings.

Typical oscillograph records of the pressure fluctuations on the original Bluestone baffle piers for the maximum discharge condition are shown in Fig. 21. A dashed line has been superimposed on each record representing a prototype pressure of absolute zero (33.9 ft of water below atmospheric). Pressures below the dashed line are purely imaginary but they have been used as a basis for comparing the severity of cavitation at the various points and for different discharge conditions and baffle shapes. The greater the drop below zero and the greater the percentage of time that the pressure is below zero, the more severe the cavitation is assumed to be. On this basis, the cavitation at piezometer No. 12 (see Fig. 20(*a*)) may be assumed to be the most severe. It will be noted that piezometer No. 12 is on the side of the baffle just downstream from the leading edge, the point where cavitation flashes become visible first in the vacuum tank (see Fig. 19(*b*)). The maximum pressure fluctuation recorded at this point was about 180 ft of water, prototype scale. The pressure was found to be below absolute zero (prototype scale) on the average of 82% of the time.

In interpreting these results, however, it should be kept in mind that in the prototype the pressure cannot drop below the vapor pressure of the liquid, or approximately absolute zero. Therefore, a fluctuation as large as the aforementioned value could not actually occur in the prototype. Some distortion of the pressure distribution in the liquid in the vicinity of a point showing cavitation may also occur due to the fact that cavitation pockets cannot form in an open-air model—a possibility that may reflect some doubt on the accuracy of pressures measured in the immediate vicinity. This is not such an important point, however, because, after it is determined that cavitation will be present in a given design, this design is usually modified until all tendencies toward



(a) LOCATION OF PIEZOMETER OPENINGS IN BAFFLE PIERS (Model of Bluestone Dam)

(b) ELECTRICAL PRESSURE MEASURING DEVICE ATTACHED TO PITOT TUBE OR PIEZOMETER OPENING

(c) CROSS SECTION OF ELECTRIC PRESSURE CELL

FIG. 20.—ARRANGEMENT OF APPARATUS FOR TESTS WITH ELECTRIC PRESSURE CELLS

cavitation are eliminated. When no cavitation pressures are present, all measurements are considered reliable.

Another observation worth noting at this point is that pressures on baffle piers are definitely fluctuating, thus accounting for the flashy nature of cavitation as observed in the vacuum tank. It will also be seen how futile it would be to try to determine the minimum pressure on a baffle pier by means of an ordinary manometer tube. This does not preclude the use of manometer

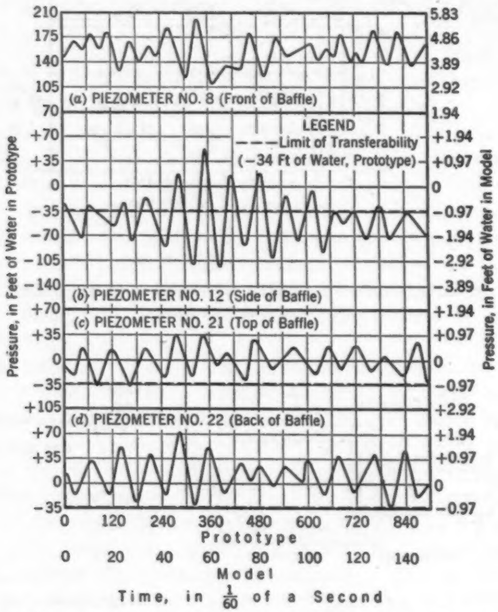


FIG. 21.—PRESSURE MEASUREMENTS ON THE ORIGINAL BAFFLE PIERS FOR BLUESTONE DAM, AT MAXIMUM DISCHARGE (PIEZOMETER LOCATIONS SHOWN IN FIG. 20(*a*))

tubes in models where the water is less turbulent, however. In such cases it is desirable to make some allowance for pressure fluctuations. It is sometimes assumed arbitrarily that the pressure as recorded by a manometer should not be allowed to drop below − 20, or − 25 ft of water (below atmospheric).

Having definitely determined by these tests and those at Carnegie Institute of Technology that the cavitation on the original Bluestone baffle piers would be quite severe, the Waterways Experiment Station undertook to develop a streamlined baffle pier, the result of which is the design shown in Fig. 18(*b*). The curve used on the sides is the natural contraction curve of a jet from a narrow slit. As before, piezometer openings were installed in the faces of two baffle piers in each row, and tests were run for the entire discharge range. No cavitation pressures occurred on the upstream baffles and cavitation pressures were found on the second row about 25% of the time for the maximum discharge condition.

Pitting of Baffle Piers of Private Power Dam

In connection with the design of the Bluestone stilling basin, the Huntington District Office made a survey of existing dams with baffle piers. Claytor Dam, a private power dam in the Huntington District, was observed to have a dentated end sill, the sides of the dentates of which had been slightly pitted. This dam had just been constructed and was soon thereafter subjected to a large spillway discharge lasting about four days. It was thought that this experience would provide an excellent opportunity to make a model-prototype study of cavitation which would greatly aid in an interpretation of the foregoing model study results. If the percentage of time that the pressure on the sides of these dentates or baffles was below the cavitation pressure during this discharge could be determined, some idea of the significance of the 25% of time determined for the streamlined Bluestone baffles would be obtained.

Models of the stilling basin at Claytor Dam were tested at both laboratories, and cavitation was observed on the sides of the baffles during the maximum discharge that prevailed during the four-day period. Tests at the Waterways Experiment Station showed that the pressure on the sides of these baffles was below absolute zero (prototype scale) about 25% of the time at this maximum discharge, agreeing almost exactly with the degree of cavitation found on the downstream row of streamlined Bluestone baffles.

As a result of these tests on Claytor Dam, it was concluded that pitting on the downstream row of baffles at Bluestone Dam would not be excessive, particularly in view of the expected infrequency of operation of the Bluestone spillway. The streamlined baffle design shown in Fig. 18(*b*), therefore, was considered satisfactory, provided that these baffles would produce the required energy dissipation. Tests were undertaken to determine the relative effectiveness of the original square-cornered baffle piers and the newly developed streamlined design.

The two lower curves in Fig. 22 show the effectiveness of the original square-cornered baffles. At the maximum discharge, a satisfactory jump can be produced with a 12-ft lower tailwater elevation than would be required to produce a jump on a level apron without baffle piers. A curve of tailwater required to produce an equally satisfactory jump was not determined for the streamlined baffles but, at the maximum discharge, it was found that a 2-ft higher tailwater level was required. Therefore, the streamlined baffles may be considered equivalent to 10 ft of tailwater depth at the maximum discharge which is still quite effective. This 2-ft additional tailwater depth was provided in the prototype by raising the crest of the stilling weir 2 ft above that provided in the original design (see Fig. 14).

Comparison of Two Methods of Testing

The two upper curves in Fig. 22 show a comparison between the results of tests made in the vacuum tank and those made with the pressure meter. These curves represent the tailwater levels required to eliminate cavitation on the upstream row of the original Bluestone baffles. The tailwater levels were raised in each case until, in the vacuum tank, cavitation flashes disappeared

and, in the open-air model, the pressure ceased to fall below absolute zero. These levels were recorded and plotted in the form of curves as shown in Fig. 22. The agreement was remarkably close, but such agreement was not obtained until some of the tests were rerun, as it was difficult to determine the exact point in the vacuum tank at which the cavitation flashes disappeared.

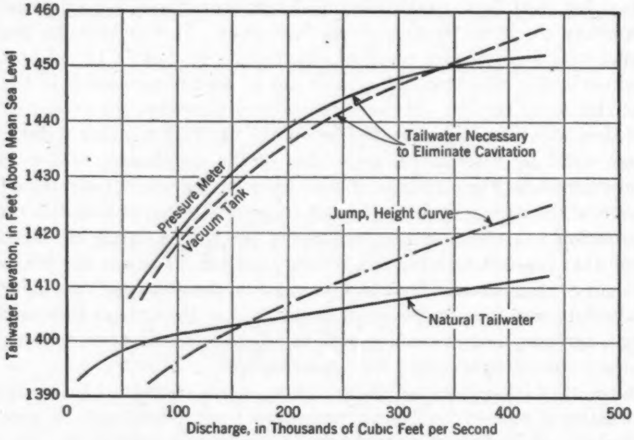

FIG. 22.—COMPARISON OF RESULTS OBTAINED BY VACUUM TANK AND PRESSURE-METER METHODS OF CAVITATION TESTING; ORIGINAL BAFFLE PIERS, BLUESTONE DAM

As a result of these tests on Bluestone Dam, it was concluded that satisfactory results can be obtained by either method of testing—the vacuum-tank or pressure-meter method. Each method, however, has some advantages over the other. The main advantage of the vacuum-tank method is that the cavitation can be seen and its extent observed. The main advantage of the pressure-meter method is that it provides a quantitative measure, permitting a comparison between different degrees of cavitation and enabling the cavitation limit to be determined more accurately and with greater ease. In the pressure-meter method, however, it is necessary to know in advance of the tests where cavitation is likely to occur in order to locate the piezometer openings properly. Also, as previously stated, there is some question in the pressure-meter method as to the effect of the failure to reproduce cavitation pockets on the pressure distribution in the surrounding liquid. The two methods can be used together very nicely, however, and this is recommended whenever possible.

Additional comments on these two methods of testing have been presented elsewhere by J. B. Tiffany, Jr., M. ASCE (20*a*), and by Professor Thomas and W. J. Hopkins (22).

ACTUAL CASES OF PITTING

Several cases of actual pitting due to cavitation have been discovered in structures built under the direction of the Corps of Engineers, the most notable of which is that at Bonneville Dam on the Columbia River. An inspection of

the spillway of this dam in 1939, two years after completion, revealed considerable erosion of the concrete which was thought to be due in part to cavitation (29*a*). Since this dam is a run-of-river dam, discharge over the spillway had been practically continuous. The spillway consists of eighteen 50 ft by 50 ft stoney gates on a concrete ogee section about 75 ft high. Water is discharged beneath the gates under a head of about 50 ft and is stilled on a horizontal apron 40 ft below the level of the spillway crest. The horizontal apron is 63 ft long and contains two rows of baffle piers placed at about the third points. The total fall from the upper pool to spillway apron is about 90 ft.

FIG. 23.—EXAMPLE OF PITTING; DOWNSTREAM FROM SPILLWAY GATE SLOTS AT BONNEVILLE DAM

SPILLWAY GATE SLOTS

Fig. 23 shows the erosion that was discovered on the side of a spillway gate pier just downstream from the gate. It will be noted that some erosion has also occurred on the crest. This is typical of all gate piers. It was not known at first whether this erosion was due to abrasion or to cavitation. It was

known, however, that the outside concrete of these piers had not attained its full strength due to cold-weather curing and the use of a pozzolanic admixture. Repair was first attempted, therefore, by refilling some of the holes with good sound gunite made with standard Portland cement, but after another year of operation the holes were found to be in as bad a condition as before. Repair was then attempted by placing ½-in. steel plates over the eroded areas, backfilled with concrete and anchored to the existing reinforcement (29*b*). Plates were placed on the crest as well as on the face of the piers. This work stood up fairly well for a while but in a few months began to fail. The lower half of the pier plate and the crest plate in some instances have been torn off and the concrete has again eroded in these areas (29*c*).

The cause of this destruction has not been determined definitely. Great pressure fluctuations on the pier face may be responsible for the ripping off of the steel plates. That cavitation is also present is indicated by the appear-

Fig. 24.—View Showing Pitting and Erosion of Baffle Piers on the Spillway Apron of Bonneville Dam

ance of the eroded areas in the concrete. However, pitting of the steel plates has not occurred except in one instance. In this instance, the pitting could have been due to local irregularities peculiar to this particular plate. As a result of these observations, it would appear that a very mild degree of cavitation is present, one which will not pit steel but which will pit concrete. If further observations prove this to be the case, the final solution to this problem may be to replace the ½-in. plates with heavier plates and to provide better anchorage so that they will not be ripped off. However, if pitting of the plates becomes general, it may be necessary to use a cavitation-resisting alloy steel or to conduct model tests to determine a shape of gate slot that will not give rise to cavitation.

Baffle Piers

The submerged spillway bucket and apron of Bonneville Dam were inspected by a diver. Considerable erosion was discovered on the floor of the apron and bucket and on all faces of the baffle piers (29*d*). The surface concrete of this part of the dam was also known to be weak due to cold-weather

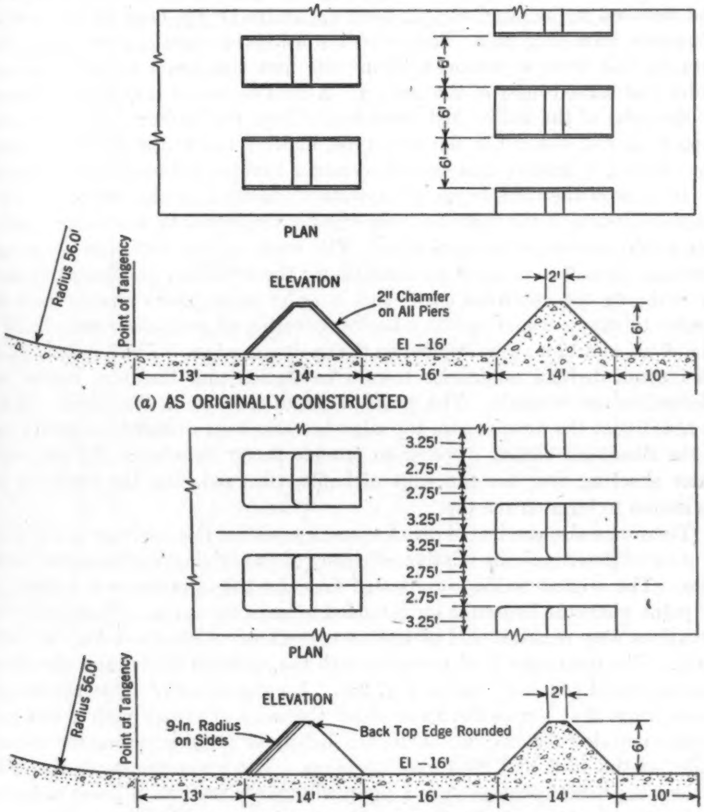

Fig. 25.—Dimensions of Baffle Piers, Spillway Apron, Bonneville Dam

curing conditions. The baffle piers, however, in addition to appearing worn all over, were deeply cut on the sides just downstream from the leading edges, indicating that cavitation may have also been a factor in this erosion. Fig. 24 shows two upstream baffles in a special caisson which was later constructed to repair some of the baffles. Fig. 25(*a*) shows the layout of these baffles on the spillway apron.

Further Model Tests of Baffle Piers

In order that these baffle piers might be properly repaired, it was thought advisable to conduct model tests in the vacuum tank at Carnegie Institute of Technology for the purpose of determining whether or not cavitation had contributed to the erosion of the baffle piers. These tests were undertaken in 1941. A model of the present spillway apron ($L_r = 1/48$) was constructed and installed in the same vacuum-tank apparatus as was used for the tests on Bluestone Dam (Fig. 16). Tests were run using the operating conditions that actually had been experienced during the first two years of operation and which had caused most of the erosion. A mild degree of cavitation appeared on the sides of the baffles just downstream from the leading edges where the deep holes had scoured in the prototype, under a few of the discharge conditions tested, indicating that cavitation might have contributed to this erosion.

In view of the mild degree of cavitation observed, it was decided to try a simple rounding of the upstream side edges of the baffles to determine whether this would eliminate the cavitation. The width of the baffle piers was also increased from 6 ft to 6.5 ft to make up for the reduction in efficiency caused by rounding the upstream edges and in order to facilitate repairs since the greater thickness would permit a thicker covering of good concrete. Radii of 6 in., 9 in., and 12 in. were studied on the upstream edges. The 9-in. and 12-in. radii eliminated all tendencies toward cavitation and the 9-in. radius was selected for use in repair. The modified design is shown in Fig. 25(*b*). It will be noted that the downstream top edge has also been rounded, as in the case of the Bluestone baffles, in order to provide better ventilation for the jet of water shooting over the top edge of baffle, thus reducing the tendency for cavitation to form on the top.

Tests were also conducted on an open-air model of this spillway ($L_r = 1/40$) in order to determine the relative efficiency of the original and modified baffle piers. The original baffles were tested first and the tailwater was lowered to the point where the hydraulic jump tended to leave the apron. These tailwater elevations were recorded and plotted in curve form as shown in Fig. 26 (solid lines). The tests were then repeated with the modified baffles and the elevations recorded (dashed lines in Fig. 26). A comparison of these curves will demonstrate that the baffles have about the same efficiency with a 6-ft gate opening and that the modified baffles are slightly more efficient than the original baffles at the 12-ft and 20-ft gate openings. The lower the curve the more efficient the baffle becomes since a jump will take place with a lower tailwater level. Repair of these baffles in accordance with the modified design, therefore, will not affect adversely the efficiency of the stilling basin.

Pitting Simulated in Vacuum-Tank Model

An attempt was made, in connection with the Bonneville tests, to simulate pitting in the model. In view of the mild nature of the cavitation that occurs in the vacuum tank on these small models, and particularly in view of the mild nature of cavitation around the Bonneville baffle piers, considerable difficulty was encountered in finding a material sufficiently weak to pit and yet strong

enough to resist abrasion by the high-velocity water. Several materials were tried consisting of various mixes of cement, sand, and plaster of Paris or Opalite. It was found that a weak material with a hard outside crust was the most successful. The hard crust resisted abrasion but would fail under the pounding of cavitation. Being weak underneath, the material would then pit and form cavities such as those that occur in the prototype. In a test of one

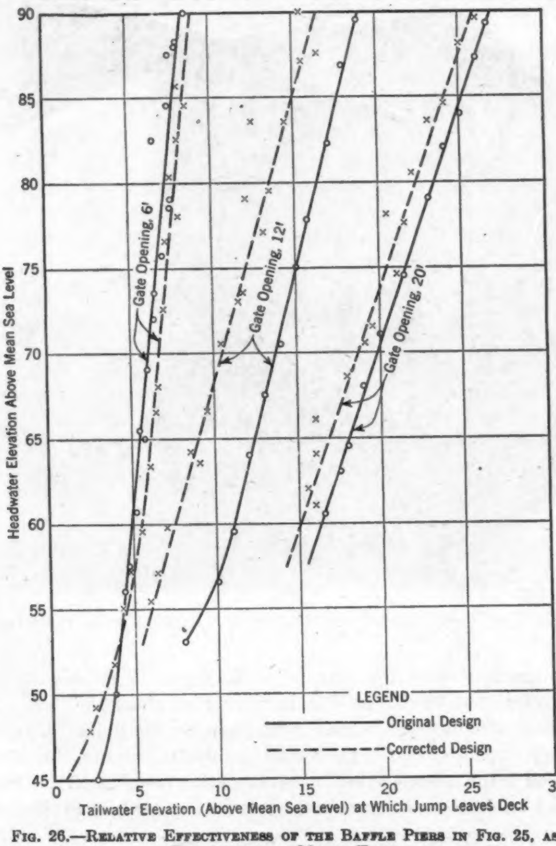

FIG. 26.—RELATIVE EFFECTIVENESS OF THE BAFFLE PIERS IN FIG. 25, AS DETERMINED BY MODEL TESTS

of the original square-cornered baffles, the model had to be "overspeeded," equivalent to subjecting the baffle pier to higher velocities than would exist in the prototype, in order to obtain any appreciable pitting. Some pitting occurred on the sides of the baffle just downstream from the leading edge, where pitting occurred in the prototype (see Fig. 24). These pitting tests were not entirely satisfactory, however, and further research on this subject will be necessary before any reasonable degree of success is possible with this small a model.

Another Example of Damage to Baffle Piers

Fig. 27 shows the effect of high-velocity flow on the baffle piers (height, 9 ft) in the stilling basin of Gatun Dam in the Canal Zone. The steel casting remaining in place is on the upstream face of the pier and is 3 in. thick. The side casting, which has been ripped off by the flow, was 2 in. thick. The front

Fig. 27.—Face Plate Ripped from the Side of a Baffle Pier in the Stilling Basin of Gatun Dam

casting was installed with the original baffle piers. The side castings were added later after considerable erosion had occurred along the sides. The side plates were anchored into the concrete with 12-in. anchor bolts. The side plates were probably ripped off by the great pressure fluctuations on the sides such as were measured in the model of the Bluestone baffles (see Fig. 21). The original erosion of the concrete on the sides was probably caused by cavitation.

Proper Use of Baffle Piers

Certain conclusions as to the proper location of baffle piers in stilling basins of high dams can be drawn from the data presented in this paper. Square-cornered, round-cornered, and streamlined baffles were tested. It is obvious from these tests that the greater the streamlining, the higher will be the velocity in which they can be used without causing cavitation. Also, since submergence produces a positive pressure tending to neutralize the negative pressure caused by high velocities, the depth of water over the baffle piers has an important

bearing on the velocity which they will stand. Since velocities are higher and depths shallower in the upstream end of a hydraulic jump basin, only streamlined baffles should be used in this location. Square-cornered baffles should be used well downstream on the apron where velocities are lower and submergence greater. The round-cornered baffles are an intermediate type. Research on this subject has not been extended far enough yet to enable one to state just what velocities and submergences each type of baffle will stand, but it is hoped that future testing will make this possible. The data presented in this paper are not intended in any way to discourage the use of baffle piers but rather to reveal some facts as to their proper use, because the use of baffle piers often results in a more economical stilling basin design and more stable hydraulic jump action.

Pitting in Shaft and Lock Culvert

Two other instances of pitting of concrete in structures built by the Corps of Engineers are of interest. Fig. 28 is a view (looking upward) of the erosion

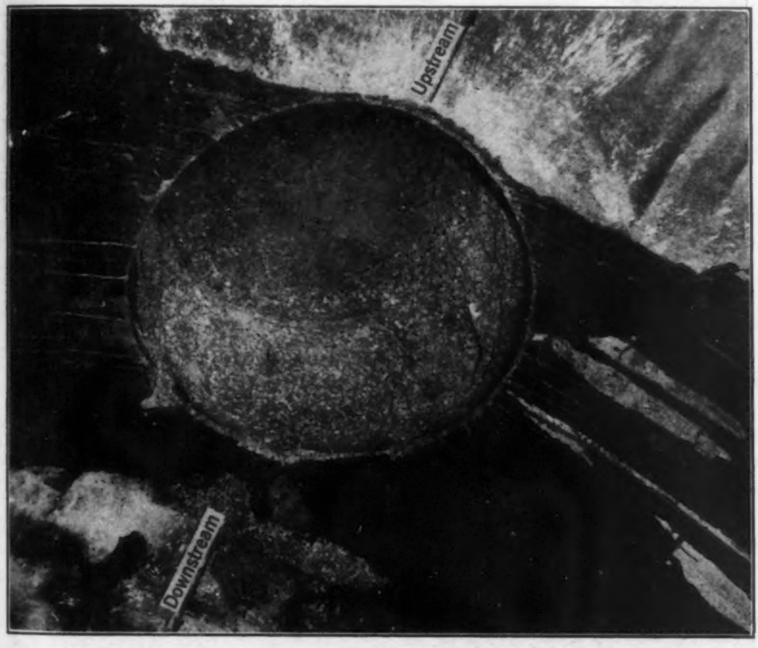

Fig. 28.—Pitting of Concrete Lining at the Bottom of a Vertical Shaft (Diameter, 7 Ft) at Mud Mountain Dam

of the concrete lining which occurred at the bottom of a vertical shaft 50 ft high at Mud Mountain Dam, in the State of Washington, through which water flowed in a downward direction for a period of about three months. Computa-

FIG. 29.—EXAMPLES OF PITTING IN THE LOCK-FILLING CULVERT OF WILSON DAM: (a) Downstream from a Constriction in the Culvert (7 ft by 9 ft); and (b) Downstream from a Sharp Bend

tions showed that cavitation probably occurred at the top of the shaft. Just why the pitting occurred at the bottom is not too clear. Perhaps the vapor pockets did not collapse until they plunged into the pool of water at the bottom of the shaft. The pitting was about 12 in. deep in places.

Fig. 29 shows two views of the pitting that was recently discovered in the filling culvert of Wilson Lock on the Tennessee River. Fig. 29(*a*) shows the pitting that occurred downstream from a constriction in the culvert (note points h, i, and j). The purpose of this constriction is explained elsewhere (23). Fig. 29(*b*) shows the pitting on the inside of a sharp bend in this culvert near its outlet end.

Instructive Lesson

An interesting example of the failure to watch for cavitation in model testing appeared in the technical press in 1940 (24). An ordinary open-air model of the siphon shown in Fig. 30 was constructed and tested. The discharges with

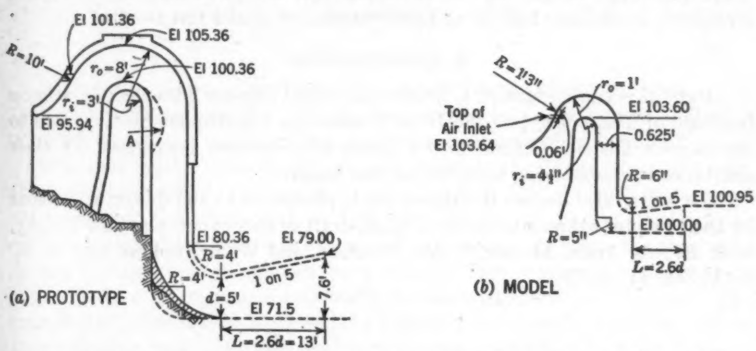

Fig. 30.—Siphon Prototype and Model in Which Discharges Were Found to Disagree Because of Cavitation in the Prototype

and without a flared outlet were determined. The flared outlet increased the discharge of the model 30% over the discharge without the flared outlet. When the full-sized siphon was built, it was also tested both with and without the flared outlet. The discharge in the prototype was increased only 3% by the flare. The writer of the article attributed this difference to a cavitation pocket that formed at point A in the prototype (Fig. 30(*a*)) but not in the model. The lesson is one that all designers should take seriously—to watch for pressures close to the vapor pressure in model studies. If the pressure at any point in an open-air model falls below the vapor pressure (prototype scale), the model is no longer reliable and either the design must be changed to raise all pressures above the vapor pressure, or the model must be tested in a vacuum tank where the action of cavitation can be simulated correctly.

Subjects for Further Research

Cavitation testing has opened a broad field for research. With improved apparatus, it may be possible to test models of entire structures, under a

vacuum, instead of just parts of these structures. Also, having the equipment, it may be possible to develop general laws for the occurrence of cavitation, say around baffle blocks, below gate slots, in curved conduits, siphons, and the like, which will be useful in design. As far as the writer knows there is only one vacuum tank suitable for the testing of hydraulic structures, that at Carnegie Institute of Technology, and only one set of dynamic pressure cells, those at the U. S. Waterways Experiment Station. Perhaps this Symposium will encourage others to undertake useful research along this line.

Certain full-sized tests also appear desirable. It would be interesting to know just how severe cavitation must be in order to damage concrete—that is, how large a cavitation pocket must be or what frequency of collapse is necessary to cause severe pitting. It would also be interesting to know how fast concrete will pit under various degrees of cavitation; also how close the cavitation streamer must be to the structure in order to cause pitting. A general model-prototype study, wherein identical tests are performed in model and prototype, would also help in an interpretation of model test results.

Acknowledgment

Grateful acknowledgment is hereby made to Professor Thomas of Carnegie Institute of Technology, to the U. S. Waterways Experiment Station, and to the various District Offices of the Corps of Engineers concerned for their assistance in assemblying material for this paper.

The writer also desires to express his appreciation to the following persons for their helpful comments on the original draft of this paper: Captain Tiffany, F. R. Brown, Assoc. M. ASCE, Mr. Schuleen, and W. J. Hopkins, and W. H. McAlpine, M. ASCE.

EXPERIENCES OF THE BUREAU OF RECLAMATION

By Jacob E. Warnock,[4] M. ASCE

Synopsis

With the trend to larger and larger hydraulic structures, cavitation and the resultant pitting have become major problems to the hydraulic designing engineer. Subatmospheric pressures in smaller structures were of little consequence, but with the increase of head in more recent structures, the approach of subatmospheric pressures to absolute zero as their limit has created previously unheard of situations. Experience in the laboratory and in the field shows that prevention of cavitation is fundamentally a function of design.

Introduction

Pitting due to cavitation is not new to the Bureau of Reclamation, U. S. Department of the Interior. Trouble was experienced as far back as 1910–1920 in outlet works, but recent examples have been more severe in extent due to the increased head. In discussing the arrangement and design of outlet works, J. M. Gaylord and J. L. Savage, Hon. M. ASCE (25), in 1923 stated that "Most of the difficulties with outlets built by the Bureau of Reclamation can be attributed to the effects of vacuum in the conduits below the regulating devices." However, it was not until recently that pitting has appeared on the surfaces of water passages normally considered to be open channels. Two examples of conduit flow are described herewith—the needle valves at Boulder Dam (Arizona-Nevada) which discharge into the atmosphere, and the balanced valve outlets at Shoshone Dam (Wyoming) which discharge into short conduits. Two examples of pitting in open channels are also shown—in the Arizona spillway tunnel at Boulder Dam and on the spillway pier faces at Parker Dam, both on the Colorado River.

The remedial measures in each case were made possible by laboratory studies. In fact, the occurrence of cavitation and pitting in the large hydraulic structures constructed in recent years would be more prevalent were it not for the availability of hydraulic laboratory facilities. A careful exploration of the pressures within a model can detect those conditions which, when transferred to a prototype structure, will cause the intermittent subatmospheric pressures producing cavitation. At one stage in the design of the spillway for Grand Coulee Dam (26), in Washington, a dentated lip at the downstream end of the apron eliminated the impingement of the high-velocity flow directly on the river bed downstream from the apron, reduced the scouring effect of the turbulent flow, and materially reduced the roughness of the water surface in the stilling pool. Minute examination of the pressures on the faces of the dentates in a

FIG. 31.—PITTING OCCURS AROUND THE PERIPHERY OF A LARGE NEEDLE VALVE, IMMEDIATELY BELOW REGIONS OF SUBATMOSPHERIC WATER PRESSURES

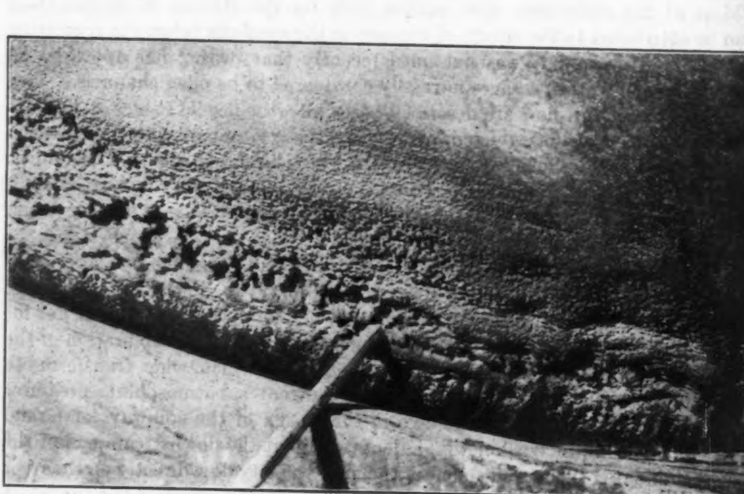

FIG. 32.—ENLARGED VIEW OF SECTION IN FIG. 31 EMPHASIZES THE SEVERE PITTING ON THE SHOULDERS OF THE NEEDLE VALVE WHICH REQUIRES EXPENSIVE MAINTENANCE BY WELDING

1 : 40 model and a 1 : 15 model showed that cavitating pressures would occur in the prototype which would have destroyed the piers in a very short time. This condition was the principal factor in continuing the laboratory studies which resulted in the adoption of the bucket type of energy dissipator.

The destruction of the conduit roof in the outlets at Madden Dam, on the Chagres River in the Isthmus of Panama, by pitting from cavitation was the incentive for a complete model study of the outlets (27) for Grand Coulee Dam. Aside from the criterion of efficiency, the emphasis throughout the tests was to prevent pressures from occurring at any point in the conduit which would cause cavitation. One of the early designs of the upper and intermediate outlets showed subatmospheric pressures of such intensity that, had the design been constructed, cavitation would, without doubt, have been so severe as to hamper, if not completely prevent, successful operation. In the original design the fact was overlooked that the frictional forces in the sloping conduit were insufficient to overcome the accelerating force due to gravity, a condition which became readily apparent in the experimental studies.

There was a period prior to the Madden Dam incident when it was difficult to demonstrate that cavitation and pitting could occur in a hydraulic structure in the same manner as it has occurred in hydraulic machinery such as marine propellers, turbines, and pumps. With the experiences at Madden Dam and in certain Bureau structures, augmented by laboratory investigations, the importance of this cavitation problem is fully recognized by Bureau engineers.

The Gaylord-Savage report (25) describes outlet structures and recounts the difficulties experienced in the excessive maintenance due to damage from cavitation. Although the theory of cavitation at that time differed materially from the current conception, the adverse condition was even then associated with extreme subatmospheric pressures. It was realized that the erosion or pitting was an action accompanying subatmospheric pressures, but the cause was not completely understood. At first the pitting was believed to be a direct result of the making and breaking of the vacuum in the immediate vicinity.

As is now the case, one of the most practical remedies applied to the discharge conduits installed in early periods was the introduction of air immediately below the regulating device. Air was admitted to the discharge conduit in a number of instances during the first years of operation, but, in the light of air-requirement tests made in recent years on both model and prototype structures, it is doubtful if the air supply in most cases was either adequate or properly installed. The location of the air inlets in the conduits is often more important than the size. Thus, improper location might have been one of the main factors contributing toward failure of some of the early systems.

Streamlining the needle tips is considered the only practicable means of eliminating damage to this part of the valve; however, damage could be reduced to a minimum by restricting the valve operation to noncritical openings determined by detailed pressure measurements on the prototype or by model tests, or both.

Damage to Needle Valves

Initial operation at Boulder Dam and Alcova Dam, in Wyoming, produced severe erosion of the needle valves in the outlet structures which was expensive to maintain, since the valves were not readily accessible. The type of damage is shown on the needle in Figs. 31 and 32. In this case, the damage was produced in a relatively short time. Detailed records are not available, but the time was probably about one month at the one-half open position with a head of 145 ft.

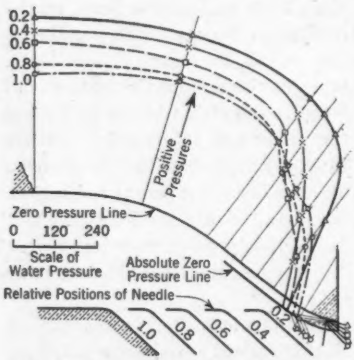

Fig. 33.—Pressure Distribution on the Nozzle of a 72-In. Needle Valve (Head, 516 Ft) Shows Regions of Low Pressure Which Correlate Perfectly with the Occurrence of Pitting

Piezometers installed in the nozzle of one of the 72-in. valves at Boulder Dam showed pressures near absolute zero in a zone (Fig. 33) immediately upstream from the region of erosion or pitting throughout the entire range of the valve. Since the installation of pressure equipment in one of the 72-in. needles would have been intricate, a homologous needle valve with an exit diameter of 5 in. was installed for testing in one of the tunnel-plug outlets at Boulder Dam. The pressure distribution on the needle and nozzle is shown in Fig. 34 for various openings of the valve under a constant head of 150 ft.

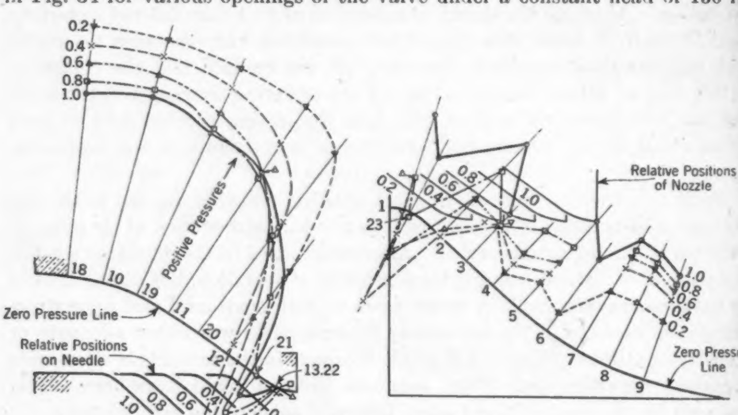

Fig. 34.—Detail Data from Extensive Tests of a 5-In. Scale-Model Needle Valve Further Confirm the Pressure Measurements and Pitting Observed on the Prototype

In general, the pressure conditions were most critical at a valve opening of approximately 40%. The results of a wear test (Fig. 35) are shown after six

days of operation under a total head on the valve of 460 ft with the valve opening of 40%—the severest condition.

A number of designs were studied in the laboratory using the same 5-in. valve and a design was developed which produced positive pressures at all valve openings and at all heads. This design, when subjected to a wear test, under the same conditions as the original design (except at an opening of 20%, the opening at which the severest conditions occurred), showed no sign of pitting on the needle after eighty-four days of operation (Fig. 36).

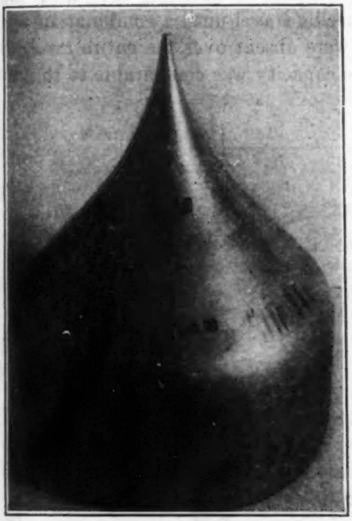

FIG. 35.—PITTING ON THE NEEDLE OF A 5-IN. VALVE, ACCORDING TO THE ORIGINAL DESIGN, AFTER SIX DAYS OF OPERATION (40% OPENING AND H = 460 FT)

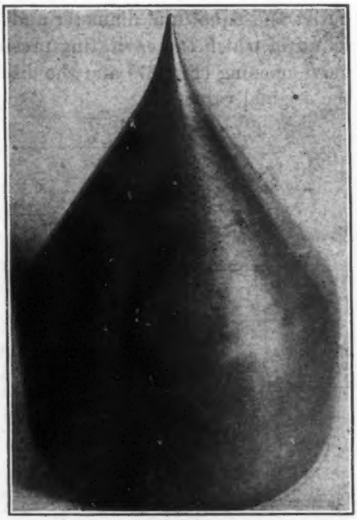

FIG. 36.—ABSENCE OF PITTING ON THE NEEDLE OF A 5-IN. VALVE, ACCORDING TO THE IMPROVED DESIGN, AFTER 84 DAYS OF OPERATION (20% OPENING AND H = 460 FT)

The original design of nozzle had an expanding water passage which tended to lower the velocity and cause a regain of velocity head. This yielded a higher discharge but created low-pressure areas in the valve. When forces in the low-pressure areas were of sufficient intensity, they produced cavitation with the accompanying pitting.

From the high-head studies of the 5-in. valve, certain specifications were developed to maintain positive pressures on the needle and nozzle of the valve at all openings. The angle between the needle and the nozzle must not be divergent in the direction of flow. The needle and nozzle profiles may be parallel and still maintain positive pressures, but a convergence of one to three degrees is preferable. The seat must be on the tangent portion of the needle; that is, the base diameter of the needle cone must be slightly larger than the outlet diameter of the nozzle. The valve nozzle should have no point of inflection; it should have a sharp edge to maintain the minimum section at

the outlet of the valve nozzle and should permit free access of air to the jet at the point of emergence.

The high-head studies on the 5-in. valve gave positive proof that the 72-in. valves were pitted by cavitation and that elimination of the severe subatmospheric pressures causing the cavitation was possible by the redesign of the hydraulic passages of the valve. In eliminating the low pressure by using a sharp-edged nozzle in the improved design the discharge capacity was reduced.

Using a 6-in. valve equipped with piezometric taps throughout the profile of the needle and the nozzle, the design was altered further by increasing the outlet and equatorial diameter and the needle travel until a combination was found in which the cavitating pressures were absent over the entire range of valve opening (Fig. 37) and the discharge capacity was comparable to that of the original valve.

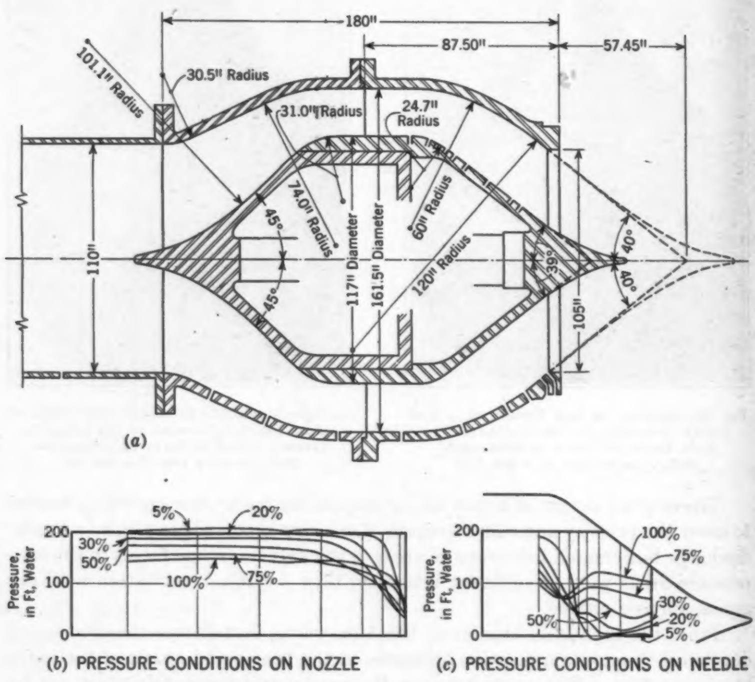

FIG. 37.—COMPLETE ABSENCE OF CAVITATING PRESSURES ON THE NEEDLE AND THE NOZZLE OF A NEW DESIGN OF NEEDLE VALVE, AS DETERMINED FROM A 6-IN. MODEL

Although the new design has not been used in a field structure, the satisfactory operation of the 5-in. valve with positive pressures throughout, under a head of 460 ft for eighty-four days, indicates similar satisfactory operation in a larger valve of the new design. As designed for Friant Dam in California, the

valve in Fig. 37 has an inlet diameter of 110 in. and an outlet diameter of 105 in.

Subsequently, sharp-edged nozzles were installed on certain valves at Boulder Dam and the pressure results show a marked improvement in distribution (Fig. 38). Field reports indicate a minimizing of pitting on those valves so equipped. Operation of the valves with the original nozzle shape at openings where the subatmospheric pressures were less severe, as indicated by model tests, has also tended to reduce the amount of pitting.

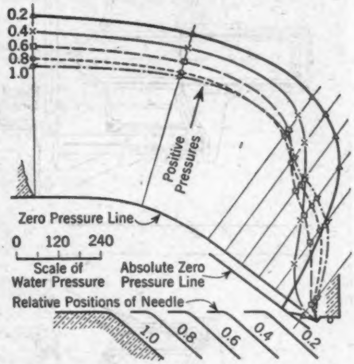

FIG. 38.—PRESSURE DISTRIBUTION ON THE NOZZLE OF THE 72-IN. NEEDLE VALVES AT BOULDER DAM, WITH REVISED PROFILE OF NOZZLE

SHOSHONE DAM BALANCED VALVES

The 58-in. balanced valves in the lower outlet tunnel in the south canyon wall at Shoshone Dam, near Cody, Wyo., were installed in May, 1915. Although this type of valve had already required considerable maintenance in the installations at Roosevelt Dam, in Arizona, and Pathfinder Dam, in Wyoming, it was adopted because of the lack of a better design.

The valves were in operation only a few seasons when it became evident that seasonal maintenance similar to that at the older installations would be required. Pitting of the downstream faces of the valve needles and severe damage to the discharge conduit walls immediately below the valves occurred during extended periods of operation. Patching with various materials or filling the pitted areas by arc-welding with different metals was of no avail. With few exceptions the patches eroded more rapidly than the parent metal.

In 1930–1931, an attempt was made to relieve the Shoshone situation by installing twenty-four 2-in. pipes and an 8-in. air duct below each valve (Fig. 39(*a*)). A marked increase in the intensity of the noise accompanying the discharging water resulted, and the experiment was considered unsuccessful. Because of the failure of the vent system, resort was made to the original method of maintenance and the valves were used as little as possible. The pitting was serious and the repairs inadequate, but a more practical method of repair was not apparent.

During the season of 1942, the valves at Shoshone were operated at almost full capacity over an extended period in order to regulate flood flow and prevent crop damage downstream. Damage to the outlet structure was severe and maintenance measures became critical.

The concrete for several feet downstream from the metal lining in each conduit had been eroded severely and most of the twenty-four 2-in. pipes embedded in the conduit during the 1931 revision had been torn out in the eroded area (Fig. 40(*a*)). The "semi-steel" (high-test gray iron) conduit liner

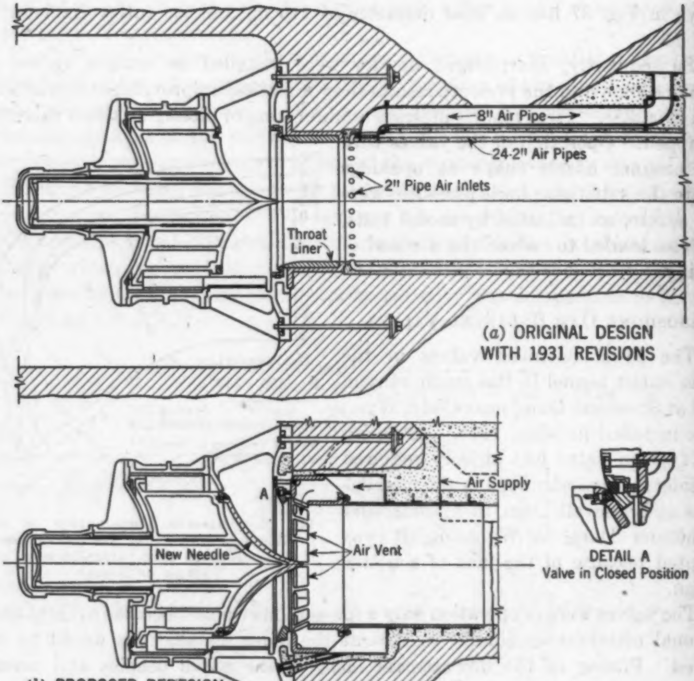

FIG. 39.—BALANCED VALVES IN THE LOWER OUTLETS AT SHOSHONE DAM

below the valve was pitted severely and the face of the needle (Fig. 40(*b*)) had badly pitted areas (by operation in previous years) on which several kinds of

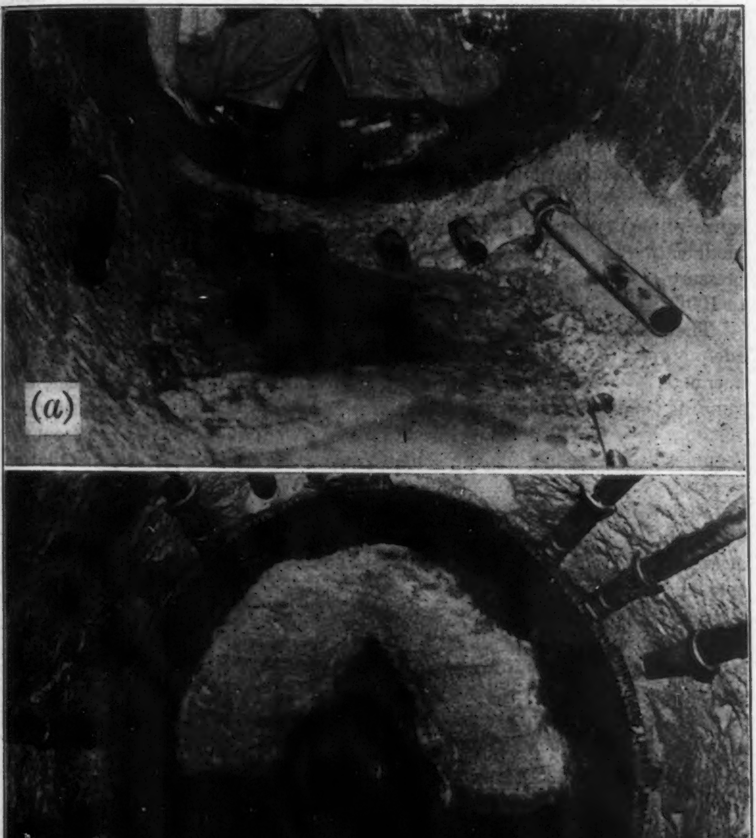

FIG. 40.—REMAINS OF 2-IN. AIR PIPES, SHOSHONE DAM: (*a*) Vent of a 52-In. Conduit Facing Downstream from the East Valve; (*b*) East Conduit

metal had been tried—none satisfactorily. The areas of greatest pitting were below and above the valve guides, where only 3/4 in. of the original 2 in. of parent metal remained. The extensive welding of previous years, on the

needle face, is apparent in Fig. 40(*b*). The end of the metal liner was cut off in 1931 when the present installation was made.

Hydraulic laboratory model studies were made to evolve means of minimizing or eliminating the severe damage, to reduce the unreasonably high seasonal maintenance, and to remove the danger of a possible failure of the water-release system. This problem involved an extensive study of the pressure distribution in the valves and the discharge conduits.

Three alternatives were developed: (*a*) The range of valve opening was determined in which damage would be minimized until materials, unobtainable due to wartime restrictions, become available; (*b*) a redesign (Fig. 39(*b*)) was developed in which adverse pressure conditions were eliminated over the entire range of operation, but at some sacrifice in the discharge capacity; and (*c*) a modification of the present installation (Fig. 39(*c*)) was developed in which pressure conditions were acceptable over a range of valve opening from 25% to 100% with no reduction in the discharge capacity.

The model tests showed that the present prototype vent system is inadequate to prevent cavitation for all except a very small range of valve openings. Insufficient air is supplied between 23% and 70% openings, and some of the 2-in. vent pipes on the invert and crown become ineffective at openings above 85%, due to eddies forming immediately downstream from the V-guides. These conditions precluded safe operation of the present installation at ranges of valve opening other than 70% to 85%. Studies of the present installation indicated that the pitting on the valve needles was most severe between openings of 14% and 25%, and that damage to the conduits resulted between 23% and 70% valve opening. The damage to the conduit at these openings probably rendered the air-supply system ineffective and aggravated the destructive action for larger valve openings.

Damage by cavitation and pitting on the valve needles and discharge conduits can be eliminated entirely by a major revision (Fig. 39(*b*)) of the needle tip, the valve seat, the conduit throat, and the aeration system. This solution will reduce maintenance costs to a minimum and the valves can be operated at any opening without fear of damage due to subatmospheric pressures; but it will reduce the discharge capacity by approximately 20%, a factor to be considered in future revisions.

Minor alterations of the present structure (Fig. 39(*c*)) will involve: (*a*) Streamlining of the sealing edge of the plunger; (*b*) removal of a part of the bronze sealing ring by chipping and grinding; (*c*) removal of the throat liner; and (*d*) revamping of the air-supply system. Aeration equivalent to three 12-in. ducts would be adequate in this arrangement, but slightly more area was recommended as information on air requirements in high-velocity flow is limited. Operation of this modified design at openings smaller than 23% will have to be avoided to prevent damage to the needle. The discharge capacity is not affected noticeably by the modification.

Since materials have been unobtainable to make either the minor alterations or the major revision, the valves were operated during the 1943 irrigation season in the valve-opening range at which the subatmospheric pressures were the least severe. After thirty-five days of operation at 75% opening, the valve

itself showed no evidence of additional pitting, and a very small amount of pitting had occurred in the extreme top of the discharge conduit. Forty-seven days of operation at 9% opening in 1942 had caused the damage shown in Fig. 40.

PARKER DAM SPILLWAY PIERS

The spillway at Parker Dam has five 50-ft by 50-ft stoney gates to pass the flood waters. These gates were also used for passing the flow of the river during the low-water season, particularly during the early years of operation, before the power plant was completed. As a result of this early scheme of

FIG. 41.—PITTED AREA ON THE FACE OF A SPILLWAY PIER IMMEDIATELY DOWNSTREAM FROM THE GATE RECESS AT THE RIGHT, OR CALIFORNIA END, OF GATE NO. 5 AT PARKER DAM

release, the gates were operated continuously over long periods, with a relatively small gate opening and a head above the spillway crest of from 40 ft to 50 ft.

An eroded condition, similar to that on the spillway faces at Bonneville Dam described in a previous paper, began to develop on the faces of the spillway piers and on the spillway crest immediately downstream from the gate slot

(Fig. 41). It first appeared below the gate which had the longest record of operation, but there was evidence of it downstream from the other gates. Subsequent operation of the other gates had gradually developed the same pattern on all ten of the pier faces in lesser degree of intensity. Photographic inspection at approximately yearly intervals discloses some increase in the extent of the area and depth of the erosion, but not sufficient to cause undue alarm, particularly since the power plant has been placed in operation and most of the low-water flow passes the dam through the turbines.

Model studies were undertaken to reveal the cause and means of eliminating pitting at Parker Dam and to prevent it at future installations. Incompleted studies, including all possible circumstances, have revealed several points of interest. The use of transparent models revealed cavitation under the end of the gate in the gate slot as a result of a vortex. Pitting, caused by the collapse of the low-pressure pockets breaking away from the bottom of the vortex, is the only logical explanation of the damage to the pier face.

A similar installation at Guernsey Dam, in Wyoming, showed no signs of erosion on the spillway face even though the gate has operated in the same range for a long period of time. This naturally raised the question as to why erosion occurred at Parker Dam and not at Guernsey Dam.

The gate slot at Guernsey Dam is considerably larger (Fig. 42) in horizontal cross section than the gate slot at Parker Dam. As a result, the vortex in the

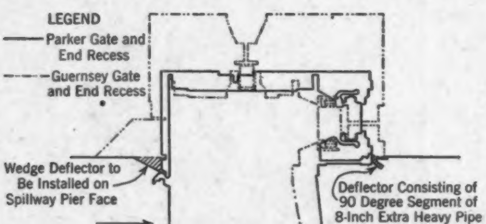

FIG. 42.—COMPARISON OF THE GATE RECESSES OF GUERNSEY DAM AND PARKER DAM, SHOWING THE LOCATION OF THE DEFLECTORS PROPOSED AS REMEDIAL MEASURES AT PARKER DAM

gate slot at Guernsey Dam was large and slow in rotation with no appreciable reduction in pressure at the core, whereas with the smaller cross section of the gate slot at Parker Dam, the angular velocity was high with a very small core and very low pressures in the core. As in the case of the cavitation zone downstream from a venturi throat, the flow condition was unstable and low-pressure pockets broke away from the bottom of the vortex. Some of the pockets collapsed against the boundary surface, resulting in the destruction of the concrete and metal.

According to the present conception of the condition, the solution appears to be the elimination of the vortex. This can be done in a number of ways, none of which is universally applicable. In the case of Parker Dam, it is proposed to install a wedge-shaped deflector (Fig. 42) upstream from the gate sufficient in extent to deflect the flow of water under the gate away from the

downstream corner of the gate slot, thus negating the formation of the vortex. An additional curved deflector consisting of a 90° segment of an 8-in. extra heavy pipe fastened to the metal at the downstream side of the gate slot will further deflect the flow away from the pier face and provide aeration down to the spillway crest. Another solution, practicable where the spillway crest is sufficiently far above the tailwater to provide drainage, is the extension of the end beams of the gates down into wells in the spillway crest, thus making them continuations of the gate slots. These gate-beam extensions will then serve as followers and will fill the gate slot as the gate is raised, providing continuity of the spillway pier face. In the case of a gate 50 ft high, the follower is considered structurally feasible in lengths to 6 ft. The model studies indicated that a follower length of from 2 ft to 3 ft is all that is necessary, since the occasion and duration of operation at the larger openings are infrequent and short.

Insertion of steel plates in the piers in the areas of pitting, as was done on the spillway piers at Bonneville Dam, is also a solution, but one remedying the effect rather than removing the cause.

Boulder Dam Spillway Tunnel

The channel spillway on the Arizona side at Boulder Dam was first placed in operation on August 6, 1941. On August 14, 1941, the drum gates were raised for a few hours and a hurried inspection was made of the tunnel. Little or no sign of erosion was apparent. Operation of the spillway was continued until December 1, 1941, at which time, because of the lowering of the reservoir elevation, it was necessary to start release of water through the tunnel plug outlet needle valves. During the four months of continuous operation, the average flow was approximately 13,500 cu ft per sec, except for several hours on October 28, when one of the drum gates dropped and the maximum flow was 38,000 cu ft per sec.

During a routine inspection of the spillway tunnels on December 12, 1941, an eroded area was discovered in the bottom of the curve connecting the inclined and horizontal portions of the spillway tunnel (Fig. 43(*a*)). The hole was approximately 115 ft long and 30 ft wide, with a maximum depth of 45 ft below invert grade.

The repair (Fig. 43(*b*)) of the damaged area has been described elsewhere (28). The chief concern here is an attempt to analyze the cause of the erosion. A number of theories have been advanced. In the opinion of the writer, the primary cause was misalinement of the tunnel a few feet upstream from the upper end of the eroded area. With an extremely high velocity down the inclined portion of the tunnel (at least 150 ft per sec), the stream followed the invert profile down to the hump; but, as it flowed over the hump, the water could not follow the sudden change in grade and a cavitation region formed between the sheet of flowing water and the concrete. The pressure in that region was the vapor pressure of the water, but since this condition was very unstable, the low-pressure pocket or cavity intermittently passed downstream

in the region of higher pressures, collapsed and disintegrated or pitted the concrete as shown in the foreground of Fig. 44. The misalinement is defined by the position of the rope in Fig. 44.

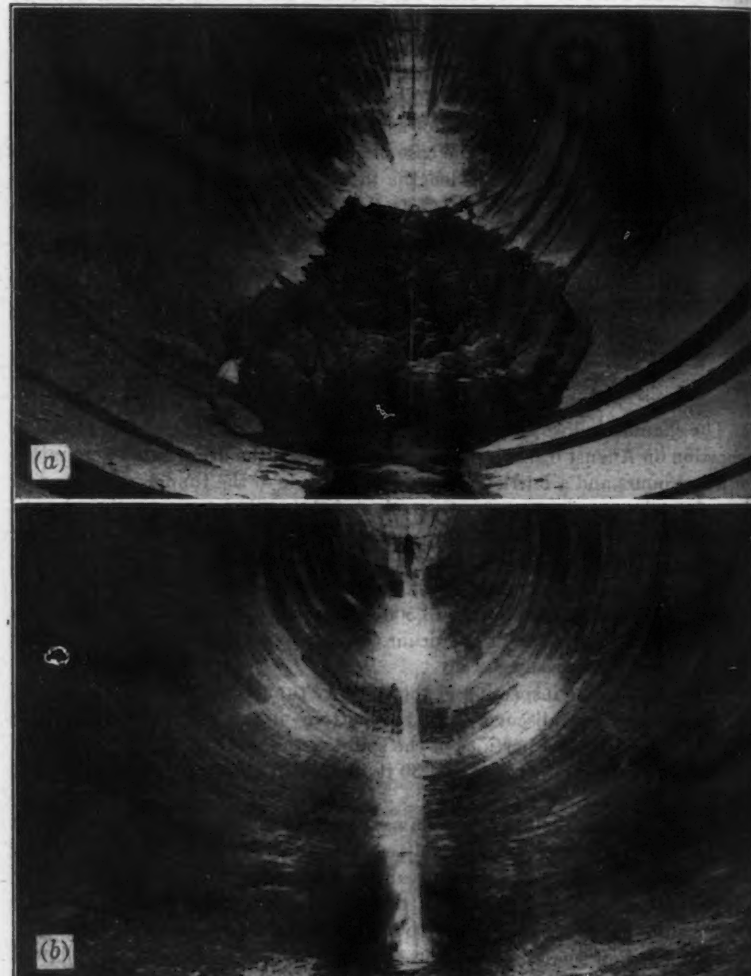

FIG. 43.—CAVITATION IN THE SPILLWAY TUNNEL ON THE ARIZONA SIDE, BOULDER DAM: (a) Eroded Area After Unwatering; (b) After Completion of Repairs

With the surface of the concrete broken by the pitting over a relatively small area, the high-velocity water had a grip on the concrete and destruction by

impingement started. Imperfections in the concrete, such as rock pockets, cold joints, porous areas, lack of bond, etc., all made the concrete more vulnerable to this attack by impingement. Furthermore, the impingement of the high-velocity water on any exposed joints would cause the energy in the water to be converted from velocity head to pressure head. This pressure was probably transmitted through the planes of weakness in the construction joints

FIG. 44.—PITTED SURFACE DOWNSTREAM FROM THE MISALINEMENT IN THE TUNNEL AT THE UPSTREAM END OF THE ERODED AREA

caused by lack of proper horizontal joint cleanup prior to placement of new concrete. The concrete, being weak in tension, was dislodged in a manner similar to freezing of concrete and the resulting expansion. The concrete was probably dislodged in quite large pieces. After the concrete lining was ripped away, the shattered rock in an underlying fault was dislodged and transported away by the water. The shattered rock in the fault contributed to the extent of the erosion and not to the cause. After the surface was broken by the pitting and the joints were exposed to direct impingement, the sheet of high-velocity water down the tunnel invert acted as a mammoth hydraulic giant.

The pitting of the concrete surface downstream from the hump is analogous to a flesh wound. Infection followed which was aggravated by the weaknesses

in the concrete and the shattered condition of the underlying rock. Under the conditions of misalinement which existed at a critical position in the inclined tunnel, it is doubtful that any material could have withstood the effects of cavitation indefinitely. Of course, perfectly sound homogeneous concrete and underlying rock would have greatly reduced the extent of the erosion.

If the rock pockets, cold joints, and other porous areas in the invert are assumed to be the primary cause of failure, it is difficult to explain why the rock pockets immediately above and below the hump have not been the source of erosion, since the velocity of the water at all three points is for all practical purposes the same. Actually, the coat of black waterproofing and mineral deposit was intact in many places, showing no effect of direct scouring by the high-velocity water immediately above and below the eroded area.

In making the repairs to the tunnel, aside from providing concrete having the most suitable qualities practicable, extra effort was made to provide a smooth continuous surface with no humps or depressions. Two major humps and several minor humps in the invert above the eroded area were entirely eliminated by bushing and grinding, using a template cut to the true radius of curvature. Rock pockets were cleaned, patched, and then ground to conform to the surrounding concrete. Accumulations of grout and mineral deposits were removed. The surface of new concrete in the eroded area was finished carefully to produce a sound, continuous, uninterrupted surface. The surface was given a final grinding with a small terrazzo machine to remove board marks and objectionable offsets, leaving an extremely smooth surface. Minor bulges in the surface were removed by bushing followed by grinding, using a template cut to the correct radius of curvature. Considerable care was used in grinding the surfaces adjacent to the old concrete lining to remove all offsets and other irregularities.

Conclusion

These illustrations are typical situations which should be avoided by designing engineers. Other such examples must exist. If these could be brought to light and explained in the discussions of this Symposium, they would be a definite contribution. Since experience seems to be the principal source of knowledge, those of the profession who are intimate with the effects, even though they have attained that knowledge the hard way and in some cases the embarrassing way, should impart their experiences so that a wide variety of instances can be available to avoid repetition in the future.

EXPERIENCES OF THE TENNESSEE VALLEY AUTHORITY

By George H. Hickox,[5] M. ASCE

Synopsis

This paper describes cavitation damage experienced by the Tennessee Valley Authority (TVA) in the sluices of Norris Dam, the repairs made to the damaged areas, and the steps taken to prevent similar damage in other structures built by the Authority.

Cavitation at Sluice Entrance, Norris Dam

As of July, 1945, TVA had experienced cavitation in only one of its structures, Norris Dam, in Tennessee. The sluices through the base of Norris Dam are similar in design to those of Madden Dam, in the Isthmus of Panama, and were under construction at the time the damage to the Madden sluices was discovered. In an attempt to prevent similar damage to the Norris sluices, the entrances were bellmouthed by the addition of a half-doughnut-shaped structure on the upstream face of the dam. Fig. 45 shows vertical and horizontal sections through the Norris sluice entrance.

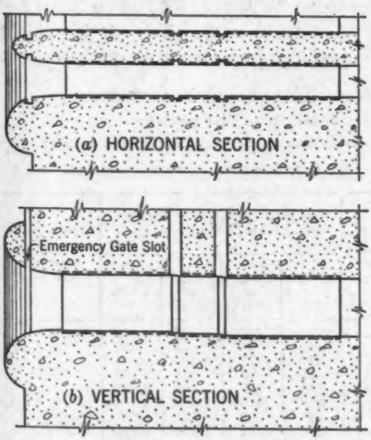

Fig. 45.—Sections Through Sluice Entrances, Norris Dam

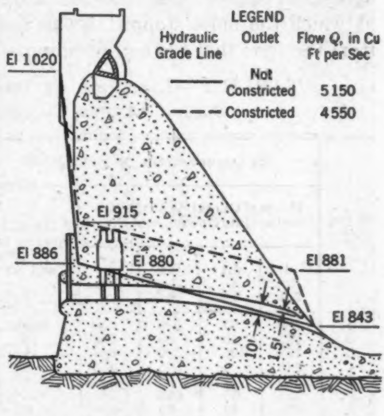

Fig. 46.—Effect of Outlet Constriction on Hydraulic Grade Line

The conduit is 5 ft 8 in. wide and 10 ft high and is lined above and below the gates with "semi-steel" (high-test gray iron). Below the liner the conduit was laid out along the trajectory of the jet so that the discharge would enter the bucket on a tangent.

[5] Senior Hydr. Engr., TVA, Hydr. Laboratory, Norris, Tenn.

Fig. 46 shows the hydraulic grade line for a discharge of 5,150 cu ft per sec and indicates that the pressure in the vicinity of the gates is relatively low, a condition favorable to cavitation. It will be noted that the low outlet contributed to the low hydraulic grade line at the entrance.

When the sluices were placed in operation with the pool at El. 1028, at the time of the release of flood water in 1937, with gates fully open, a pronounced cracking or snapping sound was heard. It seemed to originate somewhat upstream from the operating gallery in the vicinity of the sluice entrances. When the gates were closed 0.4 ft, giving a net opening of 9.6 ft, the noise stopped. It is believed that this noise was caused by cavitation occurring in the sluice entrance. An inspection made by a diver in January, 1938, showed that the sluices had not been damaged. The absence of damage, however, does not eliminate the possibility of cavitation. Accurate information on the discharge of the Norris sluices is not available but the best data at hand indicate that, with the reservoir at El. 1028, the discharges for gate openings of 10.0 ft and 9.6 ft were 5,310 and 4,920 cu ft per sec, respectively. Tests on a model of the Norris sluices, made at the TVA Hydraulic Laboratory in Norris, Tenn., showed that, with a discharge of 5,310 cu ft per sec, the prototype pressure corresponding to the model pressure immediately below the emergency gate slot at the roof of the sluice would have been 74 ft below atmospheric if such a pressure were physically possible. They also indicated that cavitation should stop when gate closure reduced the discharge to 4,850 cu ft per sec. The agreement between this value and the probable discharge of 4,920 cu ft per sec, at which the noise stopped, seems too close to be accidental. It is evident from the tests that the half-doughnut-shaped entrance structure was not satisfactory in eliminating cavitation as long as the emergency gate slot allowed the passage of water past the sharp upper corner of the entrance. Further tests showed that the low-pressure area could be eliminated by partial closure of the emergency gate slot.

TABLE 1.—EVIDENCE OF DAMAGE CAUSED BY CAVITATION, SLUICE LINERS, NORRIS DAM, IN TENNESSEE

Sluice No.	(a) OBSERVATIONS OF APRIL, 1937: Hours of Operation at the Following Gate Openings, in Feet: 0 to 5.0	5.1 to 9.3	9.4 to 10.0	Total	Depth of pitting below gate slot (in.)	(b) OBSERVATIONS OF FEBRUARY, 1938: Hours of Operation at the Following Gate Openings, in Feet: 0 to 5.0	5.1 to 9.3	9.4 to 10.0	Total	Depth of pitting below gate slot (in.)

Pitting Below Sluice Gates due to Cavitation

The sluices are lined above and below the gates with castings of so-called gray iron. In April, 1937, the liners below the sluice gates were inspected for

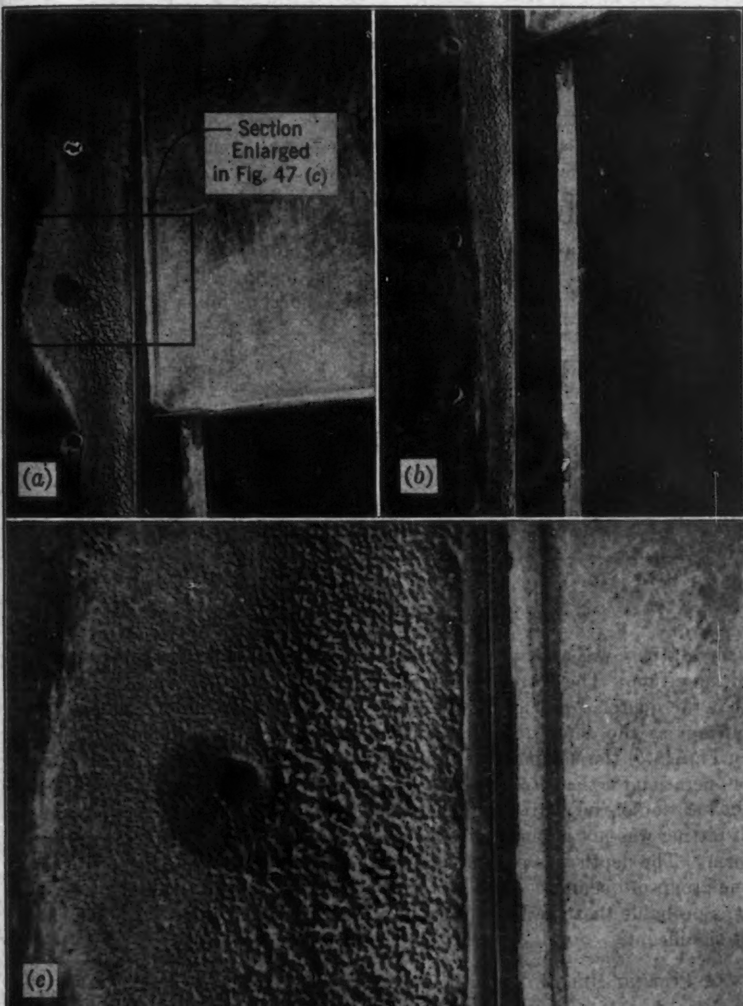

Fig. 47.—Pitting Below the Gate Slot Along the Right Side of Sluice No. 6: (a) Upper Part of Sluice; (b) Lower Part of Sluice; and (c) Enlarged Section (See Fig. 47(a))

evidence of damage due to cavitation. Table 1(a) summarizes the results of this inspection. It gives the hours of operation for gate openings of 0 ft to

5.0 ft, 5.1 ft to 9.3 ft, and 9.4 ft to 10.0 ft, and the depth and location of the deepest pitting below the gate slot. A similar inspection was made in February, 1938, and the results of this inspection are given in Table 1(*b*). The mean velocities during the period of operation varied between approximately 80 ft per sec and 100 ft per sec, depending on the reservoir elevation.

Table 1 demonstrates that the damage to the liner was progressive, increasing with the length of time the sluices were operating. In every case the depth of pitting was greater in 1938 than in 1937. Fig. 47 shows the pitting that occurred on the right side of sluice No. 6. Fig. 47(*c*) is a detailed view of the region indicated in Fig. 47(*a*). Similar pitting occurred on the left side of the sluice. In these illustrations it is interesting to note that, although the liner was pitted to a depth as great as 3/4 in., the bronze gate seat appeared to be undamaged.

An attempt was made to correlate the maximum depth of pitting with the time of operation. Fig. 48(*a*) shows the maximum depths of pitting plotted against the total time of operation for each sluice, as taken from Table 1. In

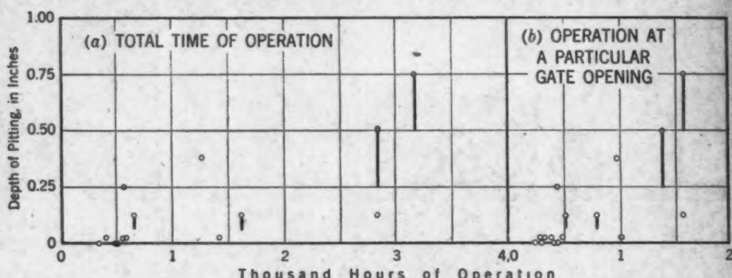

FIG. 48.—DEPTH OF PITTING VERSUS TIME OF OPERATION

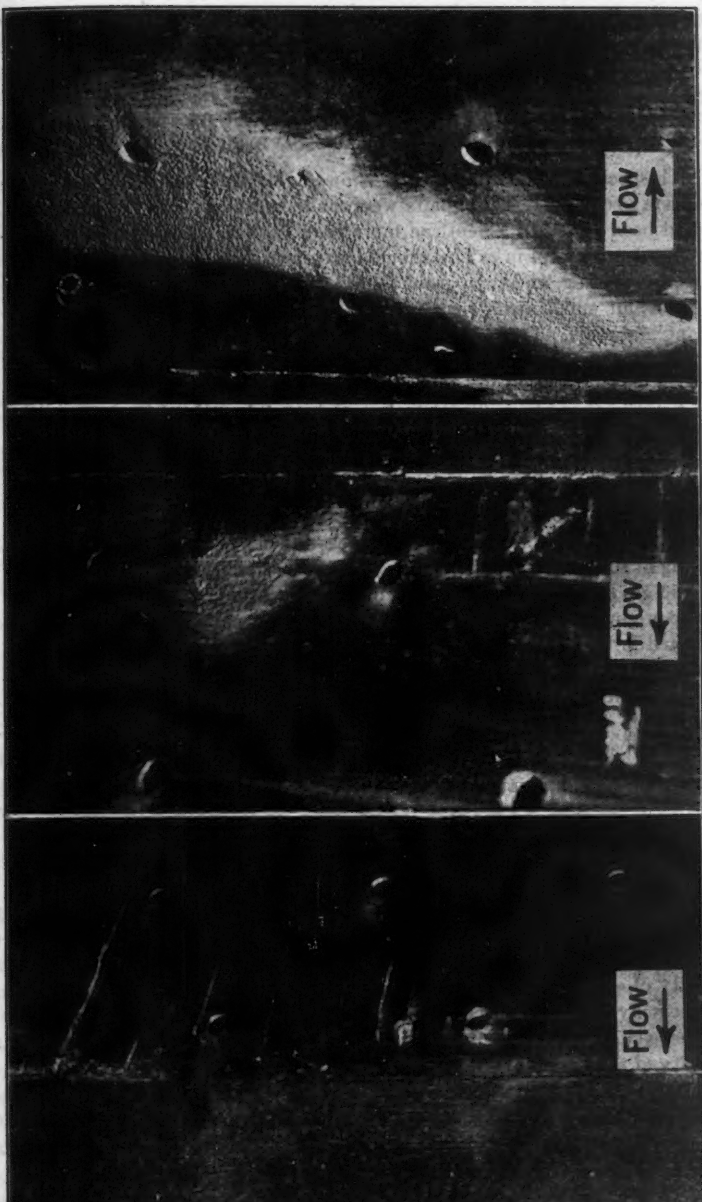
general, there was a definite increase in the depth of pitting with the total time of operation. The correlation is not too good, however, and it was thought that the depth of pitting for the total time of operation might not be as significant as the depth resulting from operation at a particular gate opening. In Fig. 48(*b*) the maximum depth of pitting has been plotted against the time of operation for the corresponding gate opening, as defined in Table 1, in which the location of the pitting is given. Where the location of the maximum depth of pitting was not given, it was assumed that the depth was more or less uniform. The depth was plotted against the maximum number of hours for any one group of openings. The correlation does not seem to be much improved. It is probable that the breakdown of operating time is not detailed enough to be significant.

PITTING BELOW IRREGULARITIES IN LINER DUE TO CAVITATION

Damage due to cavitation was noted not only below the gate slots but also downstream from the weep holes and the irregularities in the joints of the liner sections. Fig. 49(*a*) illustrates the pitting that occurred below the weep holes. Fig. 49(*b*) illustrates the effect of a slight projection into the sluices at one of



(a) Below the Weep Holes (b) Below an Obstruction at a Joint (c) Below a Mismatched Joint

Fig. 49.—Pitting Below Irregularities in the Joints of the "Semi-Steel" (High-Test Gray Iron) Liner Sections

the joints. Fig. 49(c) shows the damage that resulted from a slight mismatching of the liner sections at one of the joints. It is evident from these photographs that any irregularities, either depressions or projections, are sufficient to cause cavitation and pitting.

Repairs to Norris Sluices

The inspection of February, 1938, showed that some repairs to the sluice liners were necessary. The repairs were made as follows: All damaged parts that had been pitted to a depth of more than 3/16 in. were chipped out to a minimum depth of 1/4 in. The affected area was then built up to the original surface, by welding, and then ground smooth. The material used was chiefly mild steel but small areas were repaired experimentally with other pitting-resistant materials. Damaged parts that had been pitted to a depth of less than 3/16 in. were repaired by grinding the damaged part and any adjacent bumps or offsets, care being taken to leave only smoothly curved surfaces. Weep holes in the side walls were plugged by mild steel studs, driven tight, cut off flush with the surface, welded around the edges, and ground smooth.

In order to remove one of the causes of cavitation it was decided to raise the hydraulic grade line at the entrance by constricting the outlet. This was done by adding a concrete block 18 in. thick to the top of the sluices at the outlet as shown in Fig. 46. This constriction reduces the capacity of the sluices when operating at full gate opening but has no effect at smaller gate openings. The hydraulic grade line for full gate opening is shown in Fig. 46 for comparison with the original grade line. Three of the eight sluices, Nos. 1, 3, and 6, were constricted in this manner and the remainder were left in their original form.

After a sufficient period of operation, all sluices will be inspected to determine the effect of the constriction in preventing cavitation tendencies and of the repairs in preventing pitting. Sluice discharges since these repairs were made have been very infrequent and no inspection had been made as of July, 1945.

Model Tests for Prevention of Cavitation

Model tests were made of all sluices built by the TVA subsequent to the construction of Norris Dam. These included Hiwassee, Cherokee, Douglas, and Fontana dams.

Hiwassee Sluice.—The sluice through Hiwassee Dam is circular in section with a diameter of 8.5 ft. Ring follower gates were used to eliminate the possibility of cavitation at the gate slot. The hydraulic grade line was raised throughout by constricting the outlet diameter to 7 ft 10 in. The constriction was necessary because the sluices slope downward at a rate of 1 on 5. The possibility of cavitation at the entrance was investigated by means of models. The entrance and a portion of the sluice barrel were built at a scale of 1 : 15. A row of piezometers was placed along the crown of the entrance, special attention being paid to points of change of curvature. The shape of the entrance was a simple bellmouth. Three different forms were tested. The one in which the lowest pressures for the normal range of operation were nearly atmospheric

was selected. Fig. 50(*a*) shows the form of the entrance as it was built. A number of piezometers were installed in the prototype structure in locations similar to those of the model. Observations on these piezometers indicate that the pressures existing on the prototype are very close to those predicted by the model. There has been no indication of any cavitation tendencies. (The dotted lines in Fig. 50(*a*) indicate the presence of a metal liner in this sluice.)

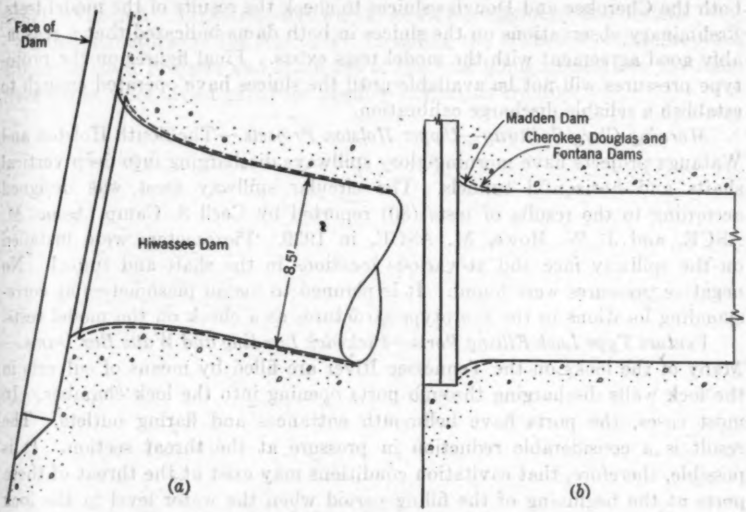


FIG. 50.—COMPARISON OF VERTICAL SECTIONS OF SLUICE ENTRANCES

Cherokee, Douglas, and Fontana Dams.—The sluices through Cherokee Dam, Douglas Dam, and Fontana Dam (see Fig. 50(*b*)) have the same cross section as those at Norris Dam. The Norris gate design was used, making it unnecessary to design new gates for these dams which were built on emergency schedules. The entrances and outlets, however, were modified to avoid the difficulties experienced at Norris.

Tests were made on a 1 : 15 scale model of the entrance at the discharges to be expected in the operation of the dams. Pressures were measured by two rows of piezometers, one row along the center line of the roof and the other in the roof adjacent to the side wall. It was found that the lowest pressures occurred in the corners rather than on the center line. This is interesting in view of the fact that in the damage reported at the Madden sluices, in which the entrance shape was quite similar (see Fig. 50(*b*)), the deepest pitting was on the side walls just below the roof rather than in the roof itself. Since the cross sections of the sluices for Madden Dam and Cherokee Dam are identical, the test results may be accepted as indicative of actual pressure conditions in the Madden sluices.

To produce satisfactory operating conditions on the spillway apron, the outlets for the Cherokee and Douglas sluices curve sharply downward and the

side walls are flared. The area was reduced 15% at the outlet to raise the hydraulic grade line at the entrance. A model of the outlet was built at a scale of 1 : 15 and piezometers were placed in the floor and side walls in the curved part to determine whether pressures might be low enough to induce cavitation. No low pressures were found.

Piezometers were installed in similar locations in the entrance and outlet of both the Cherokee and Douglas sluices to check the results of the model tests. Preliminary observations on the sluices in both dams indicated that a reasonably good agreement with the model tests exists. Final figures on the prototype pressures will not be available until the sluices have operated enough to establish a reliable discharge calibration.

Morning-Glory Spillway—Upper Holston Projects.—The South Holston and Watauga projects have morning-glory spillways discharging into deep vertical shafts and horizontal tunnels. The circular spillway crest was designed according to the results of tests (30) reported by Cecil S. Camp, Assoc. M. ASCE, and J. W. Howe, M. ASCE, in 1939. Piezometers were installed on the spillway face and at various locations in the shaft and tunnel. No negative pressures were found. It is planned to install piezometers at corresponding locations in the prototype structures as a check on the model tests.

Venturi Type Lock Filling Ports—Pickwick Landing and Watts Bar Dams.—Many of the locks on the Tennessee River are filled by means of culverts in the lock walls discharging through ports opening into the lock chamber. In most cases, the ports have bellmouth entrances and flaring outlets. The result is a considerable reduction in pressure at the throat section. It is possible, therefore, that cavitation conditions may exist at the throat of these ports at the beginning of the filling period when the water level in the lock chamber is low. Tests made on the lock at Pickwick Landing Dam showed that the minimum pressure at the throat of one port during filling was 9.6 ft below atmospheric. At the time of the test, the tailwater was 3.0 ft above its expected minimum elevation. The hydraulic grade line at the port throat was 26.6 ft below the water surface in the lock chamber. Model tests on the Watts Bar lock showed that pressures 22 ft below atmospheric existed in one of the ports for a short time at the beginning of the filling period when the tailwater was low. The pressures found in these two locks do not indicate that serious cavitation may be expected, since the minimum tailwater occurs only when the downstream reservoir is being drawn down in advance of floods. Cavitation may thus occur during only a very small part of the time, and it is believed that damage in these locks is negligible or nonexistent. The tests do show, however, that cavitation may occur. This possibility should always be investigated.

Summary

Operation of the Norris sluices indicated that, at full-gate opening, cavitation might exist. Damage to the sluice liners actually occurred wherever the smooth surface of the liner was broken by either a projection or a depression. The depth of pitting was related to the time of operation.

Repairs were made to the metal liner by grinding and welding, using several pitting-resistant materials. Pressures in the affected region were raised by constricting the sluice outlet.

Cavitation was prevented in the sluices of Hiwassee, Cherokee, Douglas, and Fontana dams by making model tests of the sluices and modifying the curvature of the entrance until the pressures at all points were high enough to avoid cavitation. Pressures were also raised by constricting the outlets.

Other structures of the Authority, including the spillways of the proposed Upper Holston Projects and the ports of the lock filling systems on the main river dams, were investigated for possible cavitation troubles.

DISCUSSION

C. A. MOCKMORE,[6] M. ASCE.—An excellent explanation of cavitation is presented by Professor Vennard. The Symposium offers some timely suggestions (which designers should bear in mind if they wish to minimize the destructive effects of cavitation)—avoidance of sharp curves and abrupt corners.

Obviously, pressures within the cavities in the flowing fluid must be low, but that does not necessitate a low pressure in the fluid a short distance from the surface of a conduit. Fig. 51(*a*) shows a cast-steel wicket gate of a water turbine operating under a head greater than 300 ft. Fig. 51(*b*) is an enlargement of one corner of this same wicket gate showing the manner in which the tough metal is worn away by cavitation. The effect of the roughness left by a milling machine during fabrication is noticeable.

Professor Vennard emphasizes the necessity that laboratory experiments should be concurrent with design to avoid the danger of cavitation. Perhaps a little extra care in fabrication would help to produce, as nearly as possible, the conditions called for in the design. Cavitation may be started by a very small irregularity in the surface of a conduit; and, once started, it may grow rapidly in destructive intensity.

JOSEPH N. BRADLEY,[7] ASSOC. M. ASCE.—The Symposium is an excellent up-to-the-minute review of cavitation theory and practice. From a practical standpoint, the causes and results of cavitation and the remedies for its elimination are fairly well understood. From a more scientific viewpoint, a clearer conception of the mechanical action which produces pitting of the boundary surface during cavitation remains forthcoming.

One form of cavitation that is not uncommon is demonstrated by the following example. The profile of one of two lower outlet conduits in Ross Dam (a project of the City of Seattle, Wash.) is shown in Fig. 52. The present outlet conduit, as indicated by the solid lines, was only partly completed in January, 1946. The conduit entrance is on the upstream face of the dam; and the downstream end discharges into a large diversion tunnel. Final plans called for a vertical bend beginning at El. 1207.44, and a horizontal section of pipe with a balanced valve at the extreme downstream end of the conduit, as indicated by the dash lines in Fig. 52(*a*). Difficulties encountered in obtaining materials during the war years made it impossible to complete the downstream portion, outlined by the dash lines. War changes many things but has little influence on the flow of a river. It was necessary to pass water through the dam during this period to supply power plants located downstream. Entirely out of this necessity the partly completed lower outlet was used for this purpose, the operators relying on a slide gate at the entrance for control.

The damage resulting during operation of the partly completed conduit is explained in the notes in Fig. 52(*b*). In approximately ninety days of actual

FIG. 53.—PITTING THAT HAS PENETRATED THROUGH A ⅝-IN. STEEL PENSTOCK PLATE

operation, over a period of about three years (during which the reservoir elevation did not exceed El. 1275), severe pitting occurred along the arch of the upstream tunnel section; and at some points this extended completely through the ⅝-in. steel plate liner. Fig. 53 shows a piece of an eroded section.

The cause of cavitation and the resultant pitting, in this case, is not a mystery. The difference in elevation between the entrance and the exit of the conduit in Fig. 52(*b*) is 42.6 ft. The vapor tension of water at Ross Dam approximates 32 ft of vacuum. The conduit acted in a manner similar to a siphon developing a suction head that tended to exceed the vapor pressure of water. This condition occurred principally in the upstream portion of the conduit where the water in the roof of the pipe vaporized, cavitation occurred,

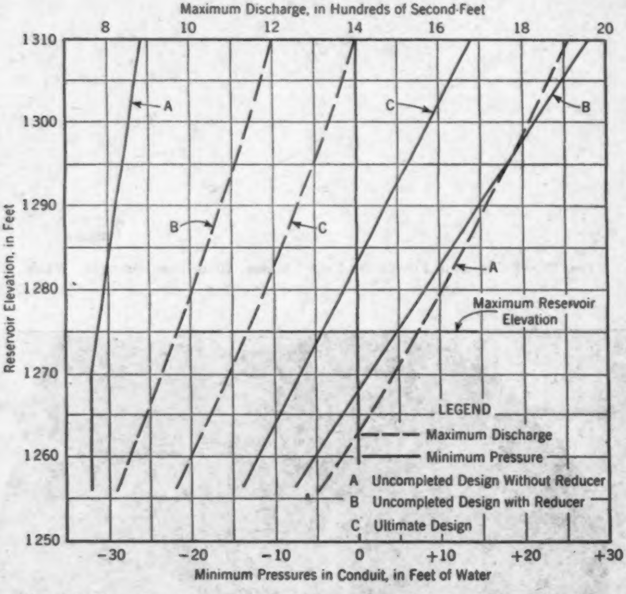

FIG. 54.—DISCHARGES AND MINIMUM PRESSURES IN LOWER BY-PASS TUNNEL

and pitting resulted. As the limiting value of negative pressure that can be developed is equal to the vapor pressure of water, under prevailing atmospheric conditions, this could occur only near the arch of the conduit. The pressure on the invert of the pipe was above the vapor pressure of water by an amount equivalent to the depth of water flowing in the conduit. With one exception, the damage was confined entirely to the roof of the conduit. One pitted area is indicated on the invert of the conduit, Fig. 52(*b*), immediately downstream from an abrupt change in grade. This was evidently the result of a localized, lowered pressure area produced by the sudden change of slope.

After the damage was discovered in 1943, it still remained impossible to obtain delivery of steel for the completion of the outlet conduits. Conse-

quently, a temporary remedy for the alleviation of cavitation was administered. The severely pitted areas were removed and replaced by new plates thus making the conduit again watertight. In addition, a reducer cone from 6.0 ft to 4.5 ft in diameter was installed at the end of the pipe, as indicated by the dotted lines in Fig. 52(*b*). The cone served to reduce velocities, thus increasing pressures throughout the conduit. The outlet now (1946) operates without evidence of cavitation.

The solid lines in Fig. 54 show the minimum computed pressures in the outlet conduit for three conditions of operation. Actual field measurements are not available. Curve A, for the uncompleted tunnel, shows that negative pressures equivalent to the vapor pressure of water existed for all reservoir elevations up to El. 1270. The maximum reservoir elevation obtainable during this period was El. 1275, which is 10 ft above the top of the present dam. Curve B, Fig. 54 (which represents the uncompleted tunnel with cone installed at downstream end), indicates the minimum pressures existing in the conduit at the present time (1946). Curve C shows the minimum pressures that can be expected after final completion of the tunnel with a valve installed at the extreme downstream end. The slide gate on the face of the dam was assumed fully open for these computations.

The dashed lines in Fig. 54 show the corresponding maximum discharges to be expected for the same three conditions of operation. For the reservoir at El. 1265, the present conduit with addition of the reducer cone (curve B) will discharge 890 cu ft per sec; for the previous condition of operation without cone (curve A, Fig. 54) the discharge was 1,430 cu ft per sec. The conical reducer results in a 38% decrease in discharge at this arbitrarily selected head. As elimination of cavitation often involves a sizeable reduction in efficiency it is difficult to convince designers that avoidance of low pressure is imperative, in high-velocity design.

Acknowledgment.—The writer wishes to express his appreciation to E. R. Hoffman, superintendent of the Department of Lighting, City of Seattle, and W. B. Wolfendale, project engineer of Ross Dam, City of Seattle, for their generosity in granting permission for the presentation of the above material.

At least twenty references on cavitation ((45) to (64)) should be added to the Bibliography of the Symposium.

J. M. Robertson,[8] Jun. ASCE.—The theory of cavitation can be divided roughly into two basic parts: The first is concerned with the occurrence of cavities—that is, the conditions under which cavities form; and the second is concerned with the dynamics of the cavities once they are formed. Professor Vennard's treatment of these two phases is good although somewhat elementary. However, in being elementary, it may represent correctly the state of knowledge on the subject.

Under the heading, "Occurrence of Cavitation," it is stated that "* * * liquids encountered in engineering practice cannot expand and cannot support tension stress." Although this assumption is the basis for the commonly accepted analysis used to indicate when and where cavities will form, it is not

[8] Asst. Prof., The Pennsylvania State College, State College, Pa.

an absolute fact. According to R. W. Boyle (65), some careful static experiments have proved that liquids can be placed under tension (see also mention of this possibility by T. C. Poulter (15)). This phenomenon is similar to that of the occurrence of supersaturated solutions. If sufficient disturbing conditions are present, the phenomenon will not occur. Also, the degree of tension which a liquid may stand without parting is probably a function of the time of application of the tension. Thus, for a very short time water may withstand a high tension although for a relatively long time it may be able to withstand very little tension. This time effect is of some significance with regard to the determination of the exact location in time and space at which a cavity will form. For example, in the flow through a nozzle, if a pressure determination indicates that negative pressures occur at the throat of the nozzle, the cavities will actually appear some distance downstream, the exact point of occurrence depending upon the flow velocity. In the case of cavitation produced by vibratory methods, it is possible that, with a very high frequency of vibration, the part of the cycle during which the liquid is in tension would not be long enough for a cavity to form. The relation between the tension a liquid can stand and the time of application of the tension is also a function of the air or gas content of the liquid. Thus, in the case of the aforementioned nozzle, it is probable that, if the flowing liquid had a large dissolved gas content, the cavities would form much nearer to the point specified by elementary theory than they would if the same liquid contained little or no dissolved gas.

The theory of the action of a cavity, once it is formed, is of concern mainly in connection with the manner in which cavitation produces erosion in near-by solids. In addition to the work on the pressures caused by the collapse of cavities mentioned by Professor Vennard, reference should also be made to the theoretical analysis presented by E. H. Kennard (66) and the hypothesis advanced by F. D. Smith (67). Mr. Smith's hypothesis is that the liberated cavities or gas bubbles undergo resonant vibrations producing intense local strains in the vicinity and the destructive effects are due to these strains. In addition to the mechanical effect of the collapsing or vibrating cavity in producing cavitation erosion, it is possible that other phenomena resulting from cavitation may assist in the action. W. T. Richards (68) in his summary of the state of knowledge on the effects of cavitation due to sonic or ultrasonic vibrations noted that high temperatures have been shown to occur at the edge of cavities, that the collapse of cavities has resulted in the creation of electrical potentials, and that cavitation has been shown to accelerate chemical reactions. In his studies of phenomena due to ultrasonic vibrations in nonmetallic (liquid) systems, K. Sollner (69) concludes that all the disruptive and destructive phenomena are caused by cavitation. It is possible that such secondary effects of cavitation as these may have an effect on the manner in which cavitation erosion occurs.

The vibratory form of apparatus for producing cavitation has been used extensively for the rapid comparison of the cavitation erosion resistance of various materials by S. L. Kerr (35). This type of apparatus may also be used to further understanding of the action of the cavities. With it cavities are

formed at a fixed frequency in a relatively restricted and known location. By high-speed photography it is possible to observe the formation, growth, and collapse of a cavity under known pressure conditions. Research, such as that of M. Kornfeld and L. Suvorov (70), along this line should yield information on the dynamical principles surrounding the life of cavities.

Fred W. Blaisdell,[9] Assoc. M. ASCE.—The Symposium authors have shown conclusively that the possibility of cavitation in hydraulic structures must be considered, not only by the designer but also by the constructor and the inspector. Several instances are cited where the cavitation can be traced to poor design. Other instances show that cavitation is also possible in well-designed structures as a result of irregularities built into the solid boundaries during construction. In fact, Mr. Harrold uses an assumed construction irregularity in his illustration of the "Principle of Vacuum Apparatus." All the authors have shown that extensive damage, costly and continuous repairs, and operating difficulties are the price paid for neglecting to consider cavitation. A conservative office design that would eliminate all possibility of cavitation might well be uneconomical. On the other hand, although a design based on laboratory tests can work close to the cavitation limit, the possibility of cavitation damage will be greatly reduced or eliminated. This has been implied by Professor Vennard under the heading, "Remedies for Pitting."

The writer well remembers the staccato hammering in the cavitation apparatus at the Massachusetts Institute of Technology in Cambridge that made conversation in its vicinity a practical impossibility. The writer does not doubt that the cavitation in the Norris sluices could be heard, as reported by Mr. Hickox. The writer would like to ask the authors if the noise level is related to the damage caused by collapse of the vapor pocket.

At the end of the third paragraph under the heading, "Damage from Cavitation, or Pitting," Professor Vennard writes,

> "In some cases, however, the pitting has stopped of itself, apparently due to a water cushion covering the eroded region and preventing direct contact of collapse point and solid material."

The writer would like to inquire if it is desirable in some instances to design for the elimination of cavitation pitting rather than for the elimination of cavitation itself. Such a design would incorporate a "water cushion" into the structure to absorb or distribute the forces resulting from the collapse of the vapor pocket rather than streamlining to eliminate cavitation. Under the heading, "Proper Use of Baffle Piers," Mr. Harrold recommends the streamlining of baffle piers to eliminate cavitation where velocities are high and static pressures are low. Streamlining requires careful formwork and excellent workmanship. Mr. Warnock mentions the extensive damage in the Boulder Dam spillway tunnel resulting from a misalinement in the tunnel invert, and Mr. Hickox shows that cavitation pitting was caused by misalinement of joints in the sluice liners at Norris Dam. These experiences show that "streamlined" baffle piers would have to be constructed carefully if all cavitation were to be

[9] Project Supervisor, U. S. Dept. of Agriculture, SCS, St. Anthony Falls Hydr. Laboratory, Minneapolis, Minn.

eliminated. On the other hand, if the piers were deliberately made narrower in a downstream direction, the vapor pockets would collapse in the liquid. Careful form work would not be required and pitting of the pier would presumably not occur. This is in line with Mr. Harrold's statement in the last paragraph under the heading, "Baffle Pier Tests," that "A cavitation streamer that leaves the baffle is assumed to be harmless, whereas one that clings to the baffle is considered harmful." On the other hand, the writer would like to ask if the pressure waves set up by the collapse of the vapor pockets might cause vibrations that would eventually weaken the pier. This important question has already been raised by Professor Vennard in the last paragraph under the heading, "Collapse of the Cavity." Perhaps he or Mr. Harrold will be willing to comment more fully in their closing discussions on the points raised in this paragraph.

The design of "water cushions" into a baffle pier might (in the words of Professor Vennard under the heading, "Remedies for Pitting") "have little appeal," but the pier would probably be cheaper to construct than if it were streamlined. The "cushioned" piers would possibly be more effective energy dissipators than would the streamlined piers. Before this method could be applied to the design of piers, it would be necessary to know how close the cavitation streamer must be to the structure in order to cause pitting (mentioned by Mr. Harrold), the location of the cavitation streamer, and how far downstream the vapor pockets travel before collapsing. It is quite apparent that much experimental work remains to be done before adequate information on cavitation and its effects will be available.

JOHN S. McNOWN,[10] Assoc. M. ASCE.—Investigations of cavitation, as indicated by the Symposium authors, have been restricted for the most part to laboratory and field observations of the factors causing cavitation and the countermeasures required for prevention. Although it is frequently possible to predict and eliminate cavitation on the basis of experience and model studies, very little is known concerning the thermodynamics of the local vaporization and the subsequent condensation of the water, the dynamics of the bubble collapse, or the manner in which boundary surfaces are pitted. Fundamental research, in time, should reveal much of this information and lead to a basic understanding of this phenomenon, but for the present it is essential that the available tools be utilized to their utmost efficiency. The writer wishes to discuss two of these tools—analytical methods, which he feels were unduly slighted in the Symposium, and the variable-pressure water tunnel.

For certain types of problems the assumption of negligible viscosity and the application of the corresponding equations of flow yield very worthwhile results, particularly since cavitation occurs in or immediately downstream from a zone of accelerated flow. Therefore, some of the statements made by Professor Vennard concerning the analytical approach are definitely misleading. The criterion for the applicability of the Bernoulli equation is not the absence of curvilinear flow, but rather the extent to which the flow can be described by the equations of irrotational motion. For example, it is obviously impossible

[10] Research Engr., Iowa Inst. of Hydr. Research, and Asst. Prof., Dept. of Mechanics and Hydraulics, State Univ. of Iowa, Iowa City, Iowa.

to apply the Bernoulli equation across rectilinear laminar flow in a pipe line, whereas the familiar vortex (Fig. 1) is called the irrotational vortex because of the excellent agreement between theory and measurement for flow which is wholly curvilinear. To be sure, uncertainties in the magnitude of the pressure, which are of importance in cavitation studies, arise in the vortex core; however, these uncertainties are caused by departures from the irrotational pattern, and not by the presence of curvilinear motion.

Irrotational motion is also approached very closely in regions of rapidly accelerated flow of the type indicated in Figs. 1(*a*) and 1(*b*). In fact, the two-dimensional counterpart of Fig. 1(*a*)—the horizontal slot—has been solved by the methods of classical hydrodynamics with remarkably close agreement between theory and experiment. In connection with tests in the variable-pressure water tunnel at the Iowa Institute of Hydraulic Research in Iowa City, the writer was able to predict, entirely by analytical means, the conditions for incipient cavitation on a mathematically defined boundary form. Hence, to describe all curved-flow problems (see heading, "Occurrence of Cavitation") as "most obscure and unpredictable" not only conveys a very false impression, but also completely ignores one useful avenue of approach.

Admittedly, only part of the problems encountered in engineering practice can be solved by analytical methods alone, and as a result many hydraulic structures can best be designed from model studies. Thus, consideration should be given to the methods of analysis and the experimental procedure for model studies of cavitation effects. For such a study, any dependent variable can be described by a function of viscous, gravitational, and cavitation effects, together with the appropriate description of boundary geometry. In general terms,

$$\mathbf{D} = f(\mathbf{R}, \mathbf{F}, \mathbf{K}, b/a, c/a, \cdots) \qquad (5)$$

in which $\mathbf{D}$ is any dependent variable in dimensionless form; $\mathbf{R}$ and $\mathbf{F}$ are the familiar Reynolds and Froude numbers; $\mathbf{K}$ is a cavitation parameter, the definition of which depends in part on the type of problem under consideration; and b/a, c/a, etc., are ratios of linear dimensions.

Three phases of cavitation research are of importance in engineering practice, and the general equation may be adapted to each of these. The first phase, and perhaps the most fundamental, is that of flow without a free surface such as flow past a submerged body or flow through a siphon spillway. Since viscous effects may be significant, the dependent variable can be expressed in terms of the Reynolds number, a cavitation parameter, and the boundary geometry:

$$\mathbf{D} = f_1(\mathbf{R}, \mathbf{K}, b/a, c/a, \cdots) \qquad (6)$$

The dimensionless parameter $\mathbf{D}$ may describe in relative terms a pressure drop, loss of head, length of cavitation pocket, amount of pitting which takes place, or some other pertinent quantity. The cavitation parameter is indicative of the tendency toward cavitation, and hence is determined by the normal center-line pressure p_0, the vapor pressure p_v, the undisturbed velocity v_0 and the

density ρ. That is,

$$\mathbf{K} = \frac{p_0 - p_v}{\frac{1}{2}\,\rho\, v^2_0} \qquad (7)$$

and a reduction in **K**, resulting from either an increase in velocity or a reduction in pressure, increases the tendency toward cavitation. In most instances where cavitation takes place, the Reynolds numbers are large and the influence of viscosity is correspondingly slight. It must be kept in mind, however, that viscosity may play an important rôle should the model scale or velocity be too small.

The second type of problem is that of flow with a free surface for which the pattern of motion is completely described by the boundary geometry, as in flow over a spillway section. Since the Froude number cannot be varied at will once the head H and the boundary geometry are determined, **F** is not an independent variable for this type of flow; and, therefore,

$$\mathbf{D} = f_2(\mathbf{K}', a/H, b/H, \cdots) \qquad (8)$$

The simulation of prototype cavitation conditions in a model spillway requires the reduction of the atmospheric pressure p_a in the model, and the cavitation parameter for this type of flow may be written

$$\mathbf{K}' = \frac{p_a - p_v}{\rho\, g\, H} = \frac{p_a - p_v}{\gamma\, H} \qquad (9)$$

A third type of problem is that of flow with a free surface in which the velocity of flow can be varied independently of the depth, as in a study of cavitation effects on baffle piers. The added independent variable necessitates the inclusion of the Froude number, and the depth of approaching flow y replaces H as the linear dimension of the flow. Hence,

$$\mathbf{D} = f_3(\mathbf{F}, \mathbf{K}, a/y, b/y, \cdots) \qquad (10)$$

in which a, b, etc., are linear dimensions of the pier. The cavitation parameter may take either of the two alternative forms:

$$\mathbf{K} = \frac{p_a - p_v}{\frac{1}{2}\,\rho\, V^2} \qquad (11a)$$

or

$$\mathbf{K}' = \frac{p_a - p_v}{\rho\, g\, y} \qquad (11b)$$

which are related by the Froude number.

For any pattern of flow, such a particular value of **K** exists that for all higher values the flow is unaffected by cavitation, just as the pattern of flow past a body tends to become independent of viscous effects if **R** exceeds a characteristic magnitude. If the value for incipient cavitation is denoted by $\mathbf{K}_i$, cavitation effects commence for $\mathbf{K} = \mathbf{K}_i$ and become more and more pronounced as **K** is reduced below the critical. Furthermore, for a given value of the cavitation parameter, essentially similar cavitation phenomena will be found for various combinations of velocity and pressure on both model and prototype. It follows that Eqs. 2, 3, and 4 in Mr. Harrold's paper—which may

be written in the form,

$$(p_a - p_v)_m = L_r(p_a - p_v)_p \qquad (12)$$

—are obtained if identical values of **K** are specified for model and prototype. That is, if $\mathbf{K}_m = \mathbf{K}_p$:

$$\frac{(p_a - p_v)_m}{\gamma H_m} = \frac{(p_a - p_v)_p}{\gamma H_p} \qquad (13)$$

and Eq. 12 is thereby obtained, provided the same liquid is used in both model and prototype. However, Eq. 3 does not completely determine **K** unless the Froude number depends on the boundary geometry. It is evidently not sufficiently general for use, say, on the baffle-pier study just discussed.

The problem of flow over a spillway section, discussed by Mr. Harrold, may be used further to illustrate an approach to the experimental determination of cavitation effects and to emphasize the important rôle of the cavitation parameter. If the discharge per unit width q is taken as the dependent variable, Eq. 8 takes the form,

$$\frac{q}{\sqrt{g}\, H^{3/2}} = C_d = f(\mathbf{K}', a/H, b/H, \cdots) \qquad (14)$$

For all values of **K** greater than $\mathbf{K}_i$, the variation of C_d with H, as determined by experiment, would be entirely independent of cavitation effects in this region, and would therefore be represented by the uppermost curve in Fig. 55. However, the onset of cavitation near the spillway crest would substantially reduce C_d, so that further tests at values of **K** less than $\mathbf{K}_i$ would yield a series of curves such as that shown schematically in Fig. 55. The lower the value of **K** or the greater the degree of cavitation, the greater will be the departure from cavitation-free conditions. In a similar manner, the effect of cavitation upon other dependent variables could be investigated.

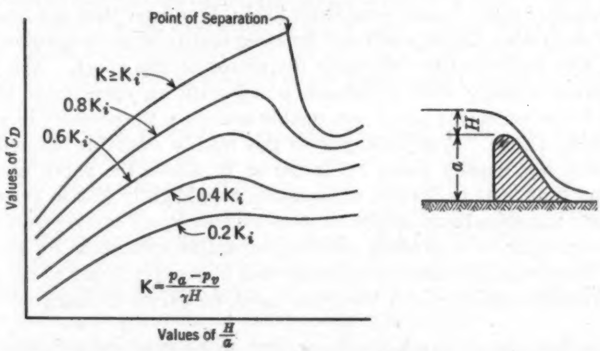

FIG. 55.—SCHEMATIC REPRESENTATION OF CAVITATION EFFECTS ON THE DISCHARGE COEFFICIENT OF A SPILLWAY

Even though it is impossible to make a model study which satisfies both the Froude and Reynolds criteria if the same fluid is used in both model and prototype, no comparable obstacle prevents the simultaneous study of cavitation

phenomena and either viscous or gravitational effects if it is possible to vary the pressure on the system. As a result, much of the laboratory work on cavitation has been performed in variable-pressure water tunnels, of which more than a dozen have been built in research laboratories throughout the world. Not unlike closed-circuit wind tunnels in design, water tunnels have been used to test the cavitation characteristics of ship screws, turbine blades, and a variety of two-dimensional and three-dimensional body forms. In many respects the water tunnel is similar to the apparatus developed at Carnegie Institute of Technology in Pittsburgh, Pa., and described by Messrs. Vennard and Harrold.

Although water tunnels can be used for the variety of studies already mentioned, to date (1946) the experiments in the variable-pressure water tunnel at the Iowa Institute of Hydraulic Research have been devoted exclusively to the measurement of the effect of cavitation on the pressure distribution around underwater bodies. Nevertheless, general conclusions from these experiments concerning the effect on cavitation phenomena of viscosity and air content are applicable to all investigations of cavitation. Measurements of the pressure distribution around a given boundary form, which were taken at different Reynolds numbers and for values of $\mathbf{K}$ both above and below $\mathbf{K}_i$, indicated that viscous effects influenced the results for relatively small values of $\mathbf{R}$ and for low intensities of cavitation. This effect was found to be exaggerated for boundary curvatures of short radius, extending in one instance to Reynolds numbers of approximately 10^6.

There is usually a large amount of air dissolved in water, and the reduction in pressure that accompanies any tendency toward cavitation will release part of this dissolved air with much the same action as that involved in the formation of water vapor in zones of cavitation. Furthermore, because the pressures are low, the air released from solution may occupy a disproportionately large volume. Since it was considered likely, therefore, that the results of a study of cavitation might be affected by the quantity of air in solution, a series of tests was performed to determine the extent of this effect. The pressure was reduced steadily with a vacuum pump until an operational limit was reached below which the pump was unable to reduce the pressure in a reasonable period of time. With reference to this readily available minimum pressure, which was usually about 1.5 lb per sq in. above the vapor pressure, it was found that tests performed at pressures only slightly (0.2 lb per sq in. or less) above this operational minimum were affected by air coming from solution in such a manner as to produce results comparable with those for smaller $\mathbf{K}$-values. For tests performed at pressures well above (0.4 lb per sq in. or more) this operational minimum, on the other hand, no effects of dissolved air were found.

For investigations directed toward the elimination of cavitation, model studies need not be conducted in variable-pressure chambers. The distribution of pressure along a boundary as determined in atmospheric-pressure models can be used to predict the tendency toward cavitation as shown by the studies at the Vicksburg (Miss.) laboratory. However, caution should be exercised in the interpretation of model results obtained in this manner, not

only because atmospheric-pressure models may indicate impossibly low prototype pressures, but also because cavitation effects may be found even though the pressure on the boundary is everywhere well above the vapor pressure. Since cavitation first occurs in the fine eddies at the surface of separation, the pressure at a boundary surface a short distance away may be affected by the resulting change in the flow pattern. In one series of experiments at the Iowa Institute of Hydraulic Research on flow past an abrupt boundary transition, although the minimum pressure and the vapor pressure were equal when $\mathbf{K} = 0.7$, cavitation effects did not vanish until the value of $\mathbf{K} = 1.8$ was reached. In other words, even though the pressure head at the boundary was more than one velocity head above the vapor-pressure head, the pressure distribution along the boundary was affected by local cavitation a short distance away.

In conclusion the writer wishes to welcome the Symposium on Cavitation in Hydraulic Structures as a worthwhile contribution to the summarization of the available information in this relatively new field, and to concur heartily with the Symposium authors in their statements concerning the need for publication of other available information and for stimulation of further research in this field.

James W. Ball,[11] Assoc. M. ASCE.—The first Symposium paper, concerning the nature of cavitation, is an excellent contribution to the engineering profession. Although it is concise and clearly written, it would not be complete without the illustrations from the remaining Symposium papers. It is gratifying to note that the authors, by using absolute instead of gage pressure as a datum, have avoided the confusing term "negative pressure approaching, or exceeding, the vapor pressure" used by so many authors of papers on cavitation. However, it seems that the term "vapor tension" should be used instead of "vapor pressure" when cavitation is concerned. Vapor tension is defined as the maximum vapor pressure that occurs when there is an abundance of liquid present. It is a special value of vapor pressure that occurs in connection with cavitation.

Gate Grooves.—The problem of cavitation erosion below gate grooves, as described for Parker Dam on the Colorado River by Mr. Warnock, is not a new one; nor is its remedy new. In 1945, Abraham Streiff, M. ASCE, cited examples of these problems that had occurred 40 years earlier (71). The two most practicable remedial measures cited by Mr. Streiff, are almost identical to those evolved independently and 40 years later. The solutions, now as then, are mainly of two types—(1) deflectors placed upstream or downstream from the gate grooves and (2) specially-shaped piers.

Shoshone Dam Balanced Valves.—To complete the story concerning cavitation in the balanced valve outlets at Shoshone Dam near Cody, Wyo., presented by Mr. Warnock in the Symposium, it is necessary to relate what happened during the 1944 and 1945 irrigation seasons. The demand for water

[11] Engr., Bureau of Reclamation, U. S. Dept. of Interior, Denver, Colo.

for irrigation and domestic use below Shoshone Dam during these two seasons was such that it has not been practicable to operate the 58-in. balanced valves in the noncritical range indicated by the model studies. As a result there has been pitting, slightly less severe, but in the same zones as before—extensive repairs being required. This is only one of many examples of the fact that scale models are invaluable instruments for determining the adequacy of proposed or existing designs of hydraulic structures.

Boulder Dam Spillway Tunnels.—Since the Symposium was presented (before the Hydraulics Division of the Society at the Annual Meeting in January, 1944), the spillway tunnel on the Nevada bank of the Colorado River at Boulder Dam has been unwatered and inspected. Numerous discontinuities in the form of protruding pipes, humps, depressions, and "gobs" of concrete on the flow boundary were found. Cavitation erosion had occurred in the surfaces downstream from several of the pipes and "gobs" of concrete. Rough areas were noted below the other discontinuities but the appearance in these cases was such that cavitation could not be established definitely as the cause. The quantity of water which passed through this tunnel in the fall of 1941 was much smaller than that discharged by the spillway on the Arizona side. It seems fortunate that the quantity was small and that the period of operation was short, for many of the discontinuities reported would have caused cavitation that might have produced destructive pitting of the magnitude of that found in the Arizona tunnel.

Temporary Needle-Valve Outlets at Grand Coulee Dam.—The flow of the Columbia River at Grand Coulee Dam exceeds the capacity of the left powerhouse during most of the low-water season; thus, some method had to be provided for releasing the excess water downstream during the inspection, repair, and maintenance operations to the underwater part of the spillway face and bucket.

The plan developed for this purpose involved the installation of eight 84-in. needle valves (available for loan from another project) between the power penstocks and the unfinished turbine draft tubes of the right powerhouse. Steel cones and elbows connected the valves to the ends of the penstocks, and special steel transition elbows, embedded in concrete anchor blocks, completed the passages from the valves to the draft tubes from which the water discharged into the tailrace downstream (Fig. 56).

One of the outlets was operated for the first time on May 25, 1945, to check operating characteristics. That cavitation was occurring in the outlet passage downstream from the needle valve over nearly the full range of valve opening was indicated by the severe vibration and noise (crepitation) at these openings. The noise resembled the crackling of a large number of small firecrackers exploding in rapid succession, with intermittent loud popping reports. The vibration was so severe that it could be detected easily through the soles of the shoes of anyone standing on the roof or on other concrete surfaces of the powerhouse in the bay in which the valve was situated. Vibrations in the concrete anchor block, encasing the transition elbow and forming the passage between it and the lower part of the draft tube, were of such intensity as to resemble sharp blows with a small hammer on the soles of the shoes of persons standing

on the anchor block. These vibrations were so severe that they were recorded at a seismograph station a short distance upstream from the dam on the shore of Roosevelt Lake.

After approximately 2 hours of operation at various valve openings (15 min at full capacity) the outlet was unwatered and inspected. Small areas of paint were missing from the inner curve of the transition elbow on both sides of the center line below the joints between the last four sections of the elbow. This condition seemed to be the result of local zones of cavitation induced by the inflection and weld seams at the joints, although no pitting of the metal could be detected. Two areas having a spongy appearance—definitely the result of cavitation—had formed in the concrete surface of the passage immediately below the areas in the elbow from which the paint had been removed. Two large areas in the original concrete of the draft tube just below the joint between the new and old construction, downstream and outward from the areas at the end of the elbow, had a pocked appearance, but it was difficult to establish this condition as cavitation erosion.

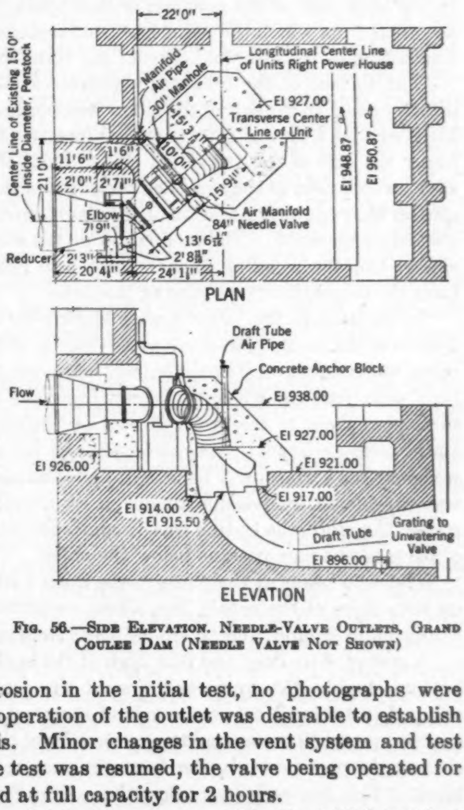

FIG. 56.—SIDE ELEVATION. NEEDLE-VALVE OUTLETS, GRAND COULEE DAM (NEEDLE VALVE NOT SHOWN)

In view of the indistinct markings and the undefined boundaries of the zones of erosion in the initial test, no photographs were taken. Moreover, additional operation of the outlet was desirable to establish evidence for study and analysis. Minor changes in the vent system and test equipment were made and the test was resumed, the valve being operated for 1 hour at various openings, and at full capacity for 2 hours.

The areas from which the paint had been removed in the initial test had increased in size, and their boundaries had become defined clearly. Although the bared metal surface in these areas showed no evidence of pitting, cavitation was considered to have been the cause of the removal of paint. The weld beads and the joints of the elbow combined to form a boundary of diverging surfaces, with the result that zones were formed immediately downstream from the joints, in which the pressure was reduced to the vapor tension of the water. The cavitation cavities forming in these zones collapsed to pit and removed the

paint as the pressure increased in the area just above the next welded joint. The fact that this condition existed to each side of the center line on the inner curve of the elbow and not at other points was attributed to the fact that the flow is analogous to that in sharp bends (considering the axis of the bends somewhere between the horizontal and vertical planes)—and these regions are subject to low pressures regardless of discontinuities in the boundary surface.

The areas of cavitation erosion adjacent to the exit of the transition elbow in the back wall of the concrete anchor block, immediately downstream from the areas from which the paint had been removed, resulted from the cavitation originating at the last weld joint of the transition elbow.

The surface of the first-stage concrete at the back of the draft tube and directly beneath the exit of the elbow was pocked extensively (Fig. 57). It was believed that a zone of cavitation was formed adjacent to the wall immediately under the exit of the transition elbow, back of the flowing jet, and that the cavities collapsed as they reached the edges of this zone, where the pressure was greater than the vapor tension of the water, eroding the surfaces to produce the pocked appearance. The inclination of the surface of the last section of the elbow, and the receding anchor-block wall immediately below, combined to form the discontinuity producing this zone.

In addition to the pitted areas, which were more distinct than at the conclusion of the initial test, there was evidence of increased damage for which the cause was not apparent immediately. A patch 6 in. by 30 in. by 4 in. deep had been torn from the concrete floor of the draft tube (Fig. 58). Although the surface adjacent to the recess formed by the removal of the patch was rough, static pressure beneath the wedge-shaped patch, with the thick edge of the wedge at the surface, was believed to have caused the patch to "pop out." It was considered inadvisable to operate the outlet unit without patching the recess; therefore, the testing was discontinued pending the repair and alteration of parts of the flow passage below the valve.

The weld beads at the joints in the inner curve of the steel transition elbow on both sides of the center line, where cavitation pitting was indicated, were chipped and ground, and all eroded areas were smoothed and repainted.

A groove, 6 in. deep and 6 in. high at the back of the anchor block, with the bottom sloping 45° downward toward the center of the anchor dome, was chipped in the wall below the exit of the steel elbow. The groove extended approximately 30 in. beyond the extremities of the exit opening and all concrete that might protrude into the flow was removed from the wall of the anchor block. This groove is just below the exit in Fig. 59.

All the pocks in the wall of the anchor block beneath the elbow and in the curved surface of the back of the draft tube were chipped and repaired and all prominent irregularities were removed. A new patch was placed in the recess of the old wedge-shaped patch after it had been chipped to form a keyway, and five dowel rods were grouted in holes drilled several inches below the bottom surface. When the testing was resumed both 18-in. air vents were opened, and observations were made with the valve at various openings, to study the variation in vibration of parts of the powerhouse structure adjacent to the

outlet and to study a phenomenon of light "flashes" reported to exist in the tailrace downstream from the outlet during its initial operation.

The vibration, although severe, was less than in the previous test when the 18-in. vent into the dome of the anchor block was closed, and no air reached the back of the outlet jet as it plunged from the transition elbow into the back of the draft tube.

"Flashes" of light resembling sheet lightning were observed in the tailrace immediately downstream from the draft-tube exit. The occurrence was irregular and varied in extent, being of a singular nature much of the time, but often having the appearance of a network of brilliant, irregular, shimmering light bands extending some distance downstream and to the sides of the outlet. When the spectacle could not be detected in darkness, it was concluded that the phenomenon was not electrical, but resulted from pressure waves that changed the refractive and reflective properties of the water as they moved outward into the tailrace. Since there were zones of cavitation in the outlet between the valve and the draft-tube exit, it was believed that the pressure waves originated from the collapse of cavitation cavities; however, it was not possible to obtain a correlation. Photographic records were unsatisfactory. The light "flashes" and crepitation accompanying the operation of the outlet were evidence that cavitation had not been eliminated. Proof of this was obtained when the outlet was unwatered after approximately 6 hours of operation.

The pitting in the transition elbow and in the back wall of the anchor-block, dome, below, and to each side of the center line of the elbow exit, was not eliminated by the grinding of the welded joints of the elbow. There was no cavitation erosion in the old concrete at the back of the draft tube or in the lower part of the anchor block. The aeration groove in the back wall of the anchor block below the exit of the transition elbow eliminated this condition.

The patch in the floor at the back of the draft tube, which had been replaced after being torn from its recess in the previous test, was missing; and there was evidence of cavitation erosion in the surrounding surface which had not been the case in previous operations (Fig. 59). The five dowels of reinforcing steel had remained in the recess, but the grout around them had been removed to a depth of from 1 in. to 2 in. below the bottom of the recess. No doubt tremendous forces were involved. Since it was desirable to establish the nature and extent of the destructive forces acting to damage the outlet, or to make it inoperable, the test was continued for 16 hours with the valve discharging at full capacity.

Examination after a total of 23 hours of operation at full capacity disclosed that, except for one area about 6 in. in diameter which had a spongy appearance, there was little change in the appearance or extent of the areas from which the paint had been removed in the sections of the steel transition elbow. Apparently the chipping and grinding of the weld beads at the joints had not reduced the discontinuities in the bounding surface sufficiently to eliminate cavitation at the inner curve of the elbow.

The pitting in the areas on the wall of the anchor block immediately below the elbow exit had deepened and increased slightly in size, and another pitted

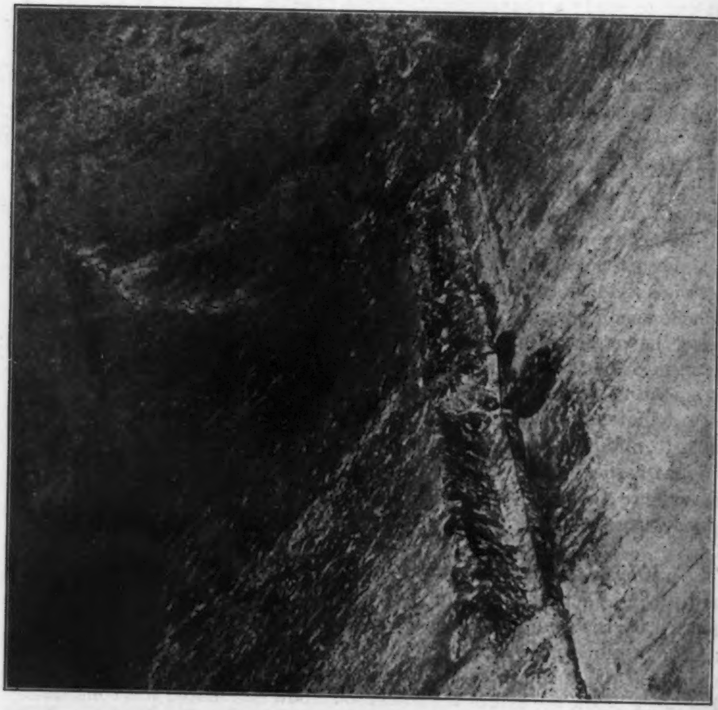

FIG. 58.—PATCH IN DRAFT-TUBE FLOOR TORN FROM A RECESS DURING THE INITIAL TEST

FIG. 59.—CAVITATION EROSION ADJACENT TO THE PATCH RECESS AFTER THE SECOND PATCH HAD BEEN TORN OUT

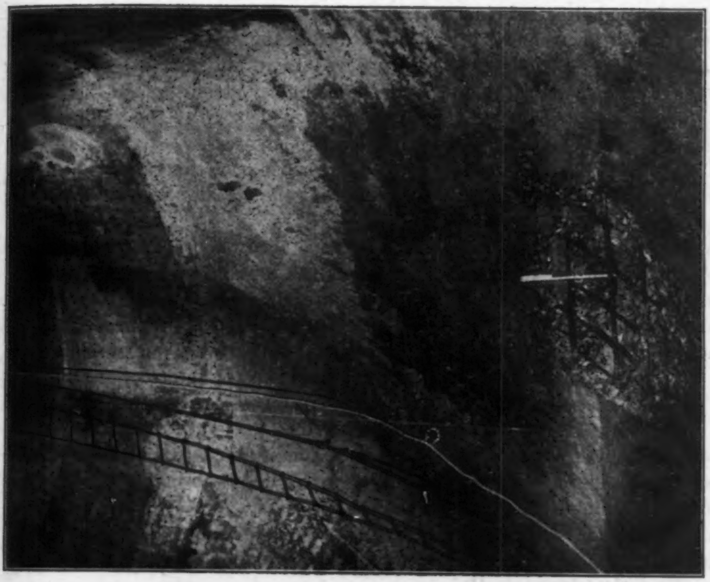

FIG. 60.—EXTENT OF CAVITATION EROSION BELOW THE ELBOW EXIT AND IN THE VICINITY OF THE PATCH RECESS AFTER OPERATING 23 HOURS AT FULL CAPACITY

area had formed directly below that which had occurred to the left of the center line and just below the exit of the elbow during the first 6 hours of operation (Fig. 60). The destructive action appeared to result from a local zone of cavitation formed when the flow near the boundary struck within the pocket just above and was deflected. This action is evidenced by the virtually undamaged surface remaining between the two eroded areas.

There was still no indication of cavitation between the back wall of the anchor block and the outlet flow, proving that the aeration groove below the elbow exit had served its purpose.

After the outlet had operated at full capacity for 23 hours, there was a band of shallow pits in the concrete surface along the top and on both sides of the recess from which the patch had been torn during the first 6 hours of operation. An area extending 5 ft below the downstream edge and approximately 18 in. to each side of the recess was pitted severely exposing several bars of reinforcing steel (Fig. 60). All the wire ties were missing from the intersections and the bars were battered severely where they had contacted one another during the test. The wear of the transverse bars occurred to the left of the natural intersection and it was not possible to force the longitudinal bars onto the worn areas by hand, indicating that tremendous forces had been involved. A short section was missing from one of the longitudinal bars, and the appearance of the remaining ends indicated a recent break due to severe vibration induced by the flowing water. The maximum depth of cavitation erosion immediately downstream from the recess was 18 in.

The source of the cavitation causing this damage was not apparent immediately, but seemed to have originated from either irregularities in the flow boundary or the tendency of the high-velocity jet from the elbow to deflect after striking the curved surface upstream. A survey of the concrete surface, adjacent to the pitted area, made several days after the test operations of August 7, 8, and 9, 1945, disclosed irregularities in the boundary surface to be the source. Longitudinal sections through the pocket and on adjacent surfaces showed a transverse discontinuity in the surface a few inches upstream from the recess (Fig. 61). The surface at this section receded suddenly to meet the concrete a short distance downstream. A maximum offset of $\frac{3}{4}$ in. was noted to the right of the patch recess. Apparently the collapse of the cavitation cavities formed in the zone just downstream from the inflection produced severe vibration with force changes that tore the patch from its recess. Once the patch was gone, a local condition, produced by the irregularity formed by this action, caused the severe damage immediately downstream.

Cavitation erosion, once started, will occur progressively where the curvature of the boundary surface is into the flow, since high-velocity flow striking the roughened surface will form small cavitation pockets, which will result in pitting the surface a short distance downstream. The two areas in the wall of the anchor block below and to the left of the exit of the transition elbow are evidence that this is the case. Later tests on the outlet indicated the same occurrence.

Some idea of the magnitude of the forces present in the draft-tube part of the outlet is indicated by the fact that two of the four cast gratings to the

valves of the unwatering pumps, in the sides of the draft-tube piers (weight about 0.75 tons) were torn from their six $\frac{3}{4}$-in. anchor bolts, which were damaged severely.

After a study and discussion of the results of the 23-hr test, it was concluded that certain alterations and repairs should be made, and a test performed to determine if satisfactory operation of the 84-in. needle valve would result at partial opening. The areas on the inner curve of the transition elbow between the joints of the steel sections from which the paint had been removed by cavitation were cleaned and repainted. The holes eroded in the back wall of the concrete anchor block immediately below the exit of the transition elbow were repaired by chipping and patching. The craterlike hole below the recess from

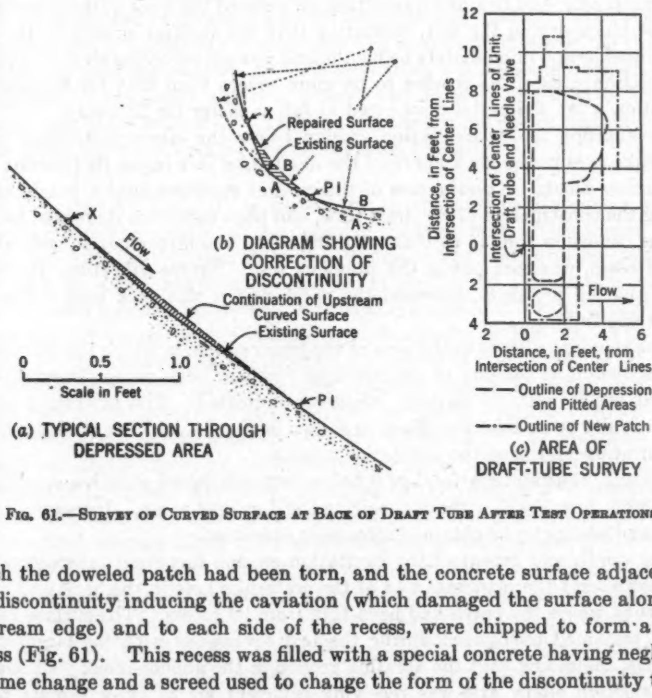

FIG. 61.—SURVEY OF CURVED SURFACE AT BACK OF DRAFT TUBE AFTER TEST OPERATIONS

which the doweled patch had been torn, and the concrete surface adjacent to the discontinuity inducing the caviation (which damaged the surface along the upstream edge) and to each side of the recess, were chipped to form a large recess (Fig. 61). This recess was filled with a special concrete having negligible volume change and a screed used to change the form of the discontinuity to one which was not conducive to cavitation.

In general the discontinuity was changed from one receding from the flow to one encroaching upon it. The difference in the two types is illustrated in Fig. 61(*b*) by the intersecting arcs AA and BB, respectively.

Since the vibration of the outlet had been much less at smaller openings, it was planned to conduct the first operation of the next test at 40% valve open-

ing, operating at this position for 24 hours or until damage was indicated. An inspection was then to be made, and the opening increased by increments to full capacity. The two 18-in. vents—one in the air manifold below the valve and the other in the dome of the anchor block—were to remain open. To assist in locating any damaged area in the vicinity of the new patch, a grid was painted on the floor of the draft tube.

Except for an occasional "bump" there was little vibration during the 24-hr test period. Apparently the back pressure from the tailwater damped the action, since severe pitting from cavitation action occurred on the inner curve of the elbow and in the anchor-block wall just below the elbow exit on each side of its center line. However, the damage was more extensive. Deep holes were eroded in the wall in an area extending several feet below the elbow exit. Intermittently, and in small quantities, air entered the vent in the dome of the anchor block during the test, indicating that the aeration groove at the back of the anchor and immediately below the exit was not receiving air continuously. This action caused the erosion to be more severe than that for the previous operation when the outlet discharged at full capacity for 23 hours.

In addition to the cavitation erosion below the elbow exit, there was a craterlike hole in the back curve of the draft tube just below its junction with the anchor block. Examination of this pocket disclosed that a patch, placed during the construction of the draft tube, had been torn from its recess, forming a local condition similar to that resulting when the larger patch, several feet downstream, was torn out in the previous test. Severe vibration, the result of fluctuating pressures, loosened the patch and it was then torn out by the high-velocity flow.

The repaired surface in the area of the larger patch, in which the discontinuity discovered at the end of the previous test had been made noncritical, remained intact with no damage whatever indicated. The alteration of the discontinuity to remove the offset, as shown in Fig. 61, had removed the source of cavitation and thus the cavitation erosion.

Testing, consuming a total of 9 hours, was continued at valve openings of 60%, 80%, and 100% without repairing the damaged areas. Inspections were made and photographs obtained after each operation.

The depth and extent of the cavitation erosion increased progressively in all areas except the upstream end of the craterlike hole in the back wall of the draft tube where the patch had been torn from its recess. The surface in this region remained unchanged during the test operations with the larger valve openings, indicating that the aeration groove in the anchor-block wall back of the transition elbow exit was receiving sufficient air to allow the jet to be directed farther downstream where it struck the roughened surface, deflected to form a cavitation zone, and caused erosion downstream.

From the tests described herein, it was concluded that the cavitation in the temporary needle-valve outlet at Grand Coulee Dam was induced mainly by local irregularities in the surface of the flow boundary and not by an over-all lowering of the pressure in the system. Attempts are being made to correct

all local discontinuities so that satisfactory operation will result at openings between 60% and 90%. Air introduced by drilling two 36-in. diameter vent holes into the dome of the anchor block has served to reduce the vibration to a minimum, but alterations to the water passage below the valves are still indicated.

From the tests made thus far it has been observed that surface discontinuities of less than $\frac{3}{4}$ in. are sufficient to produce zones of cavitation in high-velocity flow. It would be interesting to know, for a given velocity, the maximum discontinuity that would not produce a cavitation zone.

The writer wishes to propound the theory that cavitation erosion will be progressive in instances where the boundary encroaches upon, or curves into, a stream of high velocity, until a crater of sufficient size is formed to reduce the velocity (and thus the energy) to a point where impact velocities are unable to produce a reduction in pressure that would induce cavitation. Furthermore, if the curvature is moving away from the flow boundary, it is possible that the cavitation erosion will reach a depth representing a sudden enlargement; and the collapse of cavitation cavities, if any, will occur in the fluid before the boundary surface is contacted. The depth of the erosion in this case, of course, will be much less than that for the encroaching boundary.

Fred Locher,[12] Esq.—It is customary to consider cavitation as a phenomenon created by a defect in the design of the boundary. This theory is not always true and (as has been stated by Professor Vennard, who mentions the fact briefly under the heading, "Formation of the Cavity") cavitation can also result from the mixing of two jets. A typical example of this type of cavitation occurs in a jet pump, which is shown schematically in Fig. 62. The high-velocity jet from the nozzle impinges on the center of a low-velocity jet called the "driven water." The two masses combine and in so doing produce a tremendous turbulence and a large number of rapidly whirling vortices whose speed of rotation varies with the relative velocities of the two jets. The vortices are widely dispersed throughout the mixing zone, most of them being dissipated in the fluid. However, a number of the vortices (the most rapidly rotating and dangerous ones as far as cavitation and pitting are concerned) move to the boundary along the line forming the junction between the mixing zone and the driven water. When this condition occurs in a region where the average pressure in the fluid is subatmospheric, but not necessarily sufficiently low to cause cavitation, vapor pockets form at the center of the vortices. They collapse as they move to the boundaries, and at the same time travel downstream to a region of higher pressure, causing severe pitting in the region indicated in Fig. 62.

The writer conducted a series of tests on a jet pump to determine its efficiency and to find a method for reducing cavitation in the mixing tube. It was found that cavitation could be eliminated to some extent for certain operating ranges by proper design. However, the pump was controlled by a needle in the nozzle to permit operation under widely varying conditions in the field.

[12] Engr., U. S. Bureau of Reclamation, Denver, Colo.

Under these circumstances it is not possible to operate throughout the entire range without cavitation. Piezometers in the mixing tube of the model pump and on the downstream face of the nozzle did not indicate pressures lower than one half of an atmosphere; but even so, operation with these pressures produced severe cavitation in the mixing tube. Further study revealed that pitting occurred at, and immediately downstream from, the point where the mixing zone first came in contact with the walls of the mixing tube (Fig. 62).

When it became apparent that cavitation and pitting in the mixing tube were caused by vortex action, the problem of reducing or eliminating cavitation still remained unsolved. Aeration, as generally applied, would have reduced the efficiency of the jet pump to practically zero or would have made it inoperative.

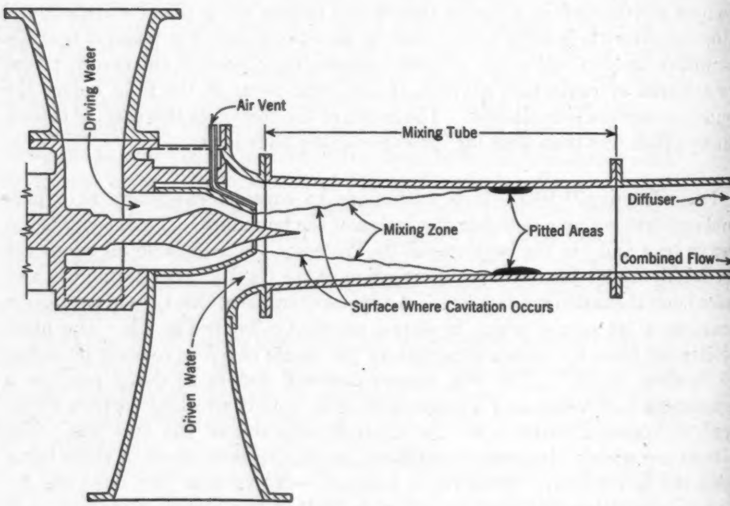

FIG. 62

A change in the boundary of the mixing tube would have had little if any effect on the ultimate results because the change would only produce a different point at which cavitation would occur. The redeeming feature, however, was the fact that a very small volume of air, admitted at the proper place, eliminated cavitation as effectively as the admission of a large quantity to other regions. The unique nature of cavitation in the jet pump required that an air vent be placed at the downstream face of the nozzle as shown in Fig. 62. The effects of this air vent were gratifying; there was no appreciable reduction in efficiency and the pitting was eliminated in the critical operating ranges. Similar vents have since been installed on a number of jet pumps with satisfactory results.

CARL E. KINDSVATER,[13] JUN. ASCE.—The Hydraulic Research Committee and the authors of the Symposium are to be congratulated on initiating this discussion of the cavitation problem as it affects civil engineers. The fact that most of the existing literature on cavitation is found in the journals of the mechanical engineers and physicists does not reflect the great accumulation of knowledge of the subject among civil engineers. As damage due to cavitation frequently appears to be an indication of faulty design, some engineers have apparently been reluctant to publicize their experiences. It is only by sharing different experiences, however, that a collective knowledge of the subject can be compiled.

A good share of the material contained in the several papers which compose the Symposium is concerned with design and operating experiences on spillways, stilling basins, and outlet conduits for high dams. It is the purpose of this discussion to present similar information from recent experiences of the Little Rock Engineer District, U. S. Corps of Engineers.

Outlet Conduits, Norfork Dam.—Norfork Dam (72), in Arkansas, completed by the Corps of Engineers in 1944, is a concrete gravity dam with eleven rectangular, gate-controlled outlet conduits located through the spillway monoliths. In many respects, Norfork is quite similar to Norris Dam, described by Mr. Hickox. In the period since February, 1944, when the reservoir was filled, a total of 1,214,000 acre-ft of flood storage has been passed through the conduits and 283,000 acre-ft has been passed over the spillway, for a recorded total of 1,497,000 acre-ft of water. In addition to this recorded flow since filling the reservoir, a considerable volume of water passed through the conduits and stilling basin during the construction period. Thus, it is estimated that approximately 2,000,000 acre-ft of water has been passed through the stilling basin in the life of the project. Since filling the reservoir, the eleven conduits have been operated more or less alternately, although seldom more than four at any one time. The longest aggregate period of operation of any one conduit was 60 days, and the average period of operation has been approximately 26 days per conduit. All conduits have been operated exclusively at full gate opening and largely at heads between 175 ft and 190 ft. However, during the

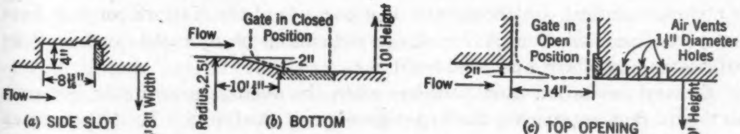

FIG. 63.—NORRIS DAM CONDUIT GATE SLOTS

construction period the head on the conduits was low and, due to the conduit slope of 1.5 in 10, conditions favored the development of subatmospheric pressures in the intake sections. Thorough examinations have disclosed no cavitation damage in the Norfork conduits.

[13] Associate Prof., Georgia School of Tech., Atlanta, Ga.; formerly Associate Hydr. Engr., U. S. Engr. Office, Little Rock, Ark.

The cavitation which apparently was experienced in the Norris Dam sluices might be classified in accordance with Professor Vennard's suggestions as (1) local cavitation and (2) general cavitation. Local cavitation ordinarily occurs in regions of excessive flow curvature such as might be caused by sharp breaks in boundary lines. Thus, local cavitation must have contributed to the causes of the pitting in the conduit liner downstream from the Norris sluice gate slots. Local cavitation is often susceptible to prevention or cure by means of simple "streamlining." A comparison of Fig. 63 with Fig. 64 reflects an attempt in

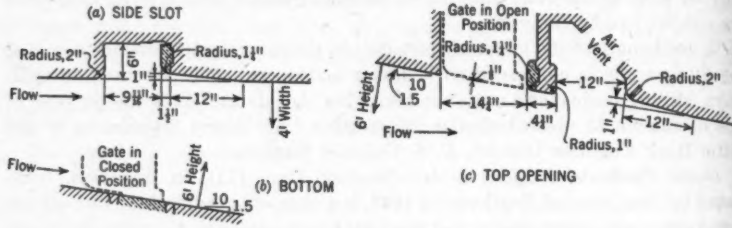

FIG. 64.—NORFORK DAM CONDUIT GATE SLOTS

the design of the Norfork gate slots to avoid some of the reported difficulties at Norris Dam. The outstanding differences in the two designs are the simple streamlining measures adopted at Norfork. The 1:12 bevel provided downstream from the gate slots and air-vent header was based on the experiments by H. A. Thomas, M. ASCE, described by Mr. Harrold under the heading, "Conduit Tests," and shown in Fig. 13(*b*). Much has since been learned about this detail of design, as will be described subsequently.

Damage has been reported to the upstream portions of conduits at a number of different dams. In this case, too, the damage may be attributed to local cavitation. The inlet curves at Norfork were based on flow-net studies, investigations of free jet curves, and the results of cavitation model studies for several similar structures. In view of some of the earlier experiences and model investigations, notably those described by the authors, this feature of design is no longer critical. Although the inlet portions of the Norfork conduits have not been examined, there have been no indications of difficulties such as those experienced at Norris and Madden dams.

General cavitation usually occurs when the average pressure at any cross section of flow approaches the vapor pressure of the liquid. In the case of an enclosed hydraulic turbine, general cavitation results when the wheel is set too high in relation to the tailwater level. Similarly, conditions favoring general cavitation must have occurred in the original, unconstricted Norris conduits because of their high setting with respect to the hydraulic grade line. It should be emphasized that in many instances local cavitation may or may not develop, depending on the average pressure on the entire system at the critical cross section; or, in other words, depending on the tendencies toward general cavitation at that section. At Norris, cavitation might not have occurred

near the gate slots and below numerous boundary irregularities had the hydraulic grade line been higher, or had the upstream portions of the conduit been set lower in relation to the grade line. The only "post-mortem" remedy for the cavitation experienced in the Norris conduits was (as described by Mr. Hickox) the addition of outlet constrictions which had the effect of raising the grade line relative to the original setting. In this connection, it is interesting to compare typical hydraulic grade lines for Norris (Fig. 46) and Norfork (Fig. 65), for the case of free discharge with the slide gates fully open. At Norfork, with the pool at El. 561, the measured flow Q per conduit is 2,200 cu ft per sec and the computed average velocity V is 92 ft per sec. Field measurements at Norfork indicate that the grade line is approximately 15 ft above the roof of the conduit at the downstream gate slot. Of this 15 ft, nearly half is accounted for by the fact that the conduit slopes continuously downward from the inlet rather than extending horizontally to a point beyond the downstream end of the gate castings. Furthermore, the conduits at Norfork have smaller cross-sectional areas than those at Norris and, for corresponding velocities, have a greater friction gradient.

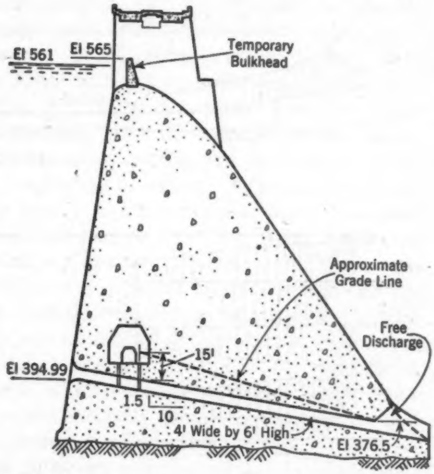

FIG. 65.—SECTION THROUGH OVERFLOW MONOLITH AND OUTLET CONDUITS, NORFORK DAM

The grade line shown in Fig. 46 for the unconstricted conduits at Norris does not correspond to that reported as the most frequent condition of operation —that is, at gate openings between 94% and 96% of full gate. For the latter condition, as for all part-gate openings, the grade line downstream from the gate will drop below that for full gate opening. Even more important, however, is the fact that, as demonstrated by field tests at Norfork, the water discharging under the gate entrains a considerable amount of air at openings as great as 90% of full gate, and for all smaller gate openings the average pressure on the roof of the conduit is reduced in inverse relation to the quantity of air supplied through roof vents (Fig. 64) or, under certain conditions, through the outlet portal.

Although it has been the usual procedure in the Little Rock District to limit continuous operation to full gate openings, it was considered important to investigate the part-gate conditions of operation at Norfork in order to determine whether the air-vent capacity provided in the design was sufficient to prevent the occurrence of excessively low pressures during the opening and

closing operations. Accordingly, a pressure tap was installed in the air vent for the upstream (emergency) gate of three different conduits, and openings in the roof of the conduit at a point just below the downstream (service) gate of all eleven conduits were utilized for measuring air pressures. During these

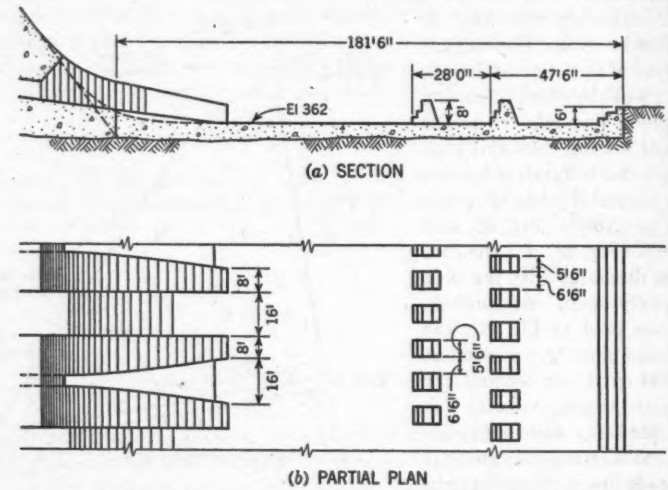

FIG. 66.—GENERAL LAYOUT OF STILLING BASIN, NORFORK DAM

tests it appeared from observations of the outlet portals that the conduits were completely filled with water and spray when the gates were opened more than 1 ft. It was also disclosed that subatmospheric pressures occurred at the roof piezometers, downstream from the gates, for all openings up to about 5.5 ft (that is, 90% of full gate opening) and that the greatest vacuum occurred when the gates were opened about 5 ft. It appears, therefore, that extended periods of operation at 94% to 96% gate opening at Norris may have been primarily responsible for the damage to parts of the conduits downstream from the partly opened gates. It is acknowledged, of course, that this method of operation did account for a higher grade line upstream from the gate and did thereby relieve undesirable conditions which apparently existed near the inlet. The prototype tests at Norfork also revealed that, apparently, as at Norris, vents in some of the conduits, were partly obstructed, and for these conduits in particular it would be extremely hazardous to operate for any length of time at part-gate openings.

Based on experiences at Norfork as compared to Norris, it might be concluded that the answer to cavitation difficulties in outlet conduits lies in designing for a high grade line in relation to critical portions of the conduit. Local boundary streamlining is certainly of value, but is frequently a difficult matter of compromise with the mechanical designer. The primary consideration is to avoid general cavitation tendencies due to a high setting or, as just described, due to part-gate operation. The provision of adequate air-vent capacity is important, too; but, as demonstrated both at Norris and Norfork,

the vents may become obstructed. It might well be the theme of this discussion to emphasize the normal departure of completed structures from the plans produced by the design office. Too much emphasis cannot be placed on the importance of carefully prepared specifications and strict inspection in order to insure that the designer's ideas are carried over to the ultimate structure.

Baffle Piers, Norfork Stilling Basin.—The stilling basin for the Norfork Dam spillway consists of a level concrete apron with two rows of stepped baffle piers and a stepped end sill, as shown in Fig. 66. Because of the war emergency need for power when the project was completed in 1944, the customary stilling basin cleanup was delayed in order that the cofferdamming and unwatering operations would not interfere with the production of power. In November, 1945, the powerhouse was shut down for repairs to the generating unit; advantage was taken of this opportunity to clean and inspect the stilling basin. As noted previously, under the heading, "Outlet Conduits, Norfork Dam," it is estimated that approximately 2,000,000 acre-ft of water had passed through the stilling basin in the period from the initial diversion operations until the time of the inspection. When the basin was unwatered, a large quantity of debris was revealed on the apron. The debris was composed of well-worn boulders and smaller stones, steel rods, pipe of all sizes, and a miscellaneous collection of battered metal scrap. Some indiscriminately scattered baffle piers, particularly in the upstream row, had suffered considerable damage. Fig. 67(*a*) shows typical damage, and Fig. 67(*b*) shows one view of the most seriously damaged pier.

In contrast to the experiences reported in the Symposium it has been concluded that the damage to the Norfork baffle piers cannot be charged to cavitation. The photographs serve to support this conclusion. It was noted that the damaged piers were located without respect to conduit location and that the greatest damage occurred on the front or upstream faces of the piers. It is believed that the piers were eroded by the recirculated debris in the basin, and that the irregular and inconsistent nature of the damage was principally a product of chance and secondarily a result of variations in concrete quality. Again it is demonstrated that the designer's efforts are of no avail in view of practical considerations over which he has no control. This conclusion is pertinent to Mr. Harrold's discussion of streamlined baffle piers. It is acknowledged that baffle piers are advantageous in some instances, and that they may logically serve as an added safety factor in stilling-basin design. However, such vulnerable devices should be used advisedly; and the safety of the dam should not depend upon their permanence. It may be expected that damage such as that experienced at Norfork would be alleviated by the early removal of debris collected during the construction period. The recirculation of a certain quantity of stone will be unavoidable, however, unless the river channel is cleared of all loose rocks for a considerable distance below the stilling basin.

Gate-Slot Model Tests.—The Bull Shoals project, proposed for construction on the White River in Arkansas, would include a dam somewhat higher than that at Norfork. Rectangular outlet conduits similar to those at Norfork except that they are 9 ft high, would be located through the overflow monoliths. As a part of the preliminary investigations for the design of Bull Shoals Dam, conduit gate slots of the Norfork type were investigated in a model study of

FIG. 67.—DAMAGED BAFFLE PIERS IN STILLING BASIN, NORFORK DAM: (a) TYPICAL DAMAGE (b) MOST SERIOUSLY DAMAGED PIER

cavitation tendencies conducted at the U. S. Waterways Experiment Station, Vicksburg, Miss. The model conduit was constructed to a scale of 1:6, and two gate-slot designs were tested. The basic, nonstreamlined slot is shown in section in Fig. 68(*a*). The Norfork-type slot is shown in Fig. 68(*b*). Each model was equipped with a large number of small piezometers, and for each a series of tests were run for a wide range of velocities. The data consisted largely of open manometer readings of average pressures at each piezometer. The pressure cell-oscillograph device described by Mr. Harrold gave inconsistent results, and these data were discarded.

The principal results of the gate-slot model tests are summarized in Fig. 68, which shows dimensionless pressure coefficients, C_d, for piezometers on the boundary of the gate-slot models. Values of C_d were computed from the relation,

$$C_d = H_d \div \frac{V^2}{2\,g} \quad \text{.......................(15)}$$

in which H_d was taken as the measured difference in head between the various gate-slot piezometers and an arbitrary upstream control piezometer. The plotted points in Fig. 68 represent test velocities ranging from 42 ft per sec to 94 ft per sec. Curves drawn through these points describe the normal pressure variations in the vicinity of the slots.

As an example in the use of Fig. 68, let it be required to determine the maximum pressure drop in the vicinity of both nonstreamlined and streamlined gate slots, referred to the normal friction grade line. In the first case, the maximum departure of the boundary pressure coefficient from the friction coefficient occurs near the downstream corner of the gate slot and has a value (Fig. 68(*a*)) of approximately 0.127. It follows from Eq. 15, therefore, that the maximum pressure drop at the boundary, referred to the normal grade line, would be $0.127 \left(\frac{V^2}{2\,g}\right)$, where $\frac{V^2}{2\,g}$ is the computed average velocity head. For the estimated maximum discharge, V is 94 ft per sec or $\frac{V^2}{2\,g}$ is 137 ft, and the resulting maximum pressure drop for the case of the nonstreamlined slot is 17.4 ft. Similarly, for the case of the streamlined slot, the maximum pressure drop is only 8.2 ft. It should be apparent from these examples that the elevation of the normal grade line (that is, the magnitude of the average pressure in the conduit at the critical cross sections) is the primary index of whether or not a local pressure drop will result in cavitation. Thus, even in the first of the foregoing examples, the 17-ft pressure drop would not be expected to result in cavitation unless the grade line was extremely low. Combination of a low grade line with such a marked local pressure drop must have been the case in the Norris sluices. It should be noted, of course, that the data included in Fig. 68 are based on average pressures rather than on instantaneous pressures such as it was hoped could be obtained with the pressure-cell device. The diagrams, therefore, tell only a part of the story, for it is recognized that momentary pressure fluctuations far exceed the damped variations shown by the manometer readings. In order to have some assurance that cavitation damage will not occur as a result of the most extreme pressure fluctuations, the manometric pressure data from the model must be compared to similar data on designs

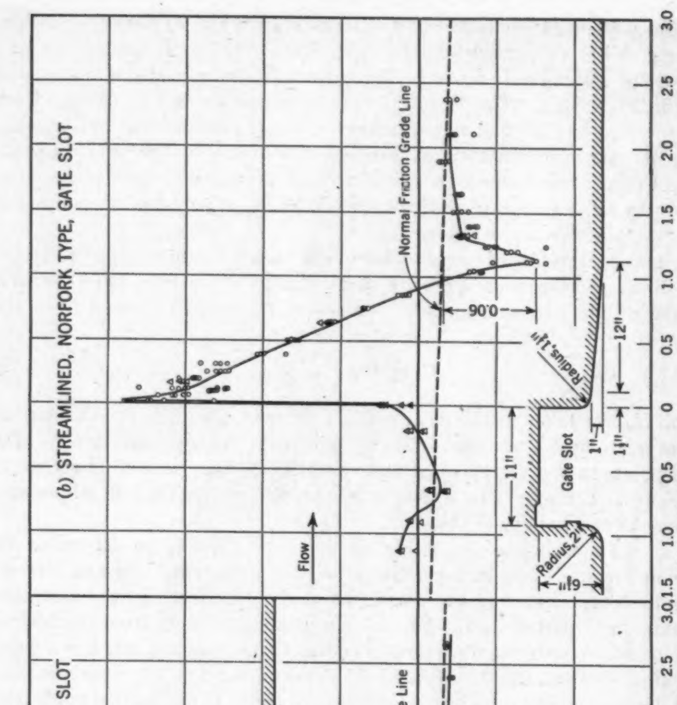

FIG. 68.—PRESSURE VARIATION IN THE VICINITY OF GATE SLOTS

which have been checked in the prototype. This is believed to be a valid and quite informative alternate procedure as compared with the infrequent opportunity to contrast a variety of designs in the prototype. A similar procedure has long been used as the most positive means of establishing the cavitation characteristics of Francis turbines.

Fig. 68(*b*), compared with Fig. 68(*a*), not only shows a marked benefit from the 1:12 bevel on the downstream edge of the gate slot but also suggests a need for further streamlining near the downstream end of the bevel. Practical considerations make it undesirable to specify a modified curve at this point, but in the case of the gate castings at Bull Shoals Dam the intersection of the bevel with the parallel side walls will be "rounded off" by grinding.

It seems reasonable to expect that the pitting of spillway gate slots described by Messrs. Harrold and Warnock would be susceptible to treatment such as that developed for the Norfork conduit gate slots. As shown in Fig. 68, local pressure variations are functions of the velocity head, and comparatively high velocities may be attained in regions near the bottom of spillway gate slots. It would appear that appropriate streamlining measures, rather than deflectors designed to eliminate the slot vortex, are the logical solution for the difficulties described. Mr. Warnock's discussion of experiences with needle-valve design aptly demonstrates that adequate streamlining cannot always be achieved by estimate.

An interesting sidelight to the tests on the gate-slot models was an accidental indication of the flow pattern in the vicinity of the slot, shown in Fig. 69. Quite unintentionally on one occasion when the model was being assembled, a small particle of heavy yellow grease was left on the top of the conduit upstream from the transparent cover plate over the test section. Several minutes after the model was adjusted to a steady velocity of approximately 38 ft per sec (model), observers spotted the grease particle as it "unrolled" in an unwavering, needle-sharp path (much smoother than the freehand lines in Fig. 69). Only once did the path divide, and in this case it joined a less sharply defined pattern being evolved in a similar manner within the slot

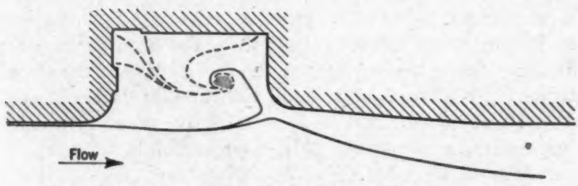

FIG. 69.—INDICATED FLOW PATTERN IN THE VICINITY OF A GATE

itself. Obviously, the path lines shown in Fig. 69 cannot be typical for the region in the center of the conduit and removed from the boundary and corner effects. It is interesting, however, to have this unusual indication of the flow pattern in the vicinity of the slot. Comparison of Fig. 69 with Fig. 68(*b*) shows that, as would be expected, the extremely high pressure measured on the downstream corner of the gate slot is directly opposite a point of sharp convex curvature in the indicated streamline.

Stilling Basin Studies.—In preliminary design studies for the Bull Shoals project it was assumed that a stilling basin similar to that at Norfork could be used. When a model of the proposed basin was investigated at the U. S. Waterways Experiment Station, it was found to operate in a very satisfactory manner for all spillway flows. However, the same setting, with the apron founded on the estimated firm rock line, did not provide sufficient tailwater depth to produce satisfactory stilling when a relatively few conduits were opened alone; that is, with no release from the powerhouse or spillway. As the tests

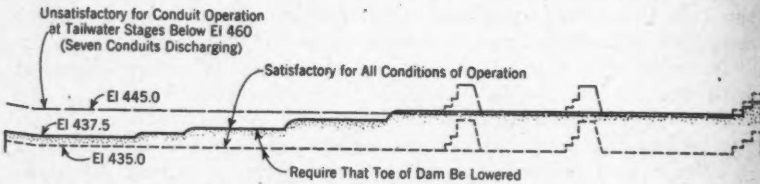

FIG. 70.—STILLING BASIN STUDIES, BULL SHOALS DAM

proceeded, it appeared that the baffle-pier type of basin would have to be lowered about 10 ft below the firm rock line in order to insure satisfactory performance for all conditions of conduit operation. An alternate type of basin, a stepped apron similar to that developed by the Tennessee Valley Authority for Cherokee Dam, was then investigated. This basin involved an average maximum lowering of 7.5 ft below the firm rock line near the toe of the dam. The new design eliminated the baffle piers entirely, thereby resulting in a considerable saving in steel and concrete. As finally developed, the stepped apron proved to be satisfactory for all conditions of operation. It is believed to be a thoroughly practical design, well suited to the tailwater conditions that prevail at Bull Shoals. A comparison of the two types is shown in Fig. 70.

Since the steps of the Bull Shoals apron design, like the baffle piers at Bluestone Dam described by Mr. Harrold, are near the toe of the dam where they receive a minimum benefit from tailwater cover, cavitation pressures may be expected to develop below the top corner of each step unless they are streamlined. Although pitting tendencies near the sharp edges of the steps might be expected to be self-healing, it was found that an elliptical step such as that shown in Fig. 70 would eliminate zones of negative pressure which had been observed below sharp-edged steps. Mr. Harrold points out that, in the case of the Bluestone tests, the streamlined baffle piers were less efficient as stilling devices than square-edged baffles. Similarly, the streamlined steps for Bull Shoals were found to sacrifice some quality of performance in comparison with preliminary tests on square-edged steps.

The writer is indebted to G. R. Schneider, Assoc. M. ASCE, and W. M. Mulholland of the U. S. Engineer Office, Little Rock, Ark., and to Fred R. Brown, M. ASCE, and associates of the U. S. Waterways Experiment Station, Lower Mississippi Valley Division, Vicksburg, for their contributions to the information from which this discussion was drawn.

E. R. VAN DRIEST,[14] Assoc. M. ASCE.—The theoretical and practical aspects of this Symposium have stimulated, in the writer, a sharp interest in the phenomenon of cavitation.

In his desire to see the actual cavitation in action, the writer made some simple tests on the flow of water through a glass venturi tube, with the following results.

A glass tube was heated and drawn into a venturi tube; after the tests it was found that the diameter of the exit and throat were 0.3967 in. and 0.1114 in., respectively. This tube was then connected by a rubber hose to the cold-water faucet in a sink, and the flow was increased until cavitation appeared strongly. After an attempt to destroy the glass by five days of such action, the writer found no destruction but, instead, a discoloration of the diffuser of the tube, which discoloration was readily washed out by an acid. The first result, therefore, was that chemicals in solution in the water entering the cavitated region can come out of solution and be deposited in concentrated form on the solid boundaries adjacent to the region. The effect could be due to supersaturation of the chemicals upon vaporization of the liquid. This result may have some consequence in the damage of surfaces; in other words, a corrosive effect may be encouraged under such conditions in addition to the well-known erosive effect.

The next result observed is by far the more interesting because it shows that tension can be sustained in a flowing fluid. Pure tension has been observed under static conditions by various experimenters. H. H. Dixon (73) obtained a tension of nearly 160 atmospheres; and the writer, after making his own observations, found that S. Skinner and F. Entwistle (74) had concluded in 1915 that tension can occur at the throat of a constricted tube although the discharges and dimensions of the tube were not given in their paper. Continuing with the writer's experiments, the succession of events leading to cavitation must be described: Water was forced through the tube very gradually until suddenly the flow would burst into terrific cavitation. Then the discharge could be diminished appreciably before the cavitation disappeared. Such cavitation always occurred about ½ in. downstream from the minimum constriction. These circumstances naturally led the writer to suspect the existence of tension in the liquid at the throat. However, it was possible to obtain cavitation at the throat when the inlet valve was adjusted a certain way, so that apparently extremely small bubbles of air were created (which could not be seen, since the water looked perfectly clear) that formed nuclei for cavitation when the pressure was brought low enough.

The appearance of the cavities downstream from the throat can be ascribed to the sudden rupture of the fluid due to the presence of free vortices (75). The zone of separation of the fluid from the wall is an opportune place for the occurrence of such vortices as there they are not too restricted by the wall. The free vortex indeed is the one simple type of motion that is easily generated and has centrifugal forces sufficient to rupture the fluid. Vorticity at the throat of the tube cannot readily fly into free vortices due to the stabilizing effect of the wall.

[14] Asst. Prof., Mech. Eng., Mass. Inst. Tech., Cambridge, Mass.

Since tension in the fluid cannot be measured with a manometer, it was necessary to compute the average tensile stress. To use the energy equation for computation, the head-loss coefficient (K_L) had to be known. Therefore, a measurement of pressure was made at the throat at the threshold of cavitation —when cavitation could be made to appear at the throat. At this threshold, the absolute pressure was found to be 30 mm Hg with a discharge of 13.8 lb per min. Such a pressure was expected since a pressure as low as vapor pressure (11 mm Hg) would not necessarily have to be reached to allow the small bubble nuclei to expand and form cavities. In the formula—

$$h_L = K_L \frac{(V_1 - V_2)^2}{2g} \qquad (16)$$

—the constant K_L was found to be 0.335.

Application of this value of K_L to the maximum flow of 16.5 lb per min just before the fluid ruptured gave 770 lb per sq ft in tension; and application to the minimum flow of 14.5 lb per min when cavitation downstream just disappeared yielded a value of 118 lb per sq ft in tension.

The foregoing demonstration proves that a fluid does not necessarily cavitate when the pressure is reduced to vapor pressure or even below—not to mention tension. Furthermore, one should be cautious of the notion that water always boils at 100° C. Water can be superheated well over 100° C without boiling; in fact, the temperature of ordinary boiling water is always greater than the true boiling temperature (75)(76). Also, water can be saturated with a gas at a pressure of 100 atmospheres and then reduced to 1 atmosphere without producing bubbles (75). Carbonated water will not effervesce unless agitated. All this leads to the conclusion that either the fluid is absolutely pure or gas is occluded in the liquid in such infinitely small bubbles that the surface tension forces are so great as to hold the fluid together. When cavitation occurs, either the pressure difference across the bubble wall must become sufficiently great to expand the bubble, or a free vortex with its tremendous centrifugal action must appear to produce bubble expansion or rupture of the fluid.

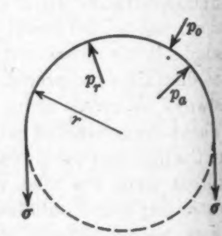

FIG. 71

It seems worthwhile at this point to investigate the mechanics of the bubble in more detail. Fig. 71 shows the bubble and the forces holding it in equilibrium. The pressures p_v and p_a are the partial pressures of the vapor and air, respectively, within the bubble; p_o is the pressure in the fluid outside the bubble; σ is the surface tension of the liquid, and r is the radius of the bubble. For equilibrium,

$$(p_v + p_a) - p_o = \frac{2\sigma}{r} \qquad (17)$$

Hence, the bubble will expand when $(p_v + p_a) > \frac{2\sigma}{r} + p_o$. Since superheating of the fluid is coincidental with boiling (certainly near the walls of the vessel), it follows that the additional energy must be necessary to overcome the surface tension of the fluid. High superheat is required at the boundaries where the bubbles grow, whereas low superheat can maintain the size of the

bubbles once they begin to rise and become larger, when p_a and σ are not effective.

Because surface tension, diameter of bubble, and viscosity have an effect on the growth of bubbles or rupture of the fluid, they should be included in a thorough dimensional analysis of any cavitation problem. For example, in the case of Fig. 17:

$$H = f(p_o, p_v, \sigma, r, \mu, \rho, g, b, c, \cdots) \quad (18)$$

in which b, c, $\cdots$, are linear dimensions. In Eq. 18 p_a is not included because it can be determined from Eq. 17. Dimensional analysis then yields:

$$\frac{H}{b} = \phi\left(\frac{p_v}{\rho\, g\, b}, \frac{p_v}{p_o}, \frac{\sigma}{b\, p_v}, \frac{\rho\, p_v\, b^2}{\mu^2}, \frac{r}{b}, \frac{b}{c}, \cdots\right) \quad (19a)$$

If it is now assumed that vortex action is the cause of the formation of bubbles and that the bubbles when formed are of appreciable size, then the products $\frac{\sigma}{b\, p_v}$ and $\frac{r}{b}$ will disappear from the function. Furthermore, the viscosity parameter $\frac{\rho\, p_v\, b^2}{\mu^2}$ will probably cover a large range during the production of strong vortices so that it too may sensibly not affect the function. This leaves only the difference between the vapor pressure and the pressure outside the bubble as effective in further enlargement of the bubble into a cavity. Hence,

$$\frac{H}{b} = \phi\left(\frac{p_o - p_v}{\rho\, g\, b}, \frac{b}{c}, \cdots\right) \quad (19b)$$

The parameter $\frac{p_o - p_v}{\rho\, g\, b}$ in Eq. 19b leads immediately to Eq. 2a or 3a since

$$\left(\frac{p_o - p_v}{\rho\, g\, b}\right)_m = \left(\frac{p_o - p_v}{\rho\, g\, b}\right)_p \quad (20)$$

whence (see Eq. 3a): $p_{om} = p_v + L_r\, p_{op} - L_r\, p_v = L_r\, p_{op} + (1 - L_r)p_v$. This procedure is essentially the same as that for the pressure cell method in which the experimenter predicts what could happen to the bubbles if he allowed a low enough pressure to exist.

In conclusion, the writer hopes that these remarks will help to clarify the physics of the cavitation phenomenon. Certainly with the development of higher dams and high-velocity structures demanding precise design, the hydraulic engineer will be stimulated to further research in this interesting field.

DUFF A. ABRAMS,[15] M. ASCE.—The third Symposium paper, by Mr. Warnock, consists mostly of a recital of some of the minor ailments that have been encountered by the Bureau of Reclamation, U. S. Department of the Interior (USBR), since about 1910, in the operation and maintenance of some of its hydraulic structures. The treatment of a "Boulder Dam Spillway Tunnel" could have been expanded to advantage, in proportion to its importance.

Boulder Dam Spillway Tunnel.—The considerable damage to a Boulder Dam spillway tunnel, discovered on December 12, 1941, is attributed to "cavitation" by Mr. Warnock, although it is apparent that this explanation is highly speculative. The same damage has been attributed by earlier USBR writers

[15] Cons. Engr., New York, N. Y.

to "erosion" (28) and to "concrete wear" (77). The only evidence given to support this claim for "cavitation" is: "The misalinement is defined by the position of the rope in Fig. 44." In the writer's opinion, a photograph of a rope is not very satisfying as scientific evidence; especially in view of certain other considerations:

1. The "misalinement" shown may have been due to any one of a number of causes that had nothing to do with the damage to the concrete lining.
2. The "misalinement" may have occurred after the damage.
3. An official report of the USBR published in 1938 stated that there was no misalinement in the Boulder Dam spillway tunnels (78) (78*a*):

> "* * * The Boulder Dam spillway system is designed with the expectation of obtaining practically streamline flow in the lower tunnel sections where maximum velocities occur. Comprehensive specification provisions for accuracy of alinement and rigid control of concrete manufacture and placement help to insure this.
>
> * * *
>
> "Since considerable care was taken in designing the shapes of the spillway transitions to eliminate negative pressures or vacuums, it is not expected that erosion will occur due to cavitation."

4. The damage was in exact accord with the teachings of model tests of concrete erosion, published by the USBR prior to damage.
5. Apparently previous inspections during seven years after completion had revealed no misalinement in the tunnel lining.
6. Even if one wished to accept the hypothesis of "cavitation," a statement by Mr. Warnock makes it impossible to do so:

> "Actually, the coat of black waterproofing and mineral deposit was intact in many places, showing no effect of direct scouring by the high-velocity water immediately above and below the eroded area."

Mr. Warnock continuously keeps before the reader the merits of many different types of model tests. The word "model" ("laboratory studies," "laboratory investigations," etc.) is used twenty times; but in all his comment on model testing he omits one of the most significant "model-prototype" relations to be found in the literature. By whatever name it is designated, the performance of the Boulder Dam spillway was exactly in accord with the teachings of model tests made by the USBR ten years earlier.

Prior to the construction of the dam, two types of model tests were conducted: (*a*) Erosion of concrete blocks by a jet of water at high velocity; and (*b*) hydraulic model tests of various spillway features.

Before discussing the model tests, it may be well to review what happened. Boulder Dam is a concrete arch-gravity structure, 727 ft high, completed by USBR in 1935. Two spillways were built. Water discharges into a side-channel spillway and then into a concrete-lined tunnel (50-ft inside diameter), inclined to the horizontal at 50°. Water storage in Lake Mead (above Boulder Dam) began in 1935; but it was six years before an opportunity arose to compare the performance of the "prototype" with the models. During four months in 1941, about 13,500 cu ft per sec was discharged by the Arizona spillway. This spillway was designed for a capacity of 200,000 cu ft per sec. The quantity discharged was about 7% of the rated capacity, and was considered so insignificant that no hydraulic model tests were made with less than equivalent

discharges of about 40,000 cu ft per sec. Nevertheless, the discharge for a short time of 7% of rated capacity produced the following rather startling results:

(a) Ripped a hole 115 ft long and 33 ft wide at the bottom of the drop in the 50-ft circular tunnel;

(b) Washed away a seven-year-old concrete lining to depths of as much as 25 ft;

(c) Excavated a hole 25 ft deep in the native rock; and

(d) Repairs required seventeen months, and cost $250,000.

The principal feature of the repairs was the placing of 1,460 cu yd of concrete. It may seem strange that the concrete lining was as much as 25 ft thick; but the bottom of the drop was in a "tunnel plug" built to seal off the upstream part of the original 50-ft diversion tunnel.

Model Tests of Concrete Erosion.—In 1931, Arthur Reuttgers and B. W. Steele, Assoc. M. Am. Soc. C. E., wrote "Tests of Concrete Blocks Subjected to High Water Jet Velocities." These tests were made two years before the first concrete was placed in Boulder Dam. The complete report was reprinted in 1938 (78*b*). The original purpose of the tests was stated as follows (78*c*):

> "Experiments were made to determine the resistance of concrete to erosive action of clear water flowing at extremely high velocities. Although the experiments were not part of the laboratory tests of hydraulic properties of spillways, they were definitely related to the practical performance of the spillway structures. Since no previously existent structures had been known to carry water at velocities of nearly 180 feet per second the investigations were of considerable importance."

Attention is directed particularly to the statements made seven years after the tests and three years after the completion of Boulder Dam to the effect that:

(a) The tests "were made to determine the resistance of concrete to erosive action of clear water,"

(b) They "were definitely related to the practical performance of the spillway structures,"

(c) "* * * the investigations were of considerable importance."

In 1938 the USBR announced the titles of forty-one volumes of reports that were in process of publication, giving technical details of all features of the design and construction of Boulder Dam and appurtenant works. Seven of these books are devoted to the $500,000 research program on cement and concrete. Perhaps it was some measure of the relative importance of the subject that the report on "Model Studies of Spillways" (78) was the first to appear of those having to do with concrete.

Sixteen small blocks of concrete, 18 in. square and 6 in. thick, were made in Denver, Colo. The mix was 1:2:4 using sand and gravel graded to 1½ in.; water-cement ratio, 0.63, by weight; and slump from 3 in. to 5 in. The blocks were cast on smooth, plane steel plates. The type of cement and the strength of concrete were not reported.

At ages of from 40 days to 138 days the blocks were subjected to a stream of water at velocities of from 100 ft per sec to 175 ft per sec. The stream was applied in a downward direction by means of a fixed nozzle that tapered from 4-in. inside diameter to 1 in. in 20 in. The test block was bolted at the required

angle, so that the stream impinged on the surface 15 in. from the nozzle. Generally the stream was applied at an angle of 90° to the bottom surface of the blocks, although angles of 5°, 30°, and 45° were also used. On some of the blocks, other methods were used, such as playing the stream in a circular slot cast in the concrete, or against an offset cast in the concrete. The treatment was continued, from a few hours to two days—in one instance for five weeks.

Typical Results of Model Tests of Concrete Erosion.—Block A–2 was subjected to water at a nozzle velocity of 175 ft per sec, at an angle of 90° for five days. It has been stated (78*d*) that this block was:

> "Unintentionally tested on upper, trowelled surface (as cast). The mortar surface was worn off in the shape of an annular ring."

The sections of Boulder Dam spillways that are subjected to the highest velocities have unformed surfaces; hence the foregoing test, made contrary to plan, gave the only information in the entire report that is directly applicable to the conditions at Boulder Dam. The remaining tests on block A–2 were made on the "formed" surface, but gave more tangible information on the dimensions of the "annular ring." At the end of a three-week test:

> "Erosion was confined to strip 1-inch wide on outside of a circle of approximately 4-inch diameter. Pits less than ½-inch deep" (78*d*).

After block A–2 had been under test at 175 ft per sec at 90° for five weeks: "Largest hole in block 1-inch deep and 12-inches square at the bottom. Rest of erosion less than ½-inch deep" (78*d*). It is not clear how a nozzle that discharged a scattered spray 4 in. in diameter could form a hole in the concrete "12-inches square at the bottom." This question would not ordinarily be important, but in this instance the information appears in an official USBR report and concerns data on which Boulder Dam was designed and built.

The tests on block A-2 were the most extended in the program. They demonstrated fully the fundamental error of applying a scattered spray, rather than a concentrated jet of water. At the same time, they showed the inability of this concrete to withstand even this mild type of erosion. In testing block F–1, the stream from the nozzle entered tangentially a "12-inch semicircular groove" cast in the concrete. After one day at 175 ft per sec: "Maximum depth of cavitation approximately ⅛ inch."

TABLE 2.—TESTS ON CONCRETE BLOCKS SUBJECTED TO HIGH WATER JET VELOCITIES

Block	Velocity*	Days	Observed data
A–1..	125	1	No appreciable erosion
A–1..	150	1	No appreciable erosion
A–1..	175	9.6	Small rough spot, some enlargement of surface pits
B–1..	175	2	Very little erosion
C–1..	175	2	Very little erosion

* Feet per second.

Because of entrainment of air, scattering of water, rebound, etc., the tests made with this setup were entirely inadequate when applied to Boulder Dam spillways. When the stream was applied at small angles the treatment was still less significant. Notes from the report on three blocks tested with the nozzle set at 5° to the test surface are presented in Table 2. Of course, "very little erosion" resulted from this scattered spray, which did not remotely resemble operating conditions at Boulder Dam. These notes are typical of the

observed data from the model tests of concrete erosion; but the destructive effects of these innocuous treatments were overlooked entirely in the design and construction of Boulder Dam.

Comparison of Model and Prototype.—Although it is apparent that the model tests of concrete erosion were inadequate to represent conditions at Boulder Dam, it is extremely interesting to note the almost perfect agreement between phenomena for model and "prototype":

Concrete model tests, 1931	Prototype tests, 1941
Under jet velocity of 175 ft per sec; cavitation of $\frac{1}{8}$ in. in one day; wore an annular ring in five days; a hole "1-inch deep and 12-inches square" in five weeks.	At a velocity estimated by Mr. Warnock of "at least 150 ft per sec," and at 7% of design capacity, 3,000 tons of rock and concrete was washed away in four months.

The superior quality of the spillway concrete, as a result of its age of seven years, was more than counterbalanced by the longer period of test. Ten years before the "prototype" was used, the model tests showed that concrete could not withstand even this mild treatment. The model tests predicted exactly the nature but not the full extent of the damage that was to occur in the spillway tunnel.

Concrete of Controlled Quality.—The two quotations (78) (78*a*) given near the beginning of this discussion, published three years after the completion of Boulder Dam, assured the profession that: "Comprehensive specification provisions for accuracy of alinement and rigid control of concrete manufacture and placement help to insure this [streamline flow at critical sections]"; and that: "* * * it is not expected that erosion will occur due to cavitation." Mr. Warnock now claims that the spillway failure was due to the very causes that were renounced years earlier:

> "Imperfections in the concrete, such as rock pockets, cold joints, porous areas, lack of bond, etc., all made the concrete more vulnerable to this attack by impingement. Furthermore, the impingement of the high-velocity water on any exposed joints would cause the energy in the water to be converted from velocity head to pressure head. This pressure was probably transmitted through the planes of weakness in the construction joints caused by lack of proper horizontal joint cleanup prior to placement of new concrete."

Horizontal Construction Joints.—The damage described by Mr. Warnock is attributed to the horizontal construction joints. Nearly three years prior to the discovery of the damage, the writer called attention to the defects of the water-air-gun method of joint cleanup that was used at Boulder Dam, and pointed out that the method (79): (*a*) Was dangerous, (*b*) should never have been specified, and (*c*) should be strictly prohibited. In response to this criticism, R. F. Blanks, M. ASCE (80), made a vigorous defense of this method, to which Mr. Warnock now attributes the severe damage of the spillway tunnel.

That reservoir water is finding its way freely into or through the horizontal construction joints at Boulder Dam is amply attested by the following:

(1) In 1940 Tom C. Mead (81) reported that:

> "Knowledge of the composition of the seepage water should help also in understanding the reason for the deposition of calcium carbonate in the foundation drains."

The mechanism here is quite plain. Cold reservoir water, about 60° F, enters the drains where they intercept the horizontal joints. In passing through the joints, the cold water became saturated with calcium hydroxide from the cement. Water in the drains is heated to about 100° F by the warm rock. Warm water cannot hold in solution as much calcium hydroxide as cold water; hence the excess hydroxide is precipitated in the drain holes, and gradually becomes carbonated from combination with the carbon dioxide in the water. It seems extremely likely that these drains will soon become entirely inoperative as a result of this deposition of carbonate.

(2) In 1945 Clarence Rawhouser, Assoc. M. Am. Soc. C. E. (82), called attention to "drilling of additional drain holes" under the middle of Boulder Dam. This was made necessary, no doubt, by the development of excessive hydrostatic uplift, due to water from the lake passing freely into the horizontal joints.

(3) In the same discussion Mr. Rawhouser gave data on one thermometer embedded in the concrete near the middle of the bottom of the dam which showed a most rapid rise in temperature for the first two years after artificial cooling was discontinued; then there was a much smaller rise for three years, followed by a drop of about 10° F during the last five years. The "unexplained" behavior of this thermometer was probably due to the gradual cooling of the hot concrete by the cold reservoir water passing freely through the joints.

(4) Mr. Warnock concludes that: "The concrete was probably dislodged in quite large pieces." If so, this was facilitated, no doubt, by hydrostatic uplift from lake water in the joints.

(5) In two places in his paper Mr. Warnock mentions the "mineral deposits" encountered in the area of the failure of the tunnel lining. These deposits were undoubtedly due to lime from the cement carried to the surface by lake water passing through the horizontal construction joints.

The Durability of Boulder Dam Concrete.—One of the most disturbing features of the damage in the Boulder Dam spillway tunnel was a report issued by representatives of the USBR. At the same time that the USBR was spending $250,000 to repair the damaged tunnel, it was informing the profession that (77):

> "Bureau of Reclamation tests indicated that concrete of ordinary proportions and controlled quality will withstand any erosive action likely to be produced in Boulder Dam spillways."

Both the concrete tests and the spillway had previously demonstrated that "concrete of ordinary proportions and controlled quality" would not do what is here claimed. The foregoing statement was published more than a year after it was known that 3,000 tons of concrete and rock had been washed out of one of the Boulder Dam spillways the first time it had been required to discharge 7% of its design capacity.

Summary.—The concrete model testing done for the design of the Boulder Dam spillways affords one of the most remarkable opportunities for "model-prototype" comparisons in engineering literature. The results of the concrete block tests in 1931 were completely corroborated ten years later by the first trial run of a Boulder Dam spillway. The model showed decided pitting at one day, and serious erosion after five weeks of exposure to a scattered spray of water at 175 ft per sec. In the spillway, 3,000 tons of concrete and rock were washed away, in four months, by water equivalent to 7% of the rated capacity.

The damage to the spillway tunnel was primarily due to erosion of the concrete (as had been shown by the model tests) and secondarily to hydrostatic uplift from reservoir water that found its way through the horizontal construction joints. This effect under a discharge of 7% of rated capacity, has a significance much more important than merely an interesting example of concrete erosion. It demonstrates that: (*a*) Concrete cannot withstand the erosive action of water flowing in these spillways; and (*b*) this spillway, having failed to withstand a discharge of 13,500 cu ft per sec, is entirely inadequate to discharge the 200,000 cu ft per sec for which it was designed.

In spite of the plain failure of the concrete in the model tests of erosion, and more than a year after the experience at the spillway tunnel representatives of the USBR issued a misleading statement on the capability of this concrete to withstand the service conditions to which it is exposed. This statement is almost certain to lure other engineers into the same types of costly and dangerous decisions that have occurred at Boulder Dam.

JOHN K. VENNARD,[16] Assoc. M. ASCE.—It is gratifying that that Symposium has stimulated so many civil engineers to place their cavitation experiences before the profession as a whole. The main purpose of the Symposium was to provide a convenient summary of theories, experiences, and references on cavitation. It is felt that the excellent discussions submitted have contributed heavily toward attaining this objective.

Professor Mockmore rightly emphasizes the necessity for care in surface finish to reduce cavitation and pitting. The importance of careful finishing of surfaces has been recognized in the propeller and turbine field for some time; on the other hand, a few tests described in the literature seem to indicate that surface roughness is quite irrelevant. This question is another ramification of the problem that has never been decided conclusively.

Professor Robertson's comment on the "elementary" treatment of cavitation theory is not taken to be a criticism since an elementary treatment was the intention of the paper. Professor Robertson raises the question of the effect on cavitation of internal tensions in a liquid, and thus encounters another unsolved problem of cavitation. Pure, air-free, unagitated water has been shown capable of withstanding enormous tensions for relatively long periods, but obviously such conditions would never be satisfied in engineering occurrences of cavitation. Nevertheless, it is possible that, even in "engineering water," tensions may exist for a sufficiently long time to contribute significantly to the rapid formation of the cavity. Future research may answer this question.

[16] Associate Prof. of Civ. Eng., Stanford Univ., Stanford University, Calif.

Thanks are due Professor Robertson for his neat summary of hypotheses and phenomena connected with cavity collapse which were not included in the original paper. This summary has served to strengthen the effectiveness of the Symposium.

The question asked by Mr. Blaisdell cannot be answered at the present time. Whether pitting may result from the collapse of cavities out of contact with the pitted area is another question for the research laboratory. Eventually, if this question is answered in the negative (assuming other advances in the knowledge of cavitation), the designer will have a valuable tool for rendering cavitation harmless.

Professor McNown indicates the possibility of dealing with some problems of cavitation caused by flow curvature by assuming a perfect fluid and applying the methods of classical hydrodynamics. Situations where this procedure can be followed, however, are a very small minority of those encountered in engineering practice; it still appears to the writer that, in the large percentage of problems in which cavitation results mainly from flow curvature, pressure reduction is quantitatively unpredictable and its causes are obscured by the complexities of three-dimensional flow. Professor McNown's remarks on a dimensionless approach to the cavitation problem, on the effect of air content, and on the use of the water tunnel have contributed materially to the value of the Symposium and are much appreciated.

Professor Van Driest's observation on the contribution of corrosive action is pertinent. Originally it was felt by numerous engineers that corrosion was the mechanism by which pitting occurred. All evidence now seems to indicate that cavity collapse is the main destructive effect, with corrosion playing a small, usually negligible, part; however, this is not to deny that there may be an effect of corrosion since metals are known to fatigue more rapidly in the presence of corrosive action.

The writer is skeptical of the validity of Professor Van Driest's conclusion concerning tension in a column of flowing water although he cannot offer conclusive refutation. The evidence that there was tension in the liquid at the throat of the constriction is certainly circumstantial; a moving liquid column (presumably containing dissolved air), sustaining tension for the time implied by Professor Van Driest, is inconceivable to the writer. Furthermore, the numerical calculations offered by Professor Van Driest do not appear convincing. The writer suspects that a change in the flow picture has produced a change in the value of K_L which Professor Van Driest has assumed to be constant; if this is the case, the calculations leading to tensions of 770 lb per sq ft and 118 lb per sq ft would be in error.

JOHN C. HARROLD,[17] Assoc. M. ASCE—The writer was pleased with the many original ideas, practical suggestions, and additional cavitation experiences presented in the discussions. They should add greatly to the value of the Symposium.

Professor Mockmore's suggestion that care in fabrication is just as important as proper design has also been learned by the Corps of Engineers through experience at Norfolk Dam (Arkansas) where, in constructing the

[17] Senior Hydr. Engr., Office of Chf. of Engrs., War Dept., Washington, D. C.

sluice gate slots described by Professor Kindsvater (Fig. 64(*a*)), the castings did not match within ½ in. in some cases and had to be ground flush after the dam was put in operation.

Messrs. Bradley and Kindsvater brought out the necessity for distinguishing between the cavitation due to a general lowering of the pressure gradient in a conduit and that due to a localized reduction caused by a discontinuity or sharp curvature in the boundary. Mr. Bradley's example (Fig. 52) showing that, in a straight uniform conduit, cavitation can occur only in the roof of the conduit because the bottom is always under higher pressure than the roof was very interesting.

The remedy described by Mr. Bradley for the low-pressure gradient in the Ross Dam (Washington) by-pass tunnel is essentially the same as that used in the Norris Dam (Tennessee) sluices (Fig. 46). In each case, the downstream end was constricted in order to raise the general pressure gradient in the conduit. Constrictions of the Norris type have been built into the sluices of some of the dams recently constructed by the Corps of Engineers.

Use of the beveled gate slot, described by Professor Kindsvater (Fig. 64(*a*)), has also become common practice with the Corps of Engineers. A general series of model tests is under way (1946) at the U. S. Waterways Experiment Station in Vicksburg, Miss., to attempt to improve the streamlining of gate slots. General tests are also under way at the Experiment Station which have for their purpose improvement in the design of the bottom edge of rectangular slide gates and the determination of the cavitation characteristics of elliptical entrance curves for rectangular sluices.

In reply to Mr. Blaisdell's question about the practicability of baffle piers with the sides cut away to form a water cushion, a model test of just such a baffle pier conducted in the vacuum tank at Carnegie Institute of Technology in Pittsburgh, Pa., in connection with the Bluestone Dam (West Virginia) tests (Fig. 18) will be described. The baffle piers for this test were 6 ft high and 5 ft wide, with a vertical upstream face and sloping downstream face as in the other tests; but the upstream face in this test was flared to an 8-ft width providing a 1½-ft overhang on each side. The upstream face was made convex in plan with a 6-ft radius and the transition from the 8-ft width to the 5-ft width was made with a concave surface, also with a 6-ft radius. The piers were spaced on 8-ft centers and were staggered in two rows as in the other tests. The following is quoted from the report on these tests:

> "The former [above] design was based on the assumption that the destructive effects of cavitation on the sides of the baffle could be eliminated by providing an area, or water pocket, for the formation of eddies in the region where cavitation would likely occur. The front of the baffle was designed in such a way as to direct the jet away from its sides, these being depressed to allow the water to feed in from behind and provide an area of positive pressure against them due to eddy formation. The behavior of this design was as expected, no pockets occurring adjacent to the pier. The jet was deflected away from the sides of the baffle, and the resulting low pressure areas were confined to the water in between the baffles. However, the effectiveness of this 'side-pocket' type of pier in energy dissipation was not as good as for the other types tested for Bluestone Dam."

Although in this particular case the "water cushion" baffles did not prove to be the best solution to the problem, the idea is basically sound and might prove more advantageous in another case. There is one practical objection to these baffles, however—they are structurally less rugged than the streamlined type. The upstream side edges being sharp and relatively thin would be subject to damage by impact from heavy drift or ice. The streamlined baffles have no projecting corners and would be less subject to damage. On the other hand, as stated by Mr. Blaisdell, the streamlined baffles also have a practical disadvantage in that the curved surfaces must be constructed more accurately.

Concerning the remaining two questions raised by Mr. Blaisdell: The writer does not know how the noise level of collapsing cavities is related to the damage caused by them; nor does he know of any instance where the structure, as a whole, failed because of the forces resulting from collapsing cavities. As stated in the writer's paper, sections of armor plating on the sides of the Bonneville (Oregon) gate piers and on the sides of the Gatun (Panama Canal) baffle piers were ripped off due to fluctuating pressures possibly involving the action of cavitation. However, the structures in these instances are of such rugged construction that no tendency toward failure of the structures, as a whole, has been noticed. Perhaps, in time, some such tendency may be observed. However, it is possible that the great width of these piers and the heavy steel reinforcement used in them may cause unit stresses resulting from the fluctuating pressures to be quite low. It is also possible that the forces themselves may not be great because the area exposed to extreme high and low pressures may not be great.

The writer appreciated the more complete theoretical analyses of the cavitation phenomenon and the model simulation thereof given by Professors McNown and Van Driest, and he was grateful that these analyses checked Eqs. 3. Their discussions also brought to light many interesting physical characteristics of the cavitation phenomenon which those not well versed in physics would not realize existed and which should be useful to practicing hydraulic engineers in interpreting cavitation experiences.

The additional cavitation experiences cited by Messrs. Ball, Locher, and Kindsvater should be helpful in future hydraulic designs.

There is one more comment on Professor Kindsvater's discussion which appears desirable. In writing about the reliability of electric pressure cells for measuring pressure fluctuations in the model of the Bull Shoals (Arkansas) sluice gate slots, Professor Kindsvater states that the cells "* * * gave inconsistent results, and these data were discarded." This may appear contrary to the statement in the writer's paper that satisfactory results can be obtained by this method of measurement. However, the statements will not seem contradictory when it is explained that the writer's statement applies to great fluctuations in pressure such as were measured on the sides of the baffle piers in the model of Bluestone Dam whereas Professor Kindsvater's statement applies to small pressure fluctuations downstream from the gate slots in the model of the Bull Shoals sluices. The pressure cells have been found unreliable in the lower range when measuring rapidly fluctuating pressures; and, as a result, further experimentation is under way (1946) at the U. S. Waterways Experiment Station to determine the causes of this trouble and the remedies

for it, if possible. It is suspected that the presence of minute air bubbles in the copper tubing leading from the piezometer openings to the cell may be the principal causes of the difficulty. Apparently, the error is inappreciable with great fluctuations in pressure; but, with small fluctuations, the results are quite inconsistent as Professor Kindsvater states. This leaves hydraulicians at present (1946) with no reliable method of measuring small fluctuations and with the necessity of applying an arbitrary factor of safety to measurements made with an ordinary water manometer.

Since the writing of the original papers of this Symposium (1944), severe pitting, due to cavitation was discovered in the outlet works control towers of Fort Peck Dam in Montana. The outlet works consist of three circular tunnels 24 ft 8 in. in diameter and about a mile long with vertical control shafts near the center. The discharge of each conduit is controlled by a cylinder gate, 27 ft 7 in. in diameter and 8 ft 2 in. high, 55 ft above the invert of the tunnel in the control shaft. The water rises vertically through an annular ring 6 ft 6 in. wide concentric with, and outside of, the 28-ft 1-in. circular shaft. It then flows laterally through six rectangular openings 8 ft 2 in. high and 7 ft 4 in. wide into the shaft; thence downward into a 24-ft 8-in. elbow which deflects the water horizontally into the 24-ft 8-in. diameter tunnel. The cylinder gate controls the six lateral openings and seats on the bottom edge of these openings. The sides and top of these openings are plane surfaces. The sides are radial with respect to the center line of the shaft and the top slopes downward in the direction of flow on a slope of 30° with the horizontal. The bottom of the opening is 6 ft 2 in. thick in the direction of flow and is shaped like the crest of an overflow dam. The sides, top, and bottom of the openings and the inside surfaces of the shaft in the vicinity of the openings are lined with semisteel armor plating. Severe pitting of these curved crests and the shaft lining in the vicinity of the openings has occurred to a maximum depth of 1½ in. The cylinder gates have been operated partly open and wide open for extended periods under heads up to 200 ft (pool to invert of tunnel). In addition, the cylinder gates themselves have been damaged by vibration and a section of the steel liner plating in the 24-ft 8-in. elbow has been torn out. Some of this damage may have been caused by the closing of the air vents in the control shaft, which was found necessary during winter operation to prevent freezing of the spray in the shaft. Very little winter operation is contemplated in the future. If the foregoing conditions continue to exist, it may be necessary to work out a change in design to remedy them. Thus far, repairs have been made in accordance with the original design.

The Corps of Engineers is constructing (1946) a large vacuum tank at the U. S. Waterways Experiment Station, similar to the tank at Carnegie Institute of Technology for the cavitation testing of various parts of flood control structures. The inside dimensions of the test chamber will be 15 ft long by 5 ft high by 5 ft wide. The test chamber has been designed for testing models with or without a free water surface.

Jacob E. Warnock,[18] M. ASCE.—Although the Symposium papers have stimulated a worthwhile budget of cavitation pitfalls to guide the efforts

[18] Chf., Hydr. Laboratory, U. S. Bureau of Reclamation, Denver, Colo.

of future designers, the writer is somewhat loath to see the discussion close. He is certain that, if every organization dealing with hydraulic structures and machinery would open its files, as the authors of the Symposium papers have done for their respective organizations, a more comprehensive list of examples of cavitation damage could be contributed. If this were done, the purpose of the Symposium (namely, that of allowing the profession at large to benefit by the experience of its individual members) would be more fully realized.

Of the many discussions submitted only one is in need of direct reply and comment. The discussion by Mr. Abrams covers the writer's portion of the Symposium very thoroughly, and it is unfortunate that much of his discussion is based on misconceptions on his part. He does not concede that cavitation can damage a concrete tunnel lining. Some of Mr. Abrams' comments are concerned with the quality and placing of concrete and are not discussed herein because they have no place in this Symposium; and, also, the subject has been fully treated in other publications. Those dealing with the subject at hand are fully discussed herein.

In his discussion of the Boulder Dam spillway tunnel, Mr. Abrams states, "* * * a photograph of a rope is not very satisfying as scientific evidence * * *" of tunnel misalinement. Actually, the misalinement was carefully surveyed. The photograph, however, was submitted because it was a more striking evidence than a contour drawing. Mr. Abrams' statements regarding the misalinement of the tunnels have no basis if the facts are considered. Certainly, the entire lining could not shift after the damage occurred without leaving evidence of such movement. Also, the misalinement indicated by the rope could not have been caused by erosion, since the black waterproofing was still on the surface of the concrete in many places after the damage had occurred.

Mr. Abrams then states, "An official report of the USBR published in 1938 stated that there was no misalinement in the Boulder Dam spillway tunnels." Careful reading of the excerpt chosen by Mr. Abrams (78*a*) will show this to be a misstatement:

> "* * * The Boulder Dam spillway system is designed with the expectation of obtaining practically streamline flow in the lower tunnel sections where maximum velocities occur. Comprehensive specification provisions for accuracy of alinement and rigid control of concrete manufacture and placement help to insure this.
>
> * * *
>
> "Since considerable care was taken in designing the shapes of the spillway transitions to eliminate negative pressures or vacuums, it is not expected that erosion will occur due to cavitation."

Nowhere in these excerpts is it stated that there was no misalinement of the tunnels. It is stated (78*a*) that, "specification provisions for accuracy of alinement" were made and that "care was taken" in design. These procedures were followed, but in spite of the precautions, the misalinement still occurred.

Mr. Abrams' understanding of "cavitation" does not agree with the accepted definition. He quotes the writer's statement:

> "Actually, the coat of black waterproofing and mineral deposit was intact in many places, showing no effect of direct scouring by the high-velocity water immediately above and below the eroded area."

and interprets it to mean that cavitation could not have occurred. Actually, this is positive evidence that cavitation did occur. Pitting or erosion due to cavitation begins a short distance downstream from a source of low pressure—in this case, the misalinement at the point shown by the rope. No measurable erosion occurred above the misalinement; and this fact constitutes strong evidence that, even with high-velocity flow, if changes in contour are not present, there is no tendency for the high-velocity water to erode the concrete. Apparently, the shearing action of the fluid against the boundary in the absence of abrasive material did not wear the concrete.

Considerable space is devoted by Mr. Abrams to a discussion of erosion of concrete test blocks, using quotations from a USBR report (78) to illustrate his points. The tests selected by Mr. Abrams to illustrate excessive concrete erosion are impingement tests. The jet of high-velocity water was pointed directly at, or at a sharp angle to the test block surface. These tests (78*e*)(78*f*) were run (quoting directly from the report)—

"* * * in order to determine the erosion produced by such extremely severe conditions * * * tests at a jet angle of 45 degrees and 90 degrees were intentionally extreme or accelerative and have no direct application to the spillways. These tests are enlightening, however, in revealing the resistance of the concrete to severe or abusive treatment."

Nowhere in the Boulder Dam tunnels is the concrete subjected to direct exposure to a jet of water traveling 175 ft per sec and impinging at a 45° or 90° angle. Flow in the Boulder tunnels is such that the streamlines are parallel, or nearly so, to the concrete surfaces. Quoting again from the report (78*g*), and referring to the test blocks,

"There was practically no evidence of wear or erosion of the concrete on any plane or jointed surface subjected to the water jet at any velocity when the angle between the jet and the block was small."

Mr. Abrams refers to the test jet as "a scattered spray" and then declares, "It is not clear how a nozzle that discharged a scattered spray 4 in. in diameter could form a hole in the concrete * * *." Actually, the "scattered spray" referred to by Mr. Abrams was a concentrated jet of water emanating from a nozzle that tapered from 4 in. in inside diameter to 1 in. in a length of 20 in. The jet impinged on the sample 15 in. from the nozzle with a velocity of 175 ft per sec; yet Mr. Abrams calls this a "mild type of erosion."

In two places Mr. Abrams calls attention to the results of tests on block A-2 and refers to a "hole 1-inch deep and 12 square inches at the bottom." Here he is quoting a typographical error (78*d*) meant to read $\frac{1}{2}$ sq. in. This should have been clear, regardless of the typesetter's omission of a diagonal line, since a photograph of the test block, included in the report, shows the area of the hole to be considerably less than 1 sq in. at the bottom.

In discussing the results of tests on block F-1, Mr. Abrams completely disregards the text of the report which states (78):

"In blocks having a cylindrical hole or semicircular groove, the apparent wear was inappreciable, except near the point of water exit from the block, see Figures 129 and 130. At those points, substantial cavitation occurred under jet velocity of 105 to 175 feet per second. The cavitation is attributed principally to outlet disturbances accompanying the sudden release of the stream from its constricting channel."

These statements are substantiated by a photograph of the block taken after testing was completed.

In connection with the foregoing discussion of cavitation and erosion, it is interesting to note the relative location of the erosion that occurred on the test blocks. Referring to tests with jet angles of 90° the report states (78e), "Areas affected had the shape of an annular ring approximately 1-inch wide around a 2-inch inside diameter circle * * *." Contrary to Mr. Abrams' description, the jet was a solid stream of water about 1 in. in diameter where it impinged on the test block surface; yet, there was no erosion within the area of impingement or within a concentric circle about 2 in. in diameter. All the measurable erosion occurred outside the 2-in. circle. A satisfactory explanation of this phenomenon is not readily apparent when one considers the known facts concerning either erosion or cavitation. Similar erosion has been experienced by others and no explanatory conclusions have been reached. Further experience and knowledge are needed to fully understand this type of surface destruction.

The comparison of model and prototype given by Mr. Abrams is not valid because of his misinterpretation of the model data. Furthermore, the nature of the damage to the prototype cannot be predicted from the model tests since cavitation did not occur in the model. Cavitation in the prototype was due to a local condition which did not exist in the model and was not expected to exist in the prototype. At velocities of about 175 ft per sec, under conditions approaching those in the prototype tunnel, there was no measurable damage to the model test blocks. At velocities of about 150 ft per sec in the prototype there was no damage to the tunnel except immediately below the misalinement.

Mr. Abrams concludes, "* * * this spillway, having failed to withstand a discharge of 13,500 cu ft per sec, is entirely inadequate to discharge the 200,000 cu ft per sec for which it was designed." This statement is certainly a pessimistic forecast which is not substantiated by the facts. Model tests showed that the tunnel was indeed capable of discharging the design flood. Cavitation is the result of high-velocity flow and the maximum velocity for 200,000 cu ft per sec will not be greater, proportionately, than that for 13,500 cu ft per sec, since the height of fall for both discharges is approximately the same. Thus, the tunnel has already been subjected to velocities which approach the maximum, and the effects of high-velocity flow in the tunnel where no imperfections exist have already been determined. Also, with increased discharges the possibility of cavitation occurring in the elbow is reduced in two ways: (1) The resulting greater depth increases the pressure at the boundary; and (2) the greater centrifugal force exerted by the greater mass of water in passing around the bend further increases the pressure at the boundary.

If the writer's paper serves no other purpose than to encourage a more wary attitude toward the performance of any hydraulic feature with respect to possible cavitation damage, he will feel that a worthy purpose has been served. It is to be hoped that in the future various individuals will feel encouraged by the candor of the Symposium authors to contribute their cavitation experiences, especially when they are novel or unexpected.

Acknowledgment is made to Messrs. Bradley, Ball, and Locher for contributing additional examples of cavitation erosion as experienced by the Bureau of Reclamation.

George H. Hickox,[19] M. ASCE.—The response to the Symposium on cavitation experiences has been very gratifying. It is clear that the difficulties caused by cavitation have been rather widespread, and are to be expected wherever high-head structures are in operation.

The experiences reported in the incompleted conduits of Ross Dam (Seattle, Wash.) by Mr. Bradley and in the temporary elbows at Grand Coulee Dam (Washington) by Mr. Ball are good examples of the way in which cavitation can be prevented, both by raising the general pressure level and by surface treatment to correct local reductions of pressure. These experiences are similar to those cited in the case of the Norris Dam (Tennessee) sluices.

Mr. Ball's notes on the beginning of cavitation damage in the Nevada tunnel of Boulder Dam (Arizona-Nevada) support the supposition that cavitation was the cause of the extensive damage in the Arizona tunnel. His description of the progressive nature of cavitation damage, supported as it is by direct evidence, is especially valuable and shows how an otherwise insignificant irregularity of surface may become a menace to the safety of an entire structure. If a smooth continuous surface, such as a tunnel, sluice, or face of a dam, contains an irregularity, either depression or projection, of sufficient size, cavitation will occur whenever the velocity is high enough and the general pressure level is low enough. If, then, the cavitation results in damage, the resulting depression may be deep enough to cause still further damage; and from that point on the effects are progressive and cumulative. For this reason, the writer wishes to endorse, heartily, Professor Kindsvater's statement that structures such as baffle piers that are subject to cavitation damage must not be depended on to insure the safety of dams.

Mr. Blaisdell asks if the noise level is related to the cavitation damage. In the case of the Norris sluices, there appeared to be a relationship between the duration of cavitation and the damage sustained, but there are no data to indicate that the rate of damage is related to the noise level. However, if a higher noise level indicates an increased intensity of cavitation, it would seem reasonable to expect that it would also be accompanied by an increased rate of damage.

Mr. Ball's observation of flashes of light in the tailrace is of interest as such flashes have also been observed on spillway aprons during the operation of sluices discharging at high velocity (83). His hypothesis that these flashes are caused by differences in the refractive and reflective properties of the water due to compression waves is probably correct. This hypothesis has been advanced by Professor Kindsvater (84). A similar explanation for the appearance of rapidly moving light bands accompanying the eruption of Paricutin volcano has been given by O. H. Gish (85). The flashes are not necessarily the result of compression waves set up by cavitation within the structure. In the case

[19] Senior Hydr. Engr., TVA, Hydr. Laboratory, Norris, Tenn.

of the sluices discharging on the apron at Cherokee and Hiwassee dams, the flashes appeared to originate in the boundary of the jet from the sluice. It seems probable that cavitation existed in the vortices set up at the sides of the jet. It is believed that the sluices themselves were free from cavitation as they had been constructed after extensive model tests; and measurements on the prototype structure disclosed no regions of low pressure. The existence of cavitation at the boundaries of a jet has been described by Mr. Locher in his discussion of the jet pump.

Professor McNown advances certain analytical methods of studying cavitation which undoubtedly have merit. It is suggested that such methods be used with considerable caution, however, since mathematical predictions based on the assumption of irrotational motion may be quite misleading. An example may be found in the case he cites in which cavitation actually occurred at a value of $\mathbf{K} = 1.8$, although the vapor pressure of the water was not reached until $\mathbf{K} = 0.7$.

Suggestions for further research are found in the various discussions. Professors Robertson and Van Driest suggest that water may be capable of supporting considerable tension while in motion, and that the formation of cavities may thereby be affected materially. Professor Robertson's assumption that the tension is a function of time is an interesting hypothesis but is subject to verification. Cavities that appear downstream from the point of lowest pressure may be caused by the formation of vortices in a region of expanding flow. This subject is certainly open to further investigation. Professor Van Driest's observations appear to indicate considerable tension in the liquid at times when no cavitation was observed. The existence of tension is possible, of course, as it is known to exist, and can be measured, in liquids at rest. His analysis does not show any definite relationship between tension and the occurrence of cavitation. It may be of interest to note, however, that, within the limits referred to by Professor McNown, most experimenters have found a good agreement between the occurrence of cavitation and the approach of boundary pressures to the vapor pressure of the liquid. It should be noted in this connection, as pointed out by Professor Kindsvater, that measurements of fluctuating pressure by a manometer are subject to considerable damping because of the relatively high frequency of the fluctuations and the large mass of the manometer fluid.

The bibliography included with the Symposium was not intended to be complete. A complete bibliography of papers on cavitation runs through many hundreds of titles.

Much investigation and research will need to be done before the mechanism of cavitation is understood. The same is true of the manner in which cavitation causes damage. The subcommittee sincerely hopes that discussers of the Symposium will be able to devote some effort to the solution of these problems. In the meantime, it is hoped that the Symposium has served to indicate the dangers that may exist when the possibility of cavitation is neglected.

Paper No. 2296

THE SAFETY OF STRUCTURES

By Alfred M. Freudenthal,[1] Assoc. M. ASCE

With Discussion by Messrs. F. H. Frankland, Elliott B. Roberts, A. G. Pugsley, Lynn Perry, Nomer Gray, I. M. Nelidov, M. Hirschthal, and Alfred M. Freudenthal.

Synopsis

The purpose of this paper is to analyze the safety factor in engineering structures in order to establish a rational method of evaluating its magnitude. The discrepancy between the highly refined procedure of modern design and the rather arbitrary manner of choosing the safety factor is seriously hampering the development of more effective design methods based upon a perfect balance of safety and economy.

The true character of the safety factor is disclosed by the introduction of a statistical concept of physical qualities, according to which the individual properties composing the structural phenomena of strain and resistance are represented by frequency distributions instead of by individual (minimum or maximum) values. The safety factor, correlating the strain induced with the resistance of the structure, may be derived from observable and measurable physical properties and phenomena.

The correlation of strain and resistance requires a careful analysis of all features of structural design, both from the points of view of the basic assumptions and of statistical interpretation. For the purpose of this analysis the available experimental and observational evidence is rather inadequate; the results obtainable at present, therefore, should be considered suggestive rather than conclusive. It is the insight gained into the essence of the safety factor that is of immediate practical interest.

The word "strain" in this paper is not to be confused with its conventional use to denote a linear measure, or proportion of stretch. It has a meaning roughly equivalent to what is commonly called "stress," but is more general as it is intended to denote the mechanical effect of load, or external conditions on the structure, the structural member, or the section. The word "resistance"

Note.—Published in October, 1945, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Lecturer in Bridge Eng., Hebrew Inst. of Tech., Haifa, Palestine.

is a general term indicating "strength" or capacity to resist failure. It can be expressed in any units appropriate to the matter under discussion.

PART 1.—GENERAL PRINCIPLES

Introduction

Structural design is generally understood to be composed of two operations—(1) The determination of the strain induced in the structure by loads and secondary effects, and (2) the comparison of the maximum strain that occurs with a rather fictitious resistance characteristic termed the "permissible stress," which is a fraction of the strength of the respective structural material. Although attempts have been made to modify this latter concept,[2,3] which is theoretically inadequate for the rational solution of any but the most simple structural problems, such new ways have not succeeded in affecting the practical procedure of design.

Structural design, like technical problems in general, must not be considered solely from the point of view of theoretical accuracy detached from the aspect of practical application. The conventional methods have proved their expediency under widely differing conditions. Although the underlying concepts have lost their original significance as a consequence of the better understanding of the behavior of structures and structural materials, it appears reasonable to retain the well-tested traditional form and to adapt it to the present improved knowledge of the problem, by redefining the basic concepts in accordance with the results of advanced research.

The fundamental, conventional concept of "allowable stress" involves a comparison between a computed maximum strain and the strength of the material, and implies the existence of a margin between the two. The justification of this margin has never been contested. As its conventional name "margin of safety" suggests, it reveals the subjective striving on the part of the designer for an adequate measure of safety as well as a consciousness of the limitations of his knowledge and the arbitrariness of his assumptions. Its real character has remained obscure, however, and its magnitude is generally estimated on the basis of subjective judgment rather than objective fact. Nothing has been done to establish a criterion for its determination on a more rational basis than the experience and judgment of the designer. The most refined design is thus deprived of its merits, the designer being free to choose the fundamental assumptions of his design largely on the basis of subjective arguments, without being compelled to ascertain their validity by the identification of the objective conditions. Research in the sphere of new materials cannot be expected to bear its full weight upon the economy of structures if the safety factor can be fixed rather arbitrarily "between 1.25 and 4.00 or even higher."[4] Therefore, the analysis of the safety factor to identify its true character and to determine its objective values has become of increasing urgency.

The Factor of Safety

The principle underlying the concept of the safety factor can be understood best by reviewing the fundamental difficulty of structural design. The computed structural characteristic ("strain") cannot be equated to the characteristic derived from observable and measurable physical properties ("resistance") because the results of an intellectual process—design—cannot be equated to the result of material perceptions—resistance. The limitations of human observation are such that no observable quality can be measured "exactly." The designer is able to assert only that a value is larger than a lower limit and smaller than an upper limit—not that it is "equal" to another value. The manifest lack of correspondence between the conceived action and the performed action in any sphere of human activity explains why no real identity may be expected in a series of actions or events which were planned to be identical. Consequently, intellectual concepts, contrived to reproduce material phenomena with a certain grade of perfection, may be correlated with material observations regarding those phenomena only by a relation of "inequality," expressed in terms of a probable correlation range. This range itself will be a function of the degree of perfection in the concept. It must therefore provide for: (1) The imperfection of human observations and actions (uncertainty); and (2) the imperfections of intellectual concepts devised to reproduce physical phenomena (ignorance). This range represents the objective minimum value of the safety margin, which is thus identified as a function of objective uncertainty as well as subjective ignorance.

With increasing perfection of design methods the element of "ignorance" can be largely eliminated; but the element of "uncertainty" is caused by circumstances that can be changed, to a certain extent, but can never be removed. Hence, the safety factor is a measure of uncertainty rather than of ignorance. The trend toward reducing its numerical value is not so much the result of improved design methods as it is the result of modified objective circumstances; that is, standardizing engineering materials by introducing quality control in production, applying standard acceptance tests by the users of such materials, and introducing stringent regulations for the control of workmanship.

The laws of structural design are derived from the principles of classical mechanics, and are based on the existence of a causal relationship between the antecedent and the consequent events. They are mostly expressed in the form of differential equations, the solution of which enables the engineer to determine all the consequences following one or a number of given antecedent events. Within the range for which the initial assumptions are valid, therefore, the designer should be able to go confidently from cause to effect, all phenomena concerned being strictly predictable. A certain number of parameters of these equations represent observable and measurable physical properties or phenomena. The application of the differential equations to structural design requires the introduction of the real values of such properties under all conceivable conditions of practical importance. Some of these values must be predicted or estimated since their observation and measurement under all relevant conditions are impracticable. Such prediction is entirely different from that based

upon differential equations. It can only refer to past experience; and the effect of chance, inherent in any activity or perception, becomes essential. The concept of deterministic causality is superseded by a new concept, in which every unknown cause is termed a "chance" cause. Systems of chance causes produce events in accordance with the law of large numbers and thus give rise to statistical laws represented by frequency distributions. Prediction based on a statistical causality, therefore, may be expressed only in terms of the probability that a certain event will occur within definite limits.

With the introduction of statistical causality the conventional conceptions of physical qualities undergo a considerable change. Every physical property is a statistical distribution so that the constancy of physical qualities is found to be of a purely statistical nature. A given quality approaches a constant value only in the sense that it may be represented by a frequency distribution within specified limits. The laws of structural design, therefore, must be considered a combination of functional and statistical relationships—functional so far as the laws of the theory of structures are concerned and statistical to the extent that real physical properties appear as parameters of the functional relations.

There are cases in which apparently functional relations are intrinsically statistic. Relationships that are important in a practical sense frequently cannot be derived from differential equations either because such equations are not known for the given case or because their solution is too difficult. The laws derived in such cases by statistical interpretation of past experience are empiric and do not represent real functional relationships. They represent the trend revealed by the correlation of assumedly relevant variables; the pertinent frequency distributions form an integral part of the information.

The interrelation between buckling resistance s_b and the slenderness ratio $\frac{l}{r}$ of steel columns is an example of the simultaneous existence of functional, empirical, and statistical laws in one and the same problem. Fig. 1 affords an illustration of the relation—

$$s_b = f\left(\frac{l}{r}\right) \qquad \text{(1)}$$

Region c defines Euler's hyperbola as derived from the differential equation of elastic buckling; region b represents the empirical laws of inelastic buckling; and region a shows the range of pure compression in which the frequency distribution of the resistance is the effect of a system of genuine chance causes only.

The value of the safety factor ζ may be derived from the condition that the maximum strain s_a induced in the structure by actual service conditions must never cause such damage as to impede its fitness for service, even were this maximum strain to coincide with the lowest value of the structure's resistance s_r

$$\zeta = \frac{s_r}{s_a} > 1 \qquad \text{(2)}$$

If $\pm \Delta s_a$ denotes the maximum range of fluctuation of actual strain about the expected value s_{ao} and $\pm \Delta s_r$ the maximum range of fluctuation of the

structure's resistance about its expected value s_{ro} the maximum strain to be expected will be $(s_{ao} + \Delta s_a)$ and the minimum resistance will never be less than $s_{ro} - \Delta s_{ro}$. According to Eq. 2 failure is just prevented if s_r (minimum) $= s_a$ (maximum) or

$$s_{ao} + \Delta s_a = s_{ro} - \Delta s_r \qquad (3)$$

Eq. 3 leads to the condition of minimum safety based on the correlation of

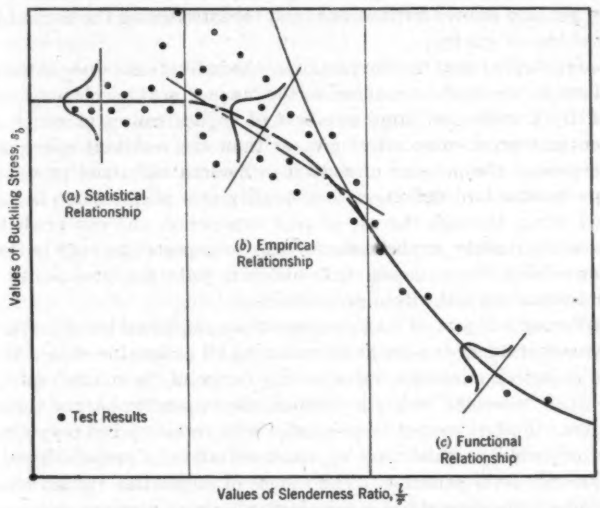

FIG. 1.—BUCKLING STRESS $s_b = f(l/r)$ OF STEEL COLUMNS

expected values of strain and resistance; thus:

$$s_{ao} = \frac{1 - \dfrac{\Delta s_r}{s_{ro}}}{1 + \dfrac{\Delta s_a}{s_{ao}}} s_{ro} = \frac{1}{\zeta} s_{ro} \qquad (4)$$

in which,

$$\zeta = \frac{1 + \dfrac{\Delta s_a}{s_{ao}}}{1 - \dfrac{\Delta s_r}{s_{ro}}} \qquad (5)$$

denotes the safety factor. For convenience, the correlation of strain and resistance may be expressed as a correlation of load and carrying capacity.

ABSOLUTE VERSUS RELATIVE, OR "ECONOMIC," SAFETY

The value of the safety factor derived from the condition of absolute safety expressed by Eq. 2 depends upon the variability of the design parameters (dimensions, weights, elasticity, strength, temperature) and of the initial and boundary conditions. The individual ranges of fluctuation determine the

ultimate ranges of variation of strain and resistance or of load and carrying capacity, in accordance with the law of statistical superposition. An increase in the individual ranges as well as in the number of parameters increases the resulting factor of safety. In order to keep this factor as low as is reasonably possible it is necessary to reduce the range of dispersion of the individual parameter by: (a) Modifying the objective circumstances and conditions under which it operates until the range of variability of the parameters of the design is that of genuine chance fluctuations; and (b) introducing the economic aspect of the problem of safety.

The requirement that the fluctuation of the individual values of the relevant material properties must be confined to the range of genuine chance fluctuation, produced by a system of large numbers of chance causes in which any one cause does not produce an effect greater than the resultant effect of all the others, expresses the purpose of control in modern industrial production and represents its standard definition.[5] A quality or a phenomenon is said to be controlled when, through the use of past experience, one can predict, within limits, how this quality or phenomenon may be expected to vary in the future. Prediction within limits means that one can state the probability that an individual value will fall within given limits.

By enforcing a régime of maximum control upon all material properties and phenomena that affect the design, eliminating all assignable causes of fluctuation, the objective minimum value of the factor of "absolute" safety is obtained. Such "absolute" safety is economically impracticable and theoretically meaningless. Failure cannot be prevented with certainty but only with a high degree of probability, which may approach certainty (a probability of 1) very closely but can never attain it. The ranges of fluctuation (which tend to become infinite to insure certainty) are thus reduced to a reasonable magnitude. A factor of safety may be based on the probability that individual values of either strain or resistance will fall beyond the ranges of either

$$s_a = s_{ao} + j\,\sigma_s \qquad (6a)$$

or

$$s_r = s_{ro} - j\,\sigma_r \qquad (6b)$$

in which σ_s and σ_r denote the standard deviation of the universes of s_a and s_r, respectively, and j is an arbitrary constant. Failure can be made highly improbable if this probability is small enough, but cannot be prevented absolutely.

The degree of safety will depend on the selection of the values of the coefficient j, resulting from a reasonable compromise between the requirements of safety and those of economy. It will be comparatively easy to reach such a compromise if the entire process of construction, beginning with the manufacture of the structural material, has been under rigorous control. If a certain level of economy is to be maintained, deficiency of control must be compensated by an increase in the risk faced by the designer.

[5] "Economic Control of Quality of Manufactured Product," by W. A. Shewart, D. Van Nostrand Co., Inc., New York, N. Y., 1931, p. 151.

Prediction from Past Experience

A structure is designed by predicting its future behavior on the strength of knowledge gained by past experience and the analysis of factual data. The computation of its safety factor requires an analysis of the variability of all influences bearing upon its resistance and the strain imposed. The quantitative information available is inadequate; where data have actually been collected they are usually presented inadequately and are thus deprived of much of their value.

Past experience concerning physical properties is generally recorded as a series of observations of the properties themselves, or of quality characteristics expressing a known relationship with the property considered. This latter relationship may be either functional (as in observing the decreasing amplitude of vibrations to determine the coefficient of damping of a material) or empirical (as in deriving the tensile strength of steel by observing the hardness of its surface).

When, in the case of some complex phenomena, research has not yet resulted in the establishment of such relationships as would be required for the resolution of the phenomenon into its fundamental components, past experience must be trusted to a correspondingly greater degree. Then past experience may be expressed either by series of observations or measurements of a characteristic manifestation of the phenomenon, or, if such evidence is inconclusive, by the ultimate limits within which all values of the characteristic may be expected to lie. Such limits will frequently be deducible from general considerations, as, for example, in delimiting the possible extreme fluctuations in the bending resistance of sections of mild steel between the resistance of an entirely plastic section with a rectangular stress distribution and that of a maximum elastic section with a triangular stress distribution.[2] Sometimes the frequency distribution itself (and thus the probability of the occurrence) of an individual event can be predicted from the knowledge of its a priori probability, which is the objective probability that an event will occur in an infinite number of trials. This probability can generally be derived by inference from collateral information at the disposal of the designer.

When dealing with material properties such as strength, elasticity, or linear dimensions—all of which affect the resistance of the structure—it will be necessary to predict their most probable values and the probable ranges of fluctuations of individual values. Observations of only a comparatively small number of samples, supplemented by relevant knowledge based on experience with the manufacture and the procedure of control and selection will be available for this purpose. The character of that process and the extent and reliability of current knowledge concerning it will determine the character and shape of the distribution function of the property considered, and therefore the accuracy of the prediction.

When dealing with external influences, such as service loads or wind pressure, that affect the strain induced in the structure the designer will have to assess the probability that certain extremes will occur; or he will be required to estimate the most probable conditions and probable ranges of fluctuations

from objective a priori probabilities based, generally, not on direct statistical evidence (which is mostly not available) but on circumstantial evidence. The form of the distribution curve of the probabilities of occurrence of certain loading conditions may be determined by the law of large numbers. For example, the probability that a certain load will occur m times in n cases is given by the binomial, which is the mth successive term of the expression $(P_p + P_q)^n$, in which P_p denotes the a priori or mathematical probability of the occurrence of the particular load and $P_q = (1 - P_p)$ the probability that it will not occur.

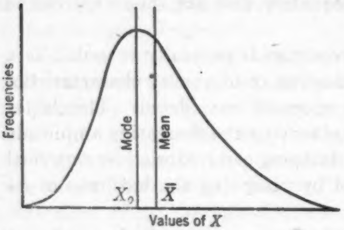

FIG. 2.—FREQUENCY DISTRIBUTION OF CHARACTERISTIC X

In order that data and statistical information may be used effectively, they will have to be condensed and presented in the form of a frequency distribution. Subsequently, the frequency distribution should be approximated by an algebraic distribution function $f(X, \bar{X}, \sigma, k)$ of the respective quality characteristic X (Fig. 2), containing the three principal statistics of the frequency distribution computed from the n observations X_n of the characteristic X; namely, its expected or mean value

$$\bar{X} = \frac{\Sigma X_n}{n} \quad (7a)$$

its standard deviation

$$\sigma = \sqrt{\frac{\Sigma(X_n - \bar{X})^2}{n}} \quad (7b)$$

and its skewness

$$k = \frac{\Sigma(X_n - \bar{X})^3}{n\sigma^3} \quad (7c)$$

If the parameters of the distribution function are chosen so that

$$\int_{-\infty}^{+\infty} f(X, \bar{X}, \sigma, k)\, dX = 1 \quad (8)$$

the integral $\int_a^b f(X, \bar{X}, \sigma, k)\, dX$ is a measure of the probability that an individual value X_n will occur within the limits $X = a$ and $X = b$.

The shape of the frequency distribution of a material property is an indication of the conditions under which this property has been, or is being, produced. In manufacturing processes an effort is generally made to attain a definite value of the characteristic property. This objective can be expressed either by stipulating a minimum value of the property or by imposing a limit on the fluctuations about its most probable value. In either case the objective cannot be achieved in any degree without imposing controls on the manufacturing process, in order to insure the systematic elimination of assignable

causes of fluctuation, thus reducing the range of dispersion of the individual values. The visible effect of such control is to produce a unimodal frequency distribution of the characteristic bell shape, which, in the ideal case of maximum control, may be expressed by the normal or Gaussian law:

$$f(X, \bar{X}, \sigma) = \Phi_o(z) = \frac{1}{2\,\pi}\, e^{-0.5z^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots (9)$$

in which e is the base of Napierian logarithms and

$$z = \frac{X - \bar{X}}{\sigma} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

The distribution functions of real properties generally deviate more or less from the ideal form expressed by Eq. 9, even if the degree of production control imposed is high. They are mostly asymmetric and the most probable or peak value of the distribution—its modal value X_o—differs from the mean value $\bar{X}$ (see Fig. 2). The first two terms of the Gram-Charlier series[6] containing the skewness k:

$$f(X, \bar{X}, \sigma, k) = \Phi_o(z) - \frac{k}{6}\,\Phi'''_o(z) = \Phi_o(z)\left[1 - \frac{k}{6}\,(3\,z - z^3)\right] \ldots . (11)$$

(in which $\Phi_o(z)$ is given by Eq. 10 and $\Phi'''_o(z)$ denotes its third derivative) will be found to furnish fair approximations of real frequency distributions of controlled physical properties and phenomena (Fig. 3).

Eqs. 10 and 11 can also be used to advantage if the probability of occurrence is based, not on experience expressed by series of direct observations, but on the knowledge or assumption of an a priori probability P_p, since they represent good approximations of the binomial law $(P_p + P_q)^n$. This law is unsuitable for practical computation if the result desired is the probability that an individual occurrence will exceed, rather than equal, $P_p + j\,\sigma$. If P_p is known, the standard deviation σ and the skewness k are given by the expressions

$$\sigma = \sqrt{P_p\, P_q\, n} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (12a)$$

and

$$k = \frac{1 - 2\,P_p}{\sigma} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots (12b)$$

If a physical property is manufactured without control, or if the designer has no conclusive evidence or knowledge of its being controlled, the best he can do toward determining the probability that individual values will fall within specified intervals is to use the theorem[7] proposed by P. L. Tchebycheff. According to this theorem, the probability that a value will fall outside the limits $\bar{X} \pm j\,\sigma$ is always smaller than $\frac{1}{j^2}$, regardless of the shape of the distribution function. The effect of quality control on the safety of structures is evident from a comparison of the accuracy of predictions based on the

FIG. 3.—COMPARISON OF OBSERVED AND THEORETICAL FREQUENCY DISTRIBUTIONS

Tchebycheff theorem with those derivable, under controlled conditions, by Eq. 10 or 11.

When imposing a standard of control on the manufacturing process of a given physical object the question necessarily arises as to whether the value aimed at should be stipulated as minimum limit or whether the inevitable dispersion of values should be controlled about an expected average. It can easily be shown that the setting of minimum limits, although still the prevalent conventional procedure, is considerably less effective in safeguarding such a limit and less reliable than the control of the fluctuations about an expected mean or most probable value. The current opinion that adequate safety can be insured only by specifying minimum limits is unfounded.

As an illustration consider the published results[8] of acceptance tests of structural shapes of silicon steel for the towers of the Golden Gate Bridge in California. The statistics have been computed, and frequency distributions of tensile strength and yield point developed from the published data, and the latter have been expressed in the form of Eq. 11 (see Fig. 3). The specifications for this bridge required minimum values of $X_m = 80{,}000$ lb per sq in. and 45,000 lb per sq in. for the tensile strength and the yield point, respectively. The integral

$$\int_0^{X_m} f(X, \bar{X}, \sigma, k)\, dX = p \qquad (13)$$

represents the "defective fraction" or the probability that an individual value will fall below the minimum limit stipulated. If two samples are taken from each melt and if the melt is accepted only when both samples prove satisfactory,[9] the probability that a given melt will be rejected will be $p^2 + 2\,p\,(1 - p) = 2\,p - p^2$ according to the binomial law. Hence, it will be more probable that a melt will be rejected than that it will be accepted only if $(2\,p - p^2) > 0.5$ or if $p > 0.3$; that is, if the defective fraction exceeds 30%, a possibility that is conceivable but under conditions of most inadequate control. Under the stipulation of a minimum limit, therefore, the chance of eliminating defective melts by the usual procedure of sampling is real only if the manufacture of the product is subjected to a practically inconceivable degree of control. Even under adequate conditions of control the occurrence of values lower than the stipulated minimum is still possible; this probability is computable by a statistical interpretation of the tests. The only possibility of reducing this probability practically to zero is by controlling the dispersion of values about an expected mean value, thus defining the minimum limit in terms of the probable extreme range of fluctuations below this mean value. The distribution functions reproducing the results of the check tests determine the range of fluctuation $\pm j\,\sigma$ about the mean, or the most probable value of X, in such a manner as to enable the designer to make the probability of an individual value smaller than $\bar{X} - j\,\sigma$ lower than any arbitrarily chosen figure. For a reasonably high level of control the introduction of $j = 3.5$ with regard to fluctuations about

[8] "Structural Applications of Steel and Light-Weight Alloys," A Symposium, *Transactions*, ASCE, Vol. 102, 1937, pp. 1328–1329.

[9] Standard Specification for Structural Steel, A.S.T.M., A-7-42, Philadelphia, Pa., 1943.

the mean value usually reduces this probability to less than 0.0001, as can be shown by evaluating the integral of Eq. 9. Fig. 3 shows that by controlling the dispersion of values around the mean, or the mode, and introducing the probable maximum range of fluctuations $\bar{X} - 2.5\,\sigma$ or $X_o - 2.15\,\sigma$ for tensile strength and $\bar{X} - 2.75\,\sigma$ or $X_o - 2.57\,\sigma$ for elastic limit, the minimum limit is safeguarded more effectively than by stipulating it in the conventional manner. This procedure should be adopted in engineering practice, and experience should be represented by the mean value $\bar{X}$ of the observations, or test results, together with its standard deviation σ and its skewness k. Only in cases in which the available data are unsuitable for statistical interpretation owing to deficiencies in scope and character will it be necessary to stipulate extreme limits for all possible values of the phenomenon or the characteristic considered. Only then will it be necessary to limit the maximum range of fluctuation by assumptions based on collateral information, and to introduce the midpoint between the extremes as a tentative approximation of the most probable value.

According to Eq. 3, the safety factor is derived from the ranges of probable maximum deviation of strain and resistance from their expected (that is, their most probable) values, which are to be considered the actual design values. Since the real distribution functions will usually be asymmetric and since, therefore, the mean value will not be identical with the modal value, it will be necessary to determine the modal value of X_o as the maximum of the function $f(X, \bar{X}, \sigma, k)$ by solving the equation

$$\frac{d}{dX}[f(X, \bar{X}, \sigma, k)] = 0 \ldots\ldots\ldots\ldots\ldots\ldots\ldots (14)$$

and introducing it as the design value and as the reference value for determining the relevant range of fluctuation.

Classification of Influence Bearing upon the Safety of Structures

The factor of safety is affected by two groups of influences:

(1) Influences that control the strain induced in the structure or the load that produces such strain; and

(2) Influences that control the resistance of the structure or its carrying capacity.

In both groups the existence of assignable causes as well as of chance causes may be presumed. Conditions for controlling all relevant properties and phenomena leading to the complete elimination of assignable causes and to the reduction of chance causes to a constant system of equivalent effects, which have been successfully imposed on highly organized industrial mass production, will necessarily be less perfect in the more individual, less standardized organization for the production of such units as civil engineering structures. In the latter case, economic considerations prevent the rigorous enforcement of conditions of maximum control, and they define a certain state of control as a limit beyond which assignable causes are to be considered

chance causes. Beyond such a specified limit any further elimination of assignable causes would not be economically justified, since the control measures, when applied beyond a reasonable scope, are not only expensive, but may become a serious obstacle, impeding the rate of progress of construction so considerably as to outweigh all economic advantages. It is reasonable, therefore, not to lay too much stress on the discrimination between assignable and chance causes, but to regard the difference as a difference of grade rather than of principle, and thus to extend the concept of "chance causes" to cover also assignable causes left unidentified, completely or beyond a certain limit, because their identification would not be worth while.

For some purposes it will even be convenient arbitrarily to present genuine assignable causes as chance causes, particularly in connection with problems of design. Extensive and intricate computations, such as are sometimes required for the exact design of complex but relatively unimportant structures, are disproportionately accurate from an economic point of view. For the most part, the maximum range that embraces all possible values of the several characteristics of design, however, can be evaluated by a short-cut method; or such a range is known by experience. By introducing the midpoint value between the extremes as the "design value," a range of artificial "chance fluctuations" is created, arbitrarily, which will affect the safety factor by expressing it as a function of the accuracy of the design. In a highly refined design, in which the conditions of strain and resistance are reproduced perfectly, genuine chance fluctuations, mostly controlled, will affect the safety factor within comparatively narrow limits. A crude design, requiring only a rapid computation of approximate values (and therefore marked by a high degree of uncertainty represented by a wide range of "artificial chance fluctuations") will lead to a considerable increase in the safety factor required.

Superposition of Individual Influences

In order to superimpose the fluctuations of the individual constituent qualities of strain and resistance, respectively, the method of statistical superposition must be introduced. In the functional relationship

$$X = F(x_1, x_2, x_3, \cdots, x_n) \qquad (15a)$$

the characteristics $x_1, x_2, x_3, \cdots, x_n$ are more or less controlled around the corresponding "design values" $x_{1o}, x_{2o}, x_{3o}, \cdots, x_{no}$ (which may be the means or the modal values) and the value of the principal characteristic X is subject to fluctuations $\pm j\sigma$ about its "design value":

$$X_o = F(x_{1o}, x_{2o}, x_{3o}, \cdots, x_{no}) \qquad (15b)$$

The range of fluctuations $\pm j\sigma$ can be determined by applying the following rule for the evaluation of the standard deviation of the resultant characteristic from the standard deviation of the constituents:[10]

$$\sigma = \sqrt{a^2_1\sigma^2_1 + a^2_2\sigma^2_2 + a^2_3\sigma^2_3 + \cdots a^2_n\sigma^2_n} \qquad (16)$$

[10] "Economic Control of Quality of Manufactured Product," by W. A. Shewart, D. Van Nostrand Co., Inc., New York, N. Y., 1931, p. 393.

in which

$$a_n = \left(\frac{\partial F}{\partial x_n}\right)_{x_n = \bar{x}_n} \quad \ldots \ldots \ldots \ldots \ldots \ldots \ldots \ldots (17)$$

Eq. 16 shows that owing to the relatively slight probability that all the component fluctuations will occur simultaneously, and in full intensity, the fluctuations of the resultant characteristic will be included within considerably narrower limits than might be inferred from the algebraic addition of the component fluctuations.

For the large number of material properties that have a bearing on the design, the level of control maintained will scarcely be uniform. The conditions of production vary considerably, not only with regard to the different structural materials but with regard to the individual stages of the construction process as well. Conditions of maximum control of certain properties may exist simultaneously with moderate control of other phenomena. In order to superimpose the fluctuations of the individual constituents of strain and resistance in spite of the different shapes of their distribution curves, the factor j (which relates the probable maximum range of fluctuations with the standard deviation of the frequency distribution) must be chosen individually for each component quality with regard to the particular degree of production control maintained. This must be done in such a way as to insure that the probability of occurrence of values beyond the range of variation considered shall be equal for each and every constituent. In other words, for strain all integrals $\int_{X_0+j\sigma}^{+\infty} f(X, \bar{X}, \sigma, k)\, dX$ of the distribution functions of the component qualities must be equal; and, for resistance, all integrals $\int_{-\infty}^{X_0-j\sigma} f(X, \bar{X}, \sigma, k)\, dX$ must be equal.

Assuming that different levels of control exist in different parts or in different stages of a construction process, distinguished by the factors j_k, j_l, j_m, etc., and leading to equal probabilities of defective individual values of the respective qualities, and considering absolute ranges of variability Δ_n of certain properties or phenomena, the range of fluctuation of the resultant characteristic X may be written in the form

$$\Delta X = \sqrt{j^2_k\, \Sigma(a_k\, \sigma_k)^2 + j^2_l\, \Sigma(a_l\, \sigma_l)^2 + j^2_m\, \Sigma(a_m\, \sigma_m)^2 \cdots + \Sigma(\Delta_n)^2}. \quad (18)$$

Safety Factor and Probability of Failure

The safety factor, as expressed by Eqs. 2 and 5, is derived from the condition that it should prevent failure even if a highly unfavorable and very improbable upward fluctuation of strain or load were to coincide with a particularly unfavorable and improbable downward fluctuation of resistance or carrying capacity. If P_s denotes the probability of occurrence of an extreme strain $(s_{a0} + \Delta s_a)$ and P_r is the probability of occurrence of the minimum resistance $(s_{r0} - \Delta s_r)$, the probability of coincidence of both extremes—that is, the probability of failure P_f—will be, according to statistical principles

$$P_f = P_s\, P_r \ldots \ldots \ldots \ldots \ldots \ldots \ldots \ldots (19)$$

Denoting by n the expected number of load repetitions during the presumed period of service of the structure, $n\,P_f$ represents the number of load repetitions during this period which might actually lead to failure. In order to prevent even a single occurrence of this critical state of the structure it is necessary to stipulate that $n\,P_f < 1$, or that $P_f = P_r\,P_s < \dfrac{1}{n}$.

Since, for known distribution functions of strain and resistance the choice of P_s and P_r determines the respective ranges of fluctuation, the foregoing

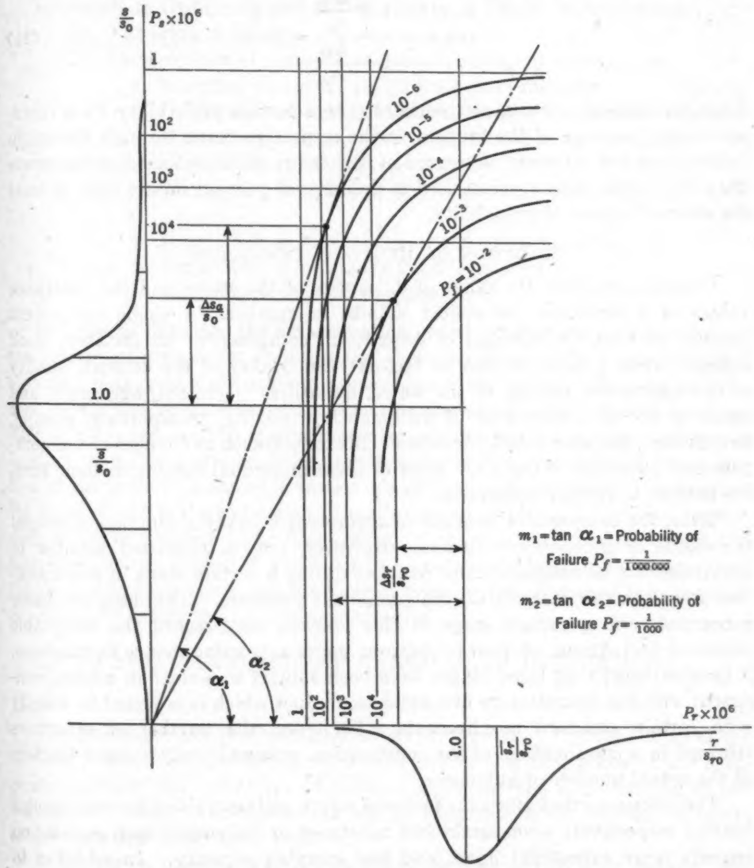

FIG. 4.—CURVES OF EQUAL PROBABILITY OF FAILURE (SEE EQ. 21)

condition expresses the necessary relation between these ranges for every probability associated with the prevention of failure. Drawing the distribution function of the resistance as abscissas and that of strain as ordinates and

indicating on each specific range of fluctuations $\frac{j\,\sigma_s}{s_{ao}}$ and $\frac{j\,\sigma_r}{s_{ro}}$, respectively, the pertinent probability of values falling outside this range, it is possible to trace the family of curves of equal probability of failure (see Fig. 4)

$$P_f = P_s\,P_r = \text{constant} \qquad (20)$$

The safety factor for each point on those curves is represented by the slope of the line connecting the respective point with the origin because

$$\tan\alpha = \frac{1 + \frac{\Delta s_a}{s_{ao}}}{1 - \frac{\Delta s_r}{s_{ro}}} = \zeta \qquad (21)$$

Since the highest safety factor pertaining to a certain probability P_f is represented by the slope of the tangent to the respective curve through the origin (which does not intersect any curve of higher probability) this slope expresses the safety factor which, when used in design, will prevent failure with at least the selected degree of probability.

Selection of Relevant Influences

Causes that affect the range of dispersion of the strain and the resistance values of a structure are almost infinite in number. A single component quality, such as the strength of concrete in compression, for instance, itself depends upon a large number of factors—the quality of the cement, quality of the aggregates, quality of the water, quantities of cement, aggregate, and water in the mix, influences of workmanship (mixing, transporting, placing, and curing), and uncontrollable external influences, such as changes of temperature and humidity of the air. Most of these individual factors, in their turn, are subject to further influences.

Thus, the compressive strength of concrete is actually a function of several thousands of independent factors. However, only a restricted number of influences will be assignable and relevant during a certain stage in the transition from the raw material to the completed structure. The designer, being concerned with a certain stage of this process, may regard the assignable causes of fluctuations relevant to previous stages as genuine chance fluctuations, if he is satisfied that those stages have been subject to a state of control consistent with the manufacture of a uniform product which is expected to comply with certain standard requirements. Therefore, the number of influences relevant in a certain stage of the construction process is only a small fraction of the actual number of influences.

The influences that affect the factor of safety will be divided into two groups bearing respectively upon strain and resistance or (whenever such correlation appears more expedient) upon load and carrying capacity. In addition to these principal groups, an intermediate group, embodying influences of the method and procedure of computation of strain, must be introduced.

The fundamental types of influences are enumerated in the following outline, separated into classes and groups in conformity with the aforementioned divisions.

Group A. Causes of Fluctuation in Strain.

I. Uncertainty and variability of loading conditions.

a. Dead load.

b. Live load (including dynamic effects).

II. Uncertainty and variability of external conditions that are independent of the load.

a. Change of temperature.

b. Wind forces.

c. Uncertainty of behavior of the subsoil.

Intermediate Group; Causes of Uncertainty of Strain Computations.

III. Variation of rigidity.

IV. Imperfection of methods and shortcomings of assumptions.

a. Accuracy of method and tolerances of numerical computation.

b. Inadequacy of assumptions concerning initial and boundary conditions, stress concentration, and secondary strain.

Group B. Causes of Fluctuation of Resistance.

V. Uncertainty and inaccuracy of the assumed mechanism of resistance.

a. Inaccuracy or inadequacy of conceived mechanism.

b. Variability of resistance limits of materials.

VI. Variation of structural dimensions.

In order to illustrate the determination of the appropriate design values of the individual component qualities and characteristics, and the establishment of ranges of dispersion about these values, some of the typical influences enumerated herein will be analyzed. Since neither the scope nor the character of the data that are assumed to represent past experience concerning these influences is adequate to the purpose of the present investigation, the following examination of the individual causes is tentative and suggestive rather than conclusive. Its main object is the indication of methods and of procedure to be adopted, deficiencies in the data to be supplied by future research. Consequently, the numerical values presented will have to be considered with some reservation, the main emphasis being laid upon the rational insight obtained into the true conditions of safety in engineering structures.

PART 2.—ANALYSIS OF PARTICULAR INFLUENCES

Dead Load

The fluctuations of the dead-load values are caused by the variability of the specific weight of the materials concerned and of the dimensions of the component parts of the structure. Therefore, the combined consideration of the tolerances of weight and dimensions will lead to a reasonably accurate estimate of the variation of the dead load.

Moreover, a discrepancy may generally be assumed to exist between the design load (mode of an assumed distribution curve) and the mean value due partly to the inaccuracy of the weights estimated (which are more frequently underrated than overrated), and partly to slight alterations of design during construction; also (except in very simple structures) the actual distribution of

the dead load is usually so intricate that its design value represents at best an approximation of the actual condition. It is a frequent experience that computations made for control purposes, after the structure has been completed, yield dead loads considerably in excess of the design load initially estimated. The following formula for the dead load w_d is suggested:

$$w_d = 1.10\, \bar{w}_d\, (1.0 \pm 0.10) \qquad (22)$$

in which $\bar{w}_d$ denotes the average dead load determined on the basis of the conventional values of the specific weights and of the nominal values of the dimensions.

Live Load

General.—Among the many instances of inconsistency between the accuracy and the refinement of design methods and the inadequacy and vagueness of the underlying assumptions, specifications concerning live loads are most conspicuous. The specification of service conditions is one of the unsatisfactory features of the conventional design. The values recommended are arbitrary and, for the most part, have no structural significance, emanating often from non-engineering quarters. A clear-cut distinction between everyday conditions of service and fictitious conditions is noticeably lacking. It is imperative that the service conditions be identified as reliably as the strain or resistance of the structure. It must be admitted, however, that the difficulties of defining the service load on which a judicious and rational design can be based are impressive, owing to the considerable spatial and temporal fluctuations of the (static) service weights, as well as to the variability of the accompanying dynamic effects.

The design live load should: (*a*) Represent the most probable actual service conditions of reasonably high frequency of occurrence; and (*b*) provide for such increase of the service load as may be expected, reasonably, during the assumed period of service of the structure, considering the general trend as well as local circumstances. Allowance should be made for possible, yet comparatively infrequent, adverse conditions of service, in the form of appropriate ranges of fluctuations about the design value, and this allowance should be embodied in the factor of safety.

In general, conventional specifications do not fulfil any of the foregoing requirements; the design loads stipulated represent, for the most part, highly unfavorable conditions, the occurrence of which is not only infrequent but improbable. Safety factors currently adopted are neither concerned with, nor do they refer to, the probability that such design live loads may actually occur, so that the numerical safety attributed to the design has no relation to the actual safety of the structure.

Intensity and Distribution of Live Loads for Buildings.—Live-load specifications should distinguish between two groups of buildings with regard to the purpose they are expected to serve; namely, buildings for human occupancy, and buildings for industrial purposes and storage. The principal difference between these groups is the character of the service loads. In buildings for

human occupancy, the intensity of dead loads and live loads may fluctuate widely, whereas in industrial, and especially in storage buildings, there is an almost constant maximum load. Since the simultaneous occurrence of such load on all parts of the structure represents actual service conditions, the probability that other conditions may occur is irrelevant.

Intensity and Distribution of Live Loads for Bridges.—The difference between the design live load of highway bridges and of railroad bridges resembles somewhat the difference between buildings for human occupancy and buildings for industrial use. A highly variable load intensity on highway bridges necessarily leads to design loads dependent upon the area loaded and subject to a wide range of chance fluctuations, whereas the service conditions of railroad bridges require the introduction of definite maximum design loads.

Adequate design loads for highway bridges can be determined, if information is available as to the character and dimensions of the most important traffic units, their weight and weight distribution, the distribution of different units along the traffic lane, velocity of traffic and dynamic effects, and the trend of future development. The only evidence so far collected that is useful practically has been for purposes of traffic research. A certain amount of information can be gleaned from these data, suggesting the following conclusions:

(1) The standard load of the modern highway bridge is the motor vehicle, of which at least three different kinds (units) must be considered—the truck, the rapid transit bus, and the passenger car. Widely varying types of such units are to be found on the highway and the average weight of such units remains considerably less than that of its heaviest type.

(2) The heaviest two-axle truck used to any considerable extent at present weighs, fully loaded, not more than 50,000 lb. It is about 30 ft long and thus represents an equivalent load of some 1,700 lb per lin ft of traffic lane. Since two thirds of the weight is carried by the rear axle the maximum concentrated load to be considered per lane is roughly 34,000 lb. The equivalent load intensity of the rapid transit bus approaches that of the heaviest truck but the distribution of axle loads is more favorable. On the other hand, the heaviest passenger car, about 20 ft long, weighs, fully loaded, not more than some 10,000 lb, resulting in a load intensity of about 500 lb per lin ft of lane. According to registration records, between one third and one fifth of all motor vehicles are trucks. Although no data are available concerning rapid transit buses, their number may be assumed to be comparatively small. It is anticipated that future expansion in the number of motor vehicles will be in passenger cars rather than in trucks. A reduction in the ratio of trucks to the total number of vehicles registered, amounting to one sixth by 1960, has been predicted.[11]

(3) The character and distribution of traffic vary with local conditions; but such conditions may change rapidly with the development or movement of industry. Since prediction concerning such matters will be highly unreliable, it is reasonable to avoid introducing too sharp regional differentiations in

[11] "Motor Transportation—A Forward View," A Symposium, *Transactions*, ASCE, Vol. 104, 1939, p. 1574.

specifications for traffic loads. A certain degree of differentiation is justified, however, with regard to the volume of traffic, which will affect the number of load repetitions, but not the load intensity.

(4) One factor that exerts considerable influence upon the load intensity is the distance between motor vehicles moving along the same traffic lane. Evaluating investigations reported by the U. S. Bureau of Public Roads,[12] the relation between the center to center spacing l of vehicles and their traveling velocity v can be approximated by the formula

$$l = \frac{L}{1 - 0.15\,v/V}\,(1 \pm 0.20) \qquad (23)$$

valid for $0 \leqq v \leqq 60$ miles per hr, in which $V = 10$ miles per hr. For trucks, $L = 40$ ft; for passenger cars, $L = 30$ ft. A speed of 10 miles per hr denotes extremely congested traffic with all vehicles moving at equal speed; speeds exceeding 40 miles per hr are possible only if the rate of movement of each vehicle is independent, distances between adjacent vehicles being such that the equivalent loads exerted are very small.

In formulating specification for the design loads of railroad bridges, the frequency of occurrence of different types of load units is irrelevant. The design load should represent the heaviest train expected to run on the given track within the assumed period of service.

Dynamic Effects of Live Loads.—The action of the service load is generally considered as static in the design of buildings and as dynamic in the design of bridges. Actually, however, only a limited number of structures is subject to genuinely static load action (dams, aqueducts, etc.). The loads acting on most structures are variable and transitory. Whether the effect of such loads is static or dynamic is thus a question of the rapidity of application of the strain.

The dynamic behavior of the load intensifies the strain induced in the structure and thus affects its safety. The "dynamic increment" I, indicating the excess of the dynamic over the static load, is conventionally considered the dynamic characteristic of the design. This concept, however expedient it may be, hardly conveys a picture of the real conditions in the structure under dynamic load action. The complex process of transfer of potential (strain) energy into kinetic (vibration) energy cannot be expressed adequately by such a simple device, based on the unjustified assumption of proportionality between the effect of a static load and that of a load moving at a certain speed. This fact, although generally recognized,[13] so far has had little effect on experimental research, which has mainly been directed at the determination of definite numerical values of the dynamic increment. It may be anticipated, therefore, that the results of such research will appear widely scattered and that final conclusions of general validity cannot be formulated.

The main reason for the inconclusiveness of impact research is the fact that only one part of the strain in a structure subject to traveling loads is functionally dependent on major assignable causes such as masses, weights,

[12] "Preliminary Results of Highway Capacity Studies," by O. K. Normann, *Public Roads*, February, 1939, Fig. 5, p. 227.

[13] "European Developments in the Study of Impact and Fatigue," by F. H. Frankland, *Civil Engineering*, April, 1940, p. 208.

velocities, dimensions, and elastic constants. The other part depends on more or less accidental circumstances and effects, such as the damping capacity of the structure, its state, the conditions of track or roadway, the wear of the wheels of the vehicles, etc. If, for the lack of a more expedient dynamic characteristic, the dynamic increment I is to be retained, and only the underlying concept is to be modified so far as to make it consistent with experience, it will be necessary to distinguish between assignable influences on this increment and chance influences, these being understood to cover genuine chance causes as well as unidentified assignable causes.

The functional relation between the average value of the increment and the load impulse has been found to be very nearly linear.[14] The range of dispersion about this "line of best fit" must be expected to be greatest for structures of medium span for which vibrations represent a substantial source of strain. In such structures the range of magnitude of the frequency of natural vibrations compares with the frequency of the real load impulses; the intensity and number of such impulses are sufficient to overcome the inertia of the structure within the period that the load is acting. For these reasons, conditions approaching resonance may be reproduced. Short-span structures protected by their rigidity and the resultant high frequencies of natural vibration, and long-span structures protected by their great masses from being excited to considerable vibrations by the short action of comparatively light service loads, may be expected to show a relatively narrow range of dispersion of values of the dynamic increment. The range of fluctuation about the mean value $\bar{I}$ thus tends to decrease with spans increasing beyond, as well as dropping below, the critical medium-span range. Practically, however, only the tendency to decrease with increasing span is manifest. For short spans the growing influence of local irregularities of the load action, and of the path of the load upon the intensity of individual impact impulses, is strong enough to reverse the opposite trend.

The genuine chance effects are of a considerably narrower range of variation in railroad bridges than they are in highway bridges. In the latter, the intensity, as well as the frequency and number of consecutive load impulses, varies within wide limits owing to the complexity of traffic conditions and the fact that the local condition of the roadway may become deteriorated to an extent that would be practically unimaginable on a railroad track in service. A similar explanation accounts for the wear of rolling surfaces of vehicle wheels —another factor that intensifies the load impact.

The mean or "line of best fit" of observations[15] pertaining to a single motor vehicle traveling at the speed v may be represented by:

$$I_o = \frac{1.50}{1 + \dfrac{V}{3v}} \qquad \text{(24)}$$

in which $V = 10$ miles per hr. The increment pertaining to n consecutive

[14] "Vibration Problems in Engineering," by S. Timoshenko, 2d Ed., D. Van Nostrand Co., Inc., New York, N. Y., 1937, p. 363.

[15] "Impact in Highway Bridges," by A. H. Fuller, *Final Report*, 2d Cong. for Bridge and Structural Eng., Springer, Berlin, 1929, p. 56.

vehicles may be derived by assuming that the probability of the simultaneous occurrence of the dynamic increment I in n vehicles is governed by chance. Hence the most probable increment in an observation of n vehicles, I_{no}, is obtained by applying Eq. 16 to Eq. 24, thus

$$I_{no} \doteq \frac{1}{\sqrt{n}} I_o = \frac{1.50}{(1 + V/3\,v)\sqrt{n}} \qquad (25)$$

The influences of the structure, and of the irregularities of the roadway and the tires, are represented by the range of fluctuations about the foregoing average. For single vehicles acting on stringers of very short span, the range may be as great as $\pm$ 100% of the average if the possibility of trucks with hard-worn tires traveling on rather worn roadways is to be provided for. The dynamic increment for n vehicles of weight W may be written in the form

$$w_l I_n = \frac{1.5\,w_l}{(1 + V/3\,v)\sqrt{n}}\left(1 \pm \frac{1.00}{\sqrt{n}}\right) \qquad (26)$$

in which $w_l = \frac{\Sigma W}{n\,l}$ denotes the load intensity in pounds per linear foot of traffic lane. If the structure is long enough to accommodate more than a single load unit per lane, the load intensity w_l becomes a function of the traveling speed of the load, because the spacing between the consecutive load units increases with increasing speed. A critical speed for which the product of load intensity and dynamic effect $(1 + I)\,w_l$ attains a maximum value, and which represents the traveling speed of the design load, is obtained by a differentiation of this product. With the resulting $v/V = 1.15$, the "critical" velocity of the design load is shown to be not more than 11.5 miles per hr. Only for comparatively short spans does one single load unit per lane, traveling at maximum speed, represent the design load.

Any presentation of the dynamic effect of the load is incomplete without a knowledge of the velocity of strain, the maximum number of consecutive load impulses, and the total number of impulses on the structure during its entire expected period of service.

In short-span steel bridges for railroads, for which the share of the dead-load strain in the total strain is almost negligible, the velocity of specific impact strain may attain a magnitude of 0.8% per sec for mild steel, the assumption being that the ultimate strain may almost attain the yield-point limit if the service load is acting under the most unfavorable conditions. With increasing spans the velocity of strain due to vibrations becomes dominant, which is in the range of magnitude of 0.2% to 0.3% per sec for mild steel. In large-span structures the maximum rate of specific strain, due to transitory load movement, will generally remain below 0.05% per sec. The rates of strain application in highway bridges are considerably lower than those in railroad bridges because the "critical" speed of the design load is less than one fifth of the traveling speed of fast trains. The strain rates in structures of low-alloy steel are necessarily higher than those for mild steel; and the values for reinforced concrete structures are considerably lower owing to the high dead-load ratio.

Load repetitions on single-track railroad bridges seldom attain 1,000 per day even for very dense traffic of about 80 to 100 trains daily, since the critical impulses in short-span structures are exerted by the locomotive driving axles only. The number of repetitions of the load of railroad bridges may thus exceed ten million for short-span structural parts if a 30-yr period of service is assumed. This number decreases rapidly with increasing spans.

In order to estimate the number of load repetitions as well as the number of consecutive load impulses on highway bridges a certain amount of evidence concerning the volume and distribution of traffic is necessary. The evaluation of traffic records[16] suggests that dense traffic is concentrated over eight consecutive hours of the day only, the maximum hourly volume reaching 6% of the daily total. For short-span structures and structural parts, the number of repetitions of the design load is determined by the number of trucks passing. This number during a 30-yr period of service will probably reach ten million on main city thoroughfares with 4,500 vehicles per day per lane. For medium and large spans, however, the design load consists of a congested, slowly moving row of vehicles extending over the entire span or the critical length of the influence line. Its maximum frequency (although extremely improbable) would be reached if all the traffic during this period were distributed exclusively in groups representing the design load. The total number of design-load repetitions during the expected period of service would thus decrease rapidly with increasing spans. The numbers estimated for single lanes are considerably larger than those for multiple-lane bridges owing to the small probability that full design loads will occur at one time on different lanes.

Changes of Temperature

Temperature changes in a structure involve chance fluctuations. The probability that extreme temperatures will occur is comparatively small. Changes of temperature within a restricted range, however, will occur frequently enough to justify their inclusion in any study concerning service conditions. Therefore, temperature changes should be divided, according to frequency of occurrence, into changes affecting normal conditions of service and changes over an extreme and infrequent range affecting the safety factor.

Wind Forces

The magnitude and distribution of wind forces are chance events. Within a certain range of wind pressures the frequency is comparatively high and, consequently, the structure can be expected to withstand wind pressure permanently and with a degree of safety equal to that required for the principal service loads. Extreme values of wind forces, such as those that occur during severe storms, need be expected on rare occasions only. Hence, wind forces should be introduced into the actual design only as far as moderate and frequently occurring values are concerned, whereas maximum effects should be anticipated in the factor of safety. Long-time records of wind velocities will furnish the material for the preparation of distribution curves from which design values and fluctuations can be derived.

[16] "An Automatic Recorder for Counting Highway Traffic," by R. E. Craig, *Public Roads*, May, 1938, p. 48.

Uncertainty in the Behavior of the Subsoil

The foundation is an integral part of the structure, and its behavior, mainly depending upon the behavior of the subsoil, exerts considerable influence on the state of strain in statically indeterminate structures. The strain resulting from such movement in the structure is either entirely neglected in the conventional design (being based mostly on the assumption that the supports always remain fixed or that they settle uniformly, by equal amounts) or it is regarded as of secondary importance. The movement of the subsoil being a reality, this attitude is not justified.

Probably maximum values of settlement differences should be estimated with the aid of selected methods defined by soil mechanics, and the range of fluctuation of the dead-load strain, such as might actually occur when these differences are most unfavorable, should be established. Such fluctuations considered as chance events, varying about the design values of the dead-load stress, will necessarily increase the dispersion of the individual stress values and, consequently, will increase the required factor of safety. Owing to the high degree of rigidity and the almost perfect elasticity of the subsoil under the action of transient loads, the mutual effect of subsoil and structure is restricted to dead-load stress only.

Variation of Structural Rigidity

The rigidity of a structural part is expressed as the product of a sectional value, such as the moment of inertia or the area, and the respective modulus of elasticity of the material, divided by the length of the member. The degree of rigidity will vary, therefore, with changes of either the modulus of elasticity or the sectional value, or both, fluctuations in length being insignificant.

It is evident that the rigidity of all parts or members of one and the same structure will not necessarily be subject to uniform variation. Allowance must be made for the fact that the rigidity of individual parts or members will differ among themselves. The effect of such variation upon the strain of redundant structures may be determined by a method which has been called "analytical experiment" by Hardy Cross,[17] M. ASCE. This method consists of the actual computation of certain characteristics of strain in a structure subject to any possible combination of variation of rigidity in its individual parts or members.

In metallic structures subject to air temperatures only, no change of the initial rigidity need be expected unless the cross sections are reduced by deterioration. In concrete and reinforced concrete structures, however, the additional deformation (creep) that occurs under action of sustained compressive loads makes the initial modulus of elasticity appear to decrease. This apparent decrease affects the state of strain, and thus the safety, of plain and reinforced concrete in which sustained compression is a dominant phenomenon, such as redundant large-span arches and pre-stressed structures.[18]

Accuracy of Methods and Tolerances of Numerical Computation

Methods of computing strain characteristics are generally based upon the assumption of perfect elasticity. This assumption is justified for metallic structures under air temperatures, and it is correct even for concrete structures strained within the range of the conventional working stresses. If the strict methods of the theory of elasticity are applied to the design, and if the respective boundary conditions are selected so as to reproduce the actual behavior, the resulting strain values are within the range of accuracy of the assumed boundary conditions.

If short-cut methods are applied as substitutes for a strict theoretical analysis, the range of error must be compensated by an appropriate increase in the general factor of safety. The functional dependence of the safety factor on the relative crudeness of the design method is thus established. The maximum range of possible error must be ascertained reliably and subsequently introduced as a constituent chance fluctuation.

Boundary Conditions, Secondary Strain and Stress Concentration

Boundary conditions are expressed in terms of displacement and the angular deflection of end sections. The boundary conditions for the supports may be derived from observations of the movement of the foundations and the subsoil. There are cases, however, in which boundary conditions are chosen rather arbitrarily or, to simplify the mathematics, without satisfactory evidence that the choice is rational.

The manner in which the boundary conditions for end sections are assumed will considerably influence the actual safety of members subject to bending or buckling. It is doubtful that any assumed degree of fixity at the ends will ever be realized precisely in the actual structure. Therefore, minimum and maximum values of the probable angular deflection at the ends should be estimated, and the mean of these values should be selected as the design value, the range of variation about the mean being considered a constituent part of the safety factor.

An important group of influences upon the safety of structures is represented by the effects of secondary strain and stress concentrations, mostly occurring at or near structural connections—thermal stresses in welds, stress concentrations around rivets, residual stresses due to rolling or cold-working, shrinkage stresses in reinforced concrete, and stress concentrations produced by surface conditions due to corrosion. The magnitude and effect of all these influences depend on a large number of chance causes and vary considerably, often in a rather erratic manner. Their effect upon the strain should be reflected in the design by reducing the resistance values rather than by increasing the intensity of the strain. In this paper, therefore, they will be treated in connection with resistance problems.

Uncertainty and Inaccuracy of the Mechanism of Resistance

The resistance of engineering structures is affected by the character of the load, by external conditions, and by the characteristic properties of structural

materials. In order to reproduce the real phenomenon in a form suitable for design, abstractions and assumptions must be introduced.

Structural resistance is defined, generally, with reference to the state of strain which delimits the fitness for service of a structure. It is principally a function of two variables, a sectional characteristic and the resistance (strength) of the material. For practically every structural material this resistance is influenced by the rate at which strain is applied—the same material that appears permanently deformable and tough under low strain rates will appear perfectly elastic and brittle under impact strain and will show increased strength.

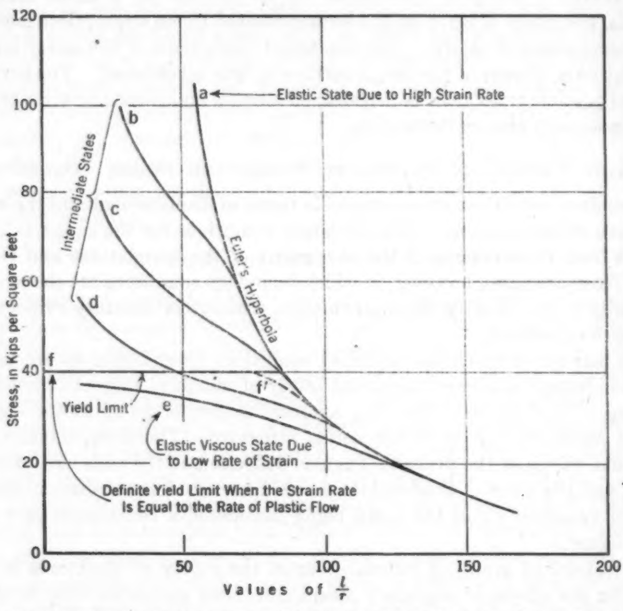

FIG. 5.—BUCKLING STRESS s_b AS FUNCTION OF SLENDERNESS RATIO l/r AND THE STRAIN RATE APPLIED

In certain cases resistance is not a function of sectional strength alone but also of the structure's stability, as in members subject to axial compression. The "buckling stress" embodies both sectional strength and geometrical criteria. Fig. 5, which presents the buckling stress as a function of the slenderness ratio l/r and of the strain rate applied, illustrates the velocity sensitiveness of the buckling phenomenon. This aspect of the buckling problem is important in the design of compressed members under conditions of impact, under which the Euler hyperbola applies over a wider range than is conventionally considered elastic, and under conditions of creep under which the elastic range is considerably diminished.

The real resistance mechanism is normally rather complex, and it is hardly possible to conceive such a mechanism that will effectively reproduce the

actual phenomenon and which is at the same time simple enough to be suitable for practical design. Every devised mechanism, therefore, is fictitious to a certain degree; but it will embody the relevant physical qualities that are determinable by simple standardized tests. The efficiency of the mechanism is ascertained by statistically interpretable experiments, and its reliability and the range of dispersion of individual values about the average trend established. Its suitability is to be judged by the simplicity of the concept, by the closeness with which experimental results are reproduced, and by the narrowness of the range of dispersion of such results about the "theoretical" course.

The range of uncertainty characterizing a certain resistance mechanism will be affected by the state defined as undesired with regard to the safety of the structure. Satisfactory correlation of the structural resistance limits which determine this state, with the material strength limits which can be observed on reproducible test specimen, has so far been attained for the most simple conditions only.

Uncertainty and Variation of Resistance Limits of Structural Materials

The mechanical resistance of engineering materials is affected by the strain field, the rate and duration of strain, the amplitude of strain cycles, and their number. The influence of the strain field is generally expressed by the conceived mechanism of resistance. Effects of local concentrations of strain due to notches, welds, or rivets are not embodied in the general mechanism of resistance but are considered by empirically reducing the resistance (strength)

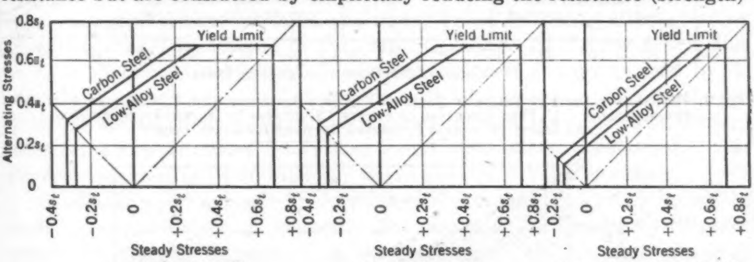

FIG. 6.—ENDURANCE LIMIT IN TERMS OF ULTIMATE TENSILE STRENGTH s_t AS FUNCTION OF AMPLITUDE OF STRESS OSCILLATIONS ABOUT STEADY STRESS

of the material in the undistorted field of strain. Since the resistance of a material relevant for purposes of structural design is its resistance at, and in, the vicinity of the heaviest concentration of strain which occurs within the areas of the structural connections, the specific resistance of the material at, or near, connections of standard shape must be determined experimentally.

The resistance-reducing effect of structural connections subject to load cycles of various amplitudes has been investigated extensively for steel.[19,20]

[19] "On the Fatigue Strength of Riveted and Welded Joints and the Design of Dynamically Stressed Structural Members Based on Conclusions Drawn from Fatigue Tests," by K. Schaechterle, *Publications*, International Assn. for Bridge and Structural Eng., Zurich, Vol. 2, 1933–1934, pp. 312–379.

[20] "On the Fatigue Strength of Riveted and Welded Joints Made of Steel St. 52," by E. H. Schulz and H. Buchholtz, *ibid.*, pp. 380–399.

Fig. 6 shows the results of the investigations in a concise form, relating the endurance limit for various amplitudes of stress cycles repeated two million times, and the tensile strength s_t. Owing to the different character of the connections different relationships are obtained for riveted and for welded con-

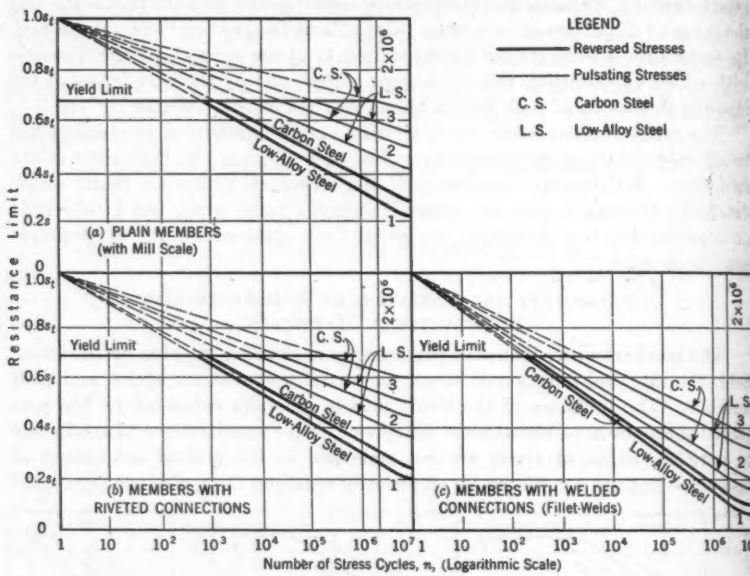

FIG. 7.—ENDURANCE LIMIT IN TERMS OF ULTIMATE TENSILE STRENGTH s_t AS FUNCTION OF NUMBER OF STRESS CYCLES ("1" FULL REVERSAL OF STRESS, "2" STRESS PULSATING BETWEEN ZERO AND LIMIT, "3" STRESS PULSATING BETWEEN 0.2 s_t AND LIMIT)

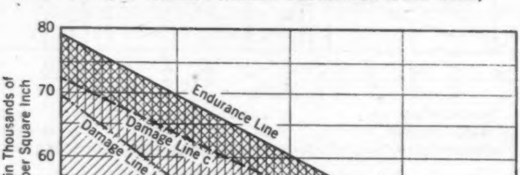

FIG. 8.—CHARACTERISTIC DAMAGE LINES AND DAMAGE RANGES

nections. Different limits are also obtained for different numbers of stress cycles (Fig. 7). The results presented in Figs. 7 and 8, however, have been derived from arbitrarily defined minimum values of the endurance limit; no statistical interpretation has been attempted and no adequate information is

available concerning the range of fluctuations of the dynamical resistance limits in general. This range will certainly exceed that pertaining to static resistance limits.

In order to ascertain the range of validity of the diagrams of Fig. 7, two different sets of conditions of load application should be considered—(1) loads inducing strain rates that exceed the rate of permanent deformation (rate of yield) of the material and (2) loads inducing lower strain rates. The fact that, in the latter case, the yield point cannot be exceeded furnishes the criterion which defines a critical number of load cycles below which the resistance under conditions of static strain is lower than that under conditions of rapid load repetition.

The picture of the dynamical resistance of metals would be incomplete without the inclusion of the concept of "damage" by overstrain which has considerable bearing on the safety of structures. The "damage range"[21,22] expresses the extent of damage with regard to the endurance limit which is caused by incidental overstrain. The "damage line" delimits this range by relating the amplitude of overstrain that can be sustained by the material without the final endurance limit being affected, to the maximum permissible number of repetitions of this overstrain cycle (Fig. 8). Information about this phenomenon is scarce and refers to conditions of total load reversal only.

The capacity of a structural material to sustain occasional overstrain without damage to its ultimate endurance limit is very important from a design point of view. According to the previously stated stipulation, the design live load should provide for service conditions of reasonably high frequency of occurrence, whereas less probable, and therefore less frequent, extreme loading conditions should be covered by the factor of safety. If the material is able to carry this occasional excess of extreme loads over the design load by its capacity to sustain occasional overstrain without damage to its ultimate endurance limit, this limit may be directly correlated with the design load without introducing any margin of safety that would otherwise be necessary to cover the fluctuations of the load intensity above the design value specified.

Resistance to "damage" by overstrain of structural materials should be made an urgent object of research. The results of such research will most certainly have some influence upon the manufacture of such materials, since it will reveal the relation of "damage sensitivity" and the general mechanical properties. Structural metals can have "damage lines" of different shapes but still have similar standard properties, such as static strength, elongation, and endurance limit. In Fig. 8 line a characterizes a material with a capacity to sustain frequent overstrains of moderate intensity, line b a variety of the same material with a capacity to sustain considerable overstrain if its frequency of occurrence is low, line c a variety with a remarkably high resistance against "damage" by frequent and high overstrain. The endurance limit as a function of the number of load repetitions is the same for all three varieties; but their performance will be different and will depend on the frequency of overstrain

[21] "Damage and Overstress in the Fatigue of Ferrous Materials," by H. W. Russel and W. A. Welcker, *Proceedings*, A.S.T.M., 1936, Pt. II, pp. 1118–1135.

[22] "Effect of Overstressing and Understressing," by J. B. Kommers, *ibid.*, 1938, Pt. II, pp. 249–268.

and its amplitudes. Every one of the three varieties of the material is suited to a particular character of load fluctuation.

Like all physical properties the resistance values of structural materials are constants in a statistical sense only; the level of control enforced in all stages of the manufacturing process determines the character of the distribution function. In Fig. 3 the distribution functions for the yield point and the tensile strength of the silicon steel manufactured for the Golden Gate Bridge have been drawn. The practical range of chance fluctuations reaches about 15% below the mean or about 12% below the modal value. Concrete is less uniform than steel; investigations[23,24] have shown maximum ranges of fluctuations of individual values of compressive strength of concrete manufactured on the site under normal control to be approximately 35% about the mean; this range is reduced to one half by control under laboratory conditions.

Fluctuations and Uncertainty in the Dimensions

The ranges of variation of the sectional resistance values can be derived from the tolerances of the linear dimensions. Since these tolerances do not generally exceed 2% to 3% the fluctuations of areas and section moduli are within the range of 4% to 6% about the mean.

Design as a process of prediction, however, is not concerned only with the initial state of the structure but also with its change in the future owing to deterioration and corrosion. These influences must be considered, therefore, in the computation of the initial safety factor.

A more detailed treatment of all influences is included in the original manuscript which has been placed on file for reference in the Engineering Societies Library in New York, N. Y.

Application of Methods Developed

The method of evaluating the appropriate safety factor will be illustrated and its practical application demonstrated by computing the working stresses to be used in the design of stringers and floor beams of highway bridges of low-alloy (silicon) steel.

In order to derive working stresses or safety factors it is necessary to establish a uniform basis of reference since both concepts have a definite meaning only in connection with a specified service load. The evaluation of this load must be the first step in any analysis of this kind. It requires the computation of the probabilities of occurrence of different groupings of pertinent load units with reference to the definition of an adequate design live load.

Under the assumption that one fourth of all vehicles are trucks or units of similar load intensity, and that only the heaviest types circulating at present are considered (see conclusion 2 under the heading "Live Load: Intensity and Distribution of Live Loads for Bridges"), the frequency of occurrence of trucks among a total number $n = t\,m$ of vehicles (in which t denotes the number of

[23] Discussion by C. E. Arnold of "Manufacturing Concrete of Uniform Quality," by William M. Hall, *Transactions*, ASCE, Vol. 96, 1932, pp. 1367–1371.

[24] "Betondruckfestigkeit," by D. Bendel, Rept. of Cong. for Reinforced Concrete, Liege, Belgium, 1930, p. 238.

traffic lanes and m the number of vehicles per lane) can be derived by the binomial law and approximated by the Gram-Charlier series. The frequency distributions for $n = 6$, 12, 24, and 96 vehicles, respectively, have been presented in Fig. 9. With the aid of Eqs. 23 and 25 and introducing $v = 11.5$ miles per hr as the "critical" speed of the design load, the design load intensities —including the dynamic effect $w_{l_o}(1 + I_o)$ pertaining to the respective modes

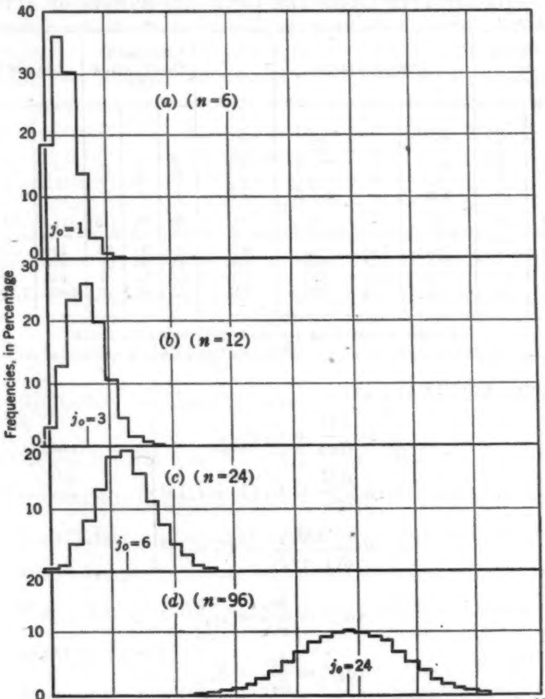

FIG. 9.—FREQUENCY DISTRIBUTION OF THE NUMBER OF TRUCKS COUNTED IN A TOTAL NUMBER n OF VEHICLES

of the distribution functions as well as the ranges of fluctuation of those functions pertaining to the probability $P_s < 0.001$ of values to fall outside this range—can be established as shown in Table 1.

For short spans the passing of a single truck per lane traveling at maximum speed may produce higher design load intensities than those given in Table 1. A direct comparison of load intensities would be misleading, however, because the difference in the ranges of fluctuation for the two types of loading results in different values of the safety factor to be applied.

Introducing the bending moment as a strain characteristic

$$s_a = M = C_1\, w_d\, l^2 + C_2\,(1 + I)\, w_l\, l^2 \qquad (27)$$

and as resistance characteristic the product of section modulus S and strength of the steel at failure s_f

$$s_r = S\, s_f \qquad (28)$$

TABLE 1.—DESIGN LIVE LOADS PER LANE AND RANGES OF FLUCTUATIONS[a]

Number of vehicles, n	Number of Trucks		Design Values				Maximum Fluctuation (%)			Loaded Length (Ft)			
	Modal	Maximum	w_{lo} (lb per ft)	$1 + I_{so}$	Col. 4 × Col. 5 (lb per ft)	Maximum w_l (lb per ft)	$+\Delta w_{lo}$	$+\Delta w_l$	$+\Delta(1+I)$	$t = 1$	$t = 2$	$t = 4$	$t = 6$
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)	(11)	(12)	(13)	(14)
6	2	5	585	1.48	865	925	25	58	28	240	120	60	40
12	3	8	510	1.33	680	830	25	63	22	480	240	120	80
24	6	14	510	1.24	630	770	25	51	17	940	470	235	117
96	24	36	505	1.12	565	745	25	47	10	3,800	1,900	950	475

[a] Ranges of fluctuation pertain to probability $P_s < 0.001$.

—and applying Eqs. 17 and 18:

$$\left.\begin{aligned} a_1 &= \frac{\partial M}{\partial w_d} = C_1\, l^2 \\ a_2 &= \frac{\partial M}{\partial w_l} = C_2\,(1 + I_o)\, l^2 \\ a_3 &= \frac{\partial M}{\partial(1 + I)} = C_2\, w_{lo}\, l^2 \end{aligned}\right\} \qquad (29)$$

and

$$\left.\begin{aligned} (a_1)' &= \frac{\partial s_r}{\partial S} = s_{fo} \\ (a_2)' &= \frac{\partial s_r}{\partial s_f} = S_o \end{aligned}\right\} \qquad (30)$$

Hence

$$s_a = s_{ao}\left(1 + \frac{\Delta s_a}{s_{ao}}\right) = [C_1\, w_{do}\, l^2 + C_2\,(1 + I_o)\, w_{lo}\, l^2]$$

$$\times \left[1 + \frac{1}{1 + \dfrac{C_1}{C_2}\dfrac{w_{do}}{w_{lo}\,(1 + I_o)}}\right]$$

$$\times \sqrt{\left(\frac{C_1}{C_2}\right)^2 \left(\frac{w_{do}}{w_{lo}}\right)^2 \left(\frac{\Delta w_d}{w_{do}}\right)^2 + \left(\frac{\Delta w_l}{w_{lo}}\right)^2 + \left[\frac{\Delta(1 + I)}{(1 + I_o)}\right]^2} \qquad (31)$$

and

$$s_r = s_{ro}\left(1 - \frac{\Delta s_r}{s_{ro}}\right) = S_o\, s_{fo}\left[1 - \sqrt{\left(\frac{\Delta S}{S_o}\right)^2 + \left(\frac{\Delta s_f}{s_{fo}}\right)}\right] \qquad (32)$$

For the freely supported short-span structural members considered (stringers and floor beams) the respective design load intensities are produced by one truck per lane traveling at a maximum speed of 50 miles per hr. The ratios $\frac{w_{do}}{w_{lo}}$ may be assumed to vary between 0.1 (for stringers) and 0.4 (for heavy floor beams). With such comparatively small effects of the dead load, the strain may be assumed to fluctuate between zero and a maximum value. The total number of strain cycles generally will reach, or even exceed, the two-million mark for bridges carrying main highways, the rate of strain induced by the rapidly moving load being in the vicinity of 0.3% per sec in structures of low-alloy steel. Since this rate exceeds considerably the intrinsic plastic flow rate of steel of about 0.05% per sec, failure will be brittle, and the structure's resistance will be a function of the ultimate tensile strength s_t of the material. For a load oscillating between zero and a maximum value, numbering a total of more than two million cycles, the actual strength of riveted structural parts (floor beams) is $s_{fo} = 0.4\, s_{to}$ and of plain members (stringers) is $s_{fo} = 0.45\, s_{to}$ (see Fig. 7).

Let: $\frac{\Delta w_l}{w_{lo}} = 0$ for one-lane and two-lane highways on which the design load is equal to the maximum load; $\frac{\Delta w_l}{w_{lo}} = 0.58$ for six-lane highways (see Table 1); $\frac{\Delta w_{do}}{w_{do}} = 0.1$ (in which, see Eq. 22, $w_{do} = 1.1\, \bar{w}_{do}$); $\frac{\Delta(1 + I)}{1 + I_e} = \frac{1.00}{(1 + I_e)\sqrt{n}}$ (see Eq. 26); $\frac{\Delta S_a}{S_e} = 0.06$; and $\frac{\Delta s_t}{s_{to}} = 0.12$ (see Fig. 3). For free supports $C_1 = C_2$. Inserting the foregoing values in Eqs. 5, 31, and 32, the ranges Δs_a and Δs_r, the safety factor ζ, and the allowable stresses $\frac{1}{\zeta} s_{fo}$ are found to be:

For stringers ($t = 1$)—

$\Delta s_a = +\,0.40\, s_{to}$; $\Delta s_r = -\,0.14\, s_{ro}$; $\zeta = 1.64$; allowable stress $s = 0.275\, s_{to}$

for floor beams ($t = 2$)—

$\Delta s_a = +\,0.32\, s_{to}$; $\Delta s_r = -\,0.14\, s_{ro}$; $\zeta = 1.54$; allowable stress $s = 0.260\, s_{to}$

for floor beams ($t = 6$)—

$\Delta s_a = +\,0.51\, s_{to}$; $\Delta s_r = -\,0.14\, s_{ro}$; $\zeta = 1.75$; allowable stress $s = 0.229\, s_{to}$.

The comparatively high value of the safety factor for six traffic lanes is due to the fact that for six vehicles the design load intensity is no longer represented by the maximum load intensity (see Fig. 9 for $n = 6$).

The data utilized in this example are not elaborate enough to enable one to evaluate the probability of failure pertaining to the foregoing safety factors. A rough estimate becomes possible, however, if the distribution functions of the constituents w_l and s_t are assumed to be representative of the frequency distributions of the resultant characteristics s_a and s_r. For the six-lane floor beam $P_s < 6\,(\frac{1}{4})^5\,(\frac{3}{4}) = 0.005$ and $P_r < 0.0001$. Therefore, the probability

of failure $P_f < 1/2{,}000{,}000$ as required for an expected number of load cycles which slightly exceeds 2,000,000.

In order to compare the foregoing with values specified in actual design a common base of reference is found in the "reduced" permissible stress s', which is the stress permissible under the action of dead load $\bar{w}_{do}$ and the static weight of the maximum live load w_l (max), if the specified safety of the design is to be maintained. Hence, for a uniformly distributed live load and freely supported span

$$s' = s \frac{\bar{w}_{do} + w_l\,(\max)}{w_{do} + (1 + I_o)\,w_{lo}} \qquad (33)$$

In the design of the Golden Gate Bridge for which the frequency distribution of the tensile strength s_t of silicon steel was established (Fig. 3), and the permissible stress specified for stringers and floor beams was 22,000 lb per sq in. to be applied with an impact increment of 50% of the live load for stringers and 25% for floor beams. For the latter, a reduction of 25% of the live load was intended to allow for the large number of traffic lanes ($n = 6$).[25] These stipulations lead to the following values for the reduced permissible stress: For stringers—$s' = 0.69 \times 22{,}000 = 15{,}000$ lb per sq in.; and for floor beams—$s' = 1.04 \times 22{,}000 = 23{,}000$ lb per sq in. The reduced permissible stresses resulting from the present analysis of the safety factor can be computed by introducing the mode of the frequency distribution (Fig. 3), $s_{to} = 87{,}000$ lb per sq in. Hence: For stringers—$s' = 0.44 \times 0.275 \times 87{,}000 = 10{,}500$ lb per sq in.; and for floor beams—$s' = 1.35 \times 0.229 \times 87{,}000 = 27{,}000$ lb per sq in.

Comparison of the foregoing values shows that even a complex design (such as that of the Golden Gate Bridge, which empirically provides for the different probabilities of occurrence of maximum load intensity in different structural parts) will not yield adequately balanced stresses and dimensions as long as the safety factor is being "selected" instead of computed by rational and objective methods. It appears that the permissible stress specified is too high for the stringers on Golden Gate Bridge, and unduly low for the comparatively long-span floor beams.

PART 3.—CONCLUSIONS

The safety factor is an objective value of correlation between actual strain and potential resistance that can be ascertained by the rational methods suggested in the paper. Loads, external conditions, and pertinent physical properties and phenomena are analyzed under the common aspect of their relation to the magnitude of the safety factor. This factor is intended to provide for relatively infrequent loading, and other conditions, whereas the design itself considers conditions of relatively frequent occurrence. The computation of the objective minimum safety factor and the consequent permissible stresses is in a balanced design of no less importance than the determination of the principal static characteristics.

[25] "The Golden Gate Bridge," Rept. of the Chf. Engr. to the Board of Directors of the Golden Gate Bridge and Highway Dist., Schwabacher-Frey, San Francisco, Calif., 1937, p. 81.

Since the safety factor, expressing the excess of possible, or potential, resistance over the computed strain to be provided in order to prevent failure with a reasonably high probability, derives its existence from the imperfection inherent in the performance of any human action and the uncertainty marking the results, as well as from the acknowledged ignorance about certain phenomena, and since it relates computed strain to actual resistance, it can refer to the design as an entity only and not to different features of it. Therefore, it can have only one value for a certain design. Individual safety factors for different influences, such as for dead load or for live load, separately, being inconsistent with the basic concept, can have no real meaning.

The current specifications and standards applying to design loads and secondary influences, as well as strength and permissible stresses, should be analyzed as to their correspondence to reality, and the objective conditions should be ascertained as a base for new and more adequate specifications. Conventional specifications seem too lenient as far as short-span structural members are concerned, and unnecessarily severe for structural members and structures of medium and long span. The use of adequately balanced permissible stresses in the different elements of a structure will solve, automatically, the problem of the occasional passage of exceptionally heavy loads, raised in connection with the transport of military equipment with very heavy axle concentrations.[26]

In spite of extensive experimental research concerning a great number of structural qualities, lack of adequate information about certain basic aspects of design calls for urgent attention and an effort to make up the deficiencies. Some of the most important effects, such as that of the rate of the induced strain, or the capacity of the material to sustain occasional overstress, have been almost neglected. The evidence applying to other phenomena and qualities which have actually been investigated has generally not been collected with regard to subsequent statistical interpretation, and therefore needs amplification.

By adopting the principle that neither design loads nor safety factors and permissible stresses should be specified arbitrarily, it will be possible not only to eliminate inadequate design, but frequently to achieve considerable economy. It will be possible, moreover, to determine correct safety factors and permissible stresses for unconventional structures or new structural forms and materials.

[26] *Civil Engineering*, February, 1941, p. 116.

DISCUSSION

F. H. FRANKLAND,[27] M. ASCE.—The structural designer is concerned with the solution of probability problems by the consideration of the various factors governing his design, such as safety, use characteristics, economy, future suitability, and durability. Although, in recent times, structural engineering has undergone changes at an accelerated pace, structural engineers have not generally kept pace with the rapid advance made in some other branches of engineering.

The author states, in the "Synopsis," that: "The word 'resistance' is a general term indicating 'strength' or capacity to resist failure." It is important that, in discussing safety factors, this use of the term "resistance" should receive general acceptance and understanding.

The safety of a design is not determined by the use of an average factor of safety but is governed by the safety factor at the weakest part. However, in most structural systems there is often a redistribution of stress, under load, throughout the system which makes the resulting safety factor greater than that of any one part:[28]

> "In practically all cases a structure designed by the use of conventional methods, with a high safety factor, will be less safe than one designed by the use of more refined methods and using a smaller safety factor. The conventional safety factor idea is that the safety factor for a particular design under given loading conditions is a constant coefficient; but actually the safety factor varies."

The skill of the designer is indicated, in part, by his understanding of the degree to which elasticity and plasticity influence the behavior of a structure because of geometrical displacements under load in the various parts and the consequent possible creation of multiaxial and other secondary stresses.

The author states (under the heading, "The Factor of Safety"):

> "With increasing perfection of design methods the element of 'ignorance' can be largely eliminated; but the element of 'uncertainty' is caused by circumstances that can be changed, to a certain extent, but can never be removed."

Nevertheless, little real betterment of design methods can be achieved by "refinements" in the application of mathematical theories unless it is accompanied by an intelligent understanding of the behavior of structures in use. Such refinements mean little when basic assumptions are wide of reality. It is of prime importance that engineers realize that there is but little excuse for the element of so-called ignorance and that the safety factor is a matter governed mainly by the degree of uncertainty. Generally accepted design methods too often neglect stress concentrations and the effects of fatigue and consider that materials possess perfectly elastic properties. It should be remembered that, for high-alloy structural steels, such as 18–8 stainless and nonferrous structural alloys like aluminum and magnesium, the elastic limit is indefinite

[27] Cons. Engr., New York, N. Y.

[28] "Modern Stress Theories," by A. V. Karpov, *Transactions*, ASCE, Vol. 102, 1937, p. 1207.

and the stress-strain curve is continuous. The general and exclusive use of the elastic theory in the design of structures is partly responsible for the lack of understanding among many engineers of the actual behavior of structural materials. The "aspect of practical application" which the author refers to in "Part 1.—General Principles: Introduction" should be clear in the mind of the designer at all times. As a consequence of the better understanding of the behavior of structures and structural materials, referred to by the author, some of the generally accepted underlying concepts of structural design are inadequate.

Recent investigations of stress distribution in structures under load clearly justify dissatisfaction with design methods which have hitherto been accepted as adequate. In this connection it would be well to study the paper "Theory of Elastic Stability Applied to Structural Design."[29]

An understanding of the theory of limit design will explain the capacity of a structural material to sustain occasional overstrain without damage to the ultimate endurance limit from the design point of view. The term "endurance limit" should not be confused with "fatigue strength." The endurance limit may be defined as the fatigue stress under complete stress reversal below which metal can withstand an infinitely large number of stress reversals without failure.

Any loaded structure will behave in a manner inconsistent with the elastic theory in that various parts and connections may be locally overstressed, sometimes beyond the local yield point of the material, thus causing plastic flow and a consequent redistribution of stress at the affected parts. The elastic theory is based on the assumption that the behavior of all parts of the structure is entirely elastic at all times when not loaded beyond the safe allowable design stresses. This assumption is obviously untrue as it ignores the element of uncertainty involved in differentials of stress in various parts of riveted, bolted, or welded construction, as well as conditions of locked-up stresses and local variations in the yield point of the material. These variations and constraints are "ironed out" by the application of service loads, and only then may a structure behave in accordance with the concepts of the elastic theory. However, should a structure be further loaded beyond this point of stress redistribution, the limit theory must be resorted to in order to care for actual conditions. In this connection consideration must be given to what Raymond J. Roark calls "damaging stress,"[30] which is:

> "* * * the least unit stress, of a given kind and for a given material and condition of service, that will render a member unfit for service before the end of its normal life. It may do this by producing excessive set, or by causing creep to occur at an excessive rate, or by causing fatigue cracking, excessive strain hardening, or rupture."

The designer should also recognize what may be called the factor of utilization, which is the ratio of the allowable stress to the ultimate strength. Where the stress is proportional to the load, this factor is the reciprocal of the safety factor. Designers in the aeronautical field use the term "margin of safety"

[29] "Theory of Elastic Stability Applied to Structural Design," by Leon S. Moisseiff and Frederick Lienhard, *Transactions*, ASCE, Vol. 106, 1941, p. 1052.

[30] "Formulas for Stress and Strain," by Raymond J. Roark, McGraw-Hill Book Co., Inc., New York and London, 2d Ed., 1943, p. 5.

to express the percentage by which the ultimate strength exceeds the design load.

Plasticity is a most valuable characteristic in any structural material when the material also possesses elasticity. If structural members did not have the ability to accommodate themselves to the redistribution of stress through this characteristic of plasticity, many bridges and buildings would not stand up no matter what numerical safety factor was used in their design by the elastic theory.

There is a distinct trend among structural engineers toward the evaluation of adjustments necessary to bring the idealized conditions embraced within the elastic theory into agreement with the realism of actual conditions as comprehended in the limit theory of design.

These comments are not offered in a spirit of criticism, but with the purpose of calling the attention of engineers to the desirability of understanding what is the true strength of a structure, and, above all, to the desirability of adopting a realistic approach to design problems.

ELLIOTT B. ROBERTS,[31] M. ASCE.—Although the validity of this paper is not questioned, it is nevertheless regrettable that the author failed to introduce a discussion of earthquake factors.

Earthquakes are frequent in certain well-recognized zones. What is not, perhaps, so generally recognized is that they may, and do, occur almost anywhere. No one could safely state that any place is perfectly free from the danger of a destructive earthquake. Evaluation of the risk in a specific location may introduce a delicate problem; it should never be ignored completely.

The subject of earthquake factors has been treated adequately by the American Standards Association,[32] and a more detailed treatment is contained in "Uniform Building Code."[33] The latter publication, of course, is the result of extensive experience gained by constructors in the most seismic areas of the United States. Experience in these areas is supported by extensive field observations and analysis of ground and building vibrations made by the United States Coast and Geodetic Survey.

A. G. PUGSLEY,[34] Assoc. M. ASCE.—The general question of structural safety is treated from the statistical standpoint by Mr. Freudenthal, and, by so doing, the author contributes to a cause that the writer has much at heart. The cause is the rationalization of current ideas and habits regarding factors of safety. In the aeronautical field, the very large numbers of aircraft involved in World War II have presented a unique opportunity to explore and apply statistical methods of approach. In this latter field it has been possible to collect much of the basic information required for such an approach—the magnitudes and variations of the loads experienced in war on a number of aeroplane structures of a given type during their life histories; the actual strengths of these structures as measured by mechanical tests representing conditions approximating the observed flight conditions; and the variation of these

[31] Lt. Comdr.; U. S. Coast and Geodetic Survey, Washington, D. C.

[32] "American Standard Building Code Requirements for Minimum Design Loads in Buildings and Other Structures," ASA—A58.1—1945, pp. 11 and 12.

[33] "Uniform Building Code," Pacific Building Officials Conference, Los Angeles, Calif., 1937.

[34] Prof. of Civ. Eng., Univ. of Bristol, Bristol, England.

strengths among structures built to the same plans. Admittedly, in many respects, even the data obtained in this relatively favored field have fallen short of what one would wish for, but a stage was reached in which the "ideal" situation visualized by the statistical approach—the correlation of loads and strengths on the one hand with recorded structural accident rates on the other—could at least be discussed in rough numerical terms.

In 1942 the writer made a very simple statement of this problem in statistical terms, intended to introduce to aircraft designers what was then a new and unfamiliar approach to the rationalization of strength factors.[35] The mathematical background of this approach, and the limitations of this simplified statement, were subsequently discussed by D. J. Bishop;[36] and the position has been admirably summed up in popular terms by W. Tye in 1944.[37]

In reading the Freudenthal paper, the writer appreciated the careful distinction made between "absolute" and "economic" safety, which lies at the root of any statistical approach. Whether all will agree that such a distinction is wise in relation to all types of civil engineering structures is open to doubt. Thus, although a statistical "philosophy" of strength was ultimately widely accepted in relation to the structures of military aircraft, it is already clear that a wider philosophy may be required to meet the needs of designers of civil aircraft. Operational and maintenance considerations in the design of civil aircraft, clothed perhaps in some economic garb, loom large compared with accident rates which, for the peace of the public mind, must be very small indeed. The simple basic aim that the writer proposed in 1942,[35] however well it fitted the military situation, may require some modification or amplification in other applications:

> "Let us start with the simple assumption that, in deciding upon the strength of an aeroplane structure, we are aiming primarily to ensure that the aeroplane shall be able to perform its duties efficiently without breaking. In practice, because of the importance of minimizing structure weight, an aeroplane cannot be made so strong as to be unbreakable, and structural failures occasionally occur under extreme conditions, such as may arise if a pilot attempts to manoeuver a large bomber too violently or if he makes a very bad landing. Structural accidents may also sometimes occur due to errors of design or workmanship or to the use of faulty material. It is natural to consider all such accidents in relation to the hours flown, and to express the history of structural failure among aeroplanes by the number of structural accidents arising in a given number of flying hours, i. e. by a structural accident 'rate.' Expressed in more precise terms, then, our basic aim is to learn how to choose aeroplane strength factors so that structural accident rates shall be as small as possible consistent with efficient production and operation."

Whatever changes may be required, however, every effort should be made to advance the process of rationalizing the engineer's position regarding the safety of structures of all types. The writer, therefore, heartily endorses the sentiments in the concluding paragraph of this paper:

[36] "Renewal of Aircraft," by D. J. Bishop, *Report and Memorandum No. 1907*, British Aeronautical Research Committee, 1942.

[37] "Factors of Safety—or of Habit?" by W. Tye, *Journal of the Royal Aeronautical Society*, Vol. XLVIII, No. 407, November, 1944, p. 487.

"By adopting the principle that neither design loads nor safety factors and permissible stresses should be specified arbitrarily, it will be possible not only to eliminate inadequate design, but frequently to achieve considerable economy. It will be possible, moreover, to determine correct safety factors and permissible stresses for unconventional structures or new structural forms and materials."

LYNN PERRY,[38] M. ASCE.—To those who have been using the word "strain" to signify the deformation and "stress" as the load per unit area, the rather nebulous new meanings that the author has used for these words is confusing. A great deal of time is required to grasp the proper understanding of the theory he has advanced. This would be unnecessary if the standard terminology had been rigidly adhered to.

The subject of "Factor of Safety" is always timely. Since it involves economy, each case should be studied and the factor fixed by personnel with sufficient vision and experience to afford the proper balance—giving weight to both the physical and the economic considerations in the particular structure.

In many countries including all Europe, the cost of materials is so high and the labor rates are so low, compared with those prevailing in the Americas, that the economic feature involved in fixing a factor of safety is entirely different. An additional feature, at least up to the end of World War II, is the remarkably stable society of even the most progressive European countries. Old structures have been used for the same purpose, with little change in the loading, for generations. Old locomotives that resemble museum pieces are still being used because it is more economical to maintain them and keep them in service than to meet the requirements that would be necessary for larger and heavier rolling equipment. Some highway bridges were built in Europe during the interim between World War I and World War II with a much more slender factor of safety than most American engineers would feel warranted in adopting. Because of this fundamental economic phase, engineers in the Americas are accustomed to using somewhat more material than engineers abroad. For economy, also, standard sections are used—frequently heavier than necessary but cheaper than an exact section, rolled to specified dimensions.

What the author has termed "uncertainty" in contradistinction to "ignorance" is always in the mind of the experienced designing engineer. There have been so many failures of well-designed structures due to overloading that the designer is prone to imagine the probability of heavier locomotives, trucks, and trailers, larger impact on grandstands, heavier floor loadings, and more violent wind storms than has been provided for in past design. The writer has calibrated and posted loadings for many old highway bridges. Most, if not all, of these were well designed with an adequate factor of safety for any conceivable load that could possibly cross the bridge—that is, from the viewpoint of the designer in 1890. When a loaded 10-ton truck crashes into an end post or fascia girder of such a bridge, it is simply "too bad" and the computation of a factor of safety based on the probable maximum load degenerates to an academic discussion.

With Eqs. 6a and 6b, the author computes the maximum strain and the lowest value of the structure's resistance using equations containing arbitrary constants. In principle this is no different from current practice.

[38] Designing Engr., Dept. of Water and Sewers, Miami, Fla.

In Eq. 22, the author suggests that the computed dead load be increased 10%. This may be a constructive suggestion. Concrete and curtain walls seldom weigh 10% more than the estimate. The main steel members do not exceed the estimate by any such amount. In some cases, a series of complex details might be heavier than the preliminary estimate but a 10% leeway would certainly be adequate. Failures inspected by the writer have not been caused by the weakness of details.

Under the heading, "Part 2.—Analysis of Particular Influences: Live Load," the author seems to have missed the primary purpose of the specifications: To make every person concerned with the design thoroughly understand that the final design will be safe under the loadings specified. Such specified loadings do take into consideration the immediate requirements and the estimated future requirements in so far as it is possible to estimate. Steel is sold by the ton and concrete by the cubic yard. It is obvious that money can be saved in either case by decreasing the load or by increasing the allowable unit stresses. After considering all the factors involved, the owner specifies the loadings and allowable unit stresses and makes an effort toward economy by securing the best grade of material and workmanship obtainable at the time and place.

Considerable information is available about axle concentration. Highway bridges in the United States are designed for safe peacetime traffic. When bridges designed for such traffic become subjected to military loadings, the factors of safety disappear. Military traffic, however, can be rigidly regulated: Speed can be reduced to a creep; traffic can be reduced to one way; only one vehicle can be permitted on a span; and unbelievably heavy loads can be moved over a bridge without failure. It is the firm conviction of the present generation of designers that structures will be safe for any load to which they are likely to be subjected during the expected and estimated useful life of the structure. This was also the conviction of the designers of the mauve decade; but any person who imagines that a very old firm will not purchase larger elevator cable and move the largest and heaviest safe from the basement to an upper story and roll it across a floor without any attempt to spread the load is naive indeed. The effect of this procedure might be included as an element of "uncertainty." Police powers can prevent the overloading of structures in a thoroughly regimented military or bureaucratic society, and the uncertain and evasive human element can be eliminated. Under such control, the factor of safety could be materially reduced, with resulting economies.

The change in temperature affecting a structure cannot be greatly in error. A feature that has been noted recently, and on which investigations are still in progress, is the thermal coefficient of expansion of concrete. Undetermined qualities inherent in the coarse aggregate appear to influence this constant as much as $\pm$ 50% from the time-worn value of 0.0000065. Further research in this field will be of definite value in the construction of highways and curbs and may even influence specifications for structures.

Structures, designed in many places for a wind load of 30 lb per sq in., have withstood storms for years and have given satisfactory service. For the higher buildings in Miami, Fla., this load has been increased 50%. Observations over a longer period of time will be necessary before a reasonably safe estimate for this loading can be made. Unfortunately, maximum wind velocities are

reported as the maximum recorded values, sustained continuously over a period of 5 min. Wind comes in gusts and the dynamic effect of the highest velocity observed would lead to a more justified design. In some of the most severe storms since accurate anemometers have been available, the instruments either were not calibrated sufficiently high to register the maximum velocities or were destroyed together with the structures in which they were installed. In the Aleutian Islands, where high wind velocities prevail, the wind is frequently accompanied by fine snow which seals the orifices of the pitot-type anemometer or clogs the vanes of the revolving type, thus invalidating or impairing the accuracy and reliability of the readings. Nevertheless, a few reliable records of wind velocities of more than 150 miles per hr are available, and the factor of safety under such exposures has not been regarded as wasteful.

Steel has been referred to as "the only elastic structural material." For many years, steel developing a strength, to the yield point, of 30,000 lb per sq in. in tension was standard. Almost uniformly, engineers used a working stress of 16,000 lb per sq in. in tension for such material—a factor of safety of 1.87. Some years ago, it was learned that a very small additional amount of manganese would raise the elastic limit to 40,000 lb per sq in. or more without materially affecting other physical values. Thus, the new product would carry 33% more load safely, and the cost of the steel for a structure would be reduced correspondingly. However, it was years before the profession as a whole was willing to raise the value of the working stress to 18,000 lb per sq in. Later this value was recognized and increased to 20,000 lb per sq in. In some current specifications the use of 22,000 lb per sq in. is allowed, indicating a factor of safety of 1.82; and, as the tests actually show from 41,000 lb per sq in. to 42,000 lb per sq in., the factor of safety may be even higher. The author has computed factors of safety under an assumed set of conditions and has reached values of from 1.54 to 1.75, resulting in a fair correlation.

It is doubtful whether the manufacturers of building materials have obtained final perfection in their effort to produce a homogeneous structural material economically. Structural steel test specimens cut from the top of the ingot, after rolling, usually develop about 4,000 lb per sq in. more stress in tension than similar specimens cut from the bottom of the ingot. Further research may eliminate this differential entirely; but, for the time being, the lower value will have to be used for design. Too frequently, no value is given. It is usual to specify that the test specimens shall be cut with their longest dimension in the direction of the rolling for uniformity and because specimens, in tension, usually develop a higher unit strength when pulled at right angles to the direction of rolling. However, steel details are designed with little reference to the direction of rolling and any excess strength inherent in the material increases the factor of safety.

A factor of safety, to be adequate, must take care of the inherent lack of homogeneity in the material, some items on which more accurate measurements will be available in the future, local consideration, and the human element.

"High rigidity" and "almost perfect elasticity" of subsoil should be the subjects for other discussions.

Nomer Gray,[39] Assoc. M. ASCE.—It is inevitable that the attention of structural engineers will be directed with increasing frequency to a re-examination of the entire subject of factors or margins of safety. When consideration is given to the profound part played by this factor in the design of structures, the wonder is that it has not been continuously the subject of discussion. Certainly the device of using "working stresses," although perfectly justifiable on the ground of expediency, has diverted attention from this most important element of design. However, the true reason is the inherent complexity of the problem—a complexity which becomes more evident from a study of this paper.

Studies leading to refinements in the methods of stress calculation have persisted at a high level of activity for years, and devising new variations on old and tried methods of stress calculation can be classed as an occupational ailment. Although it leaves much to be desired, current knowledge of materials has been enhanced greatly since the 1920's, thus materially reducing this element of "uncertainty" in design. These two statements do not necessarily sponsor higher working stresses, but rather question the validity of a uniform factor of safety for a great variety of members in a structure regardless of function.

An extreme example may be found in the selection of the required sectional area for the main cables of suspension bridges. The three "uncertainties" requiring the use of a safety factor may be simply stated as: (1) Accuracy of method of stress calculation; (2) uniformity of material; and (3) present and future validity of the design loading.

In regard to uncertainty (1), few members in the entire field of structures inspire as little doubt as to the correctness of the computed stress. With respect to uncertainty (2), the material used in the cables of large bridges is remarkably uniform. Taking the wire used in the George Washington Bridge cables as an example, the variation in yield point is recorded[40] as from 170 kips per sq in. to 189 kips per sq in.—a spread of 10%; and the variation in ultimate strength is from 225 kips per sq in. to 240 kips per sq in.—only 6.4%. These are extremes. Actually, the separate values cluster closely around the mean (the standard deviation is small).

It is in respect to uncertainty (3), however, that this member (the cable) is almost unique. For long-span highway bridges, the ratio of dead to live load is frequently 5 to 1. There is little uncertainty about the design dead load and an excess of 10% may be regarded as extreme if the weight is calculated with moderate care. Any major increase in the dead load arising from alterations made during the life of the structure is certain to occur only after an analysis, and the justification of the increase can be decided at that time. There is very little uncertainty regarding the dead load.

An increase of 100% in the live load will only produce an approximate 17% increase in the cable stress; and such an increase could not take place without adequate warning, for the stiffening system would be seriously overstressed (and perhaps fail) before this large increase in live load could occur.

[39] Civ. Engr., Dept. of Public Works, City of New York, New York, N. Y.

[40] "George Washington Bridge: Materials and Fabrication of Steel Structure," by Herbert J. Baker, *Transactions*, ASCE, Vol. 97, 1933, p. 366, Table 9.

In spite of the uniquely certain character of material and stress in the cables, however, the working stress is commonly set at 80 kips per sq in. This gives a factor of safety of approximately 2.1 based upon the least value of yield point and 2.8 if based upon ultimate strength; and, as the cable wire does not have a pronounced yield point, the latter value is more significant. In the light of the foregoing, some decrease in the factor of safety appears entirely justifiable.

In view of the firmly established and completely accepted meaning associated with the word "strain," its use in a different sense by the author is unfortunate.

Throughout the paper the use of the technique and nomenclature of the mathematics of statistics is evident. The statistical approach alone cannot give the answer, for the determination of a factor of safety involves questions of a philosophical nature. Statistics can present the facts upon which a judgment may be made, however. The author is to be congratulated for having so fully developed the statistical approach to this inherently complex and difficult problem.

I. M. Nelidov,[41] M. ASCE.—A very erudite and comprehensive treatise on the safety of structures and on the factor of safety in particular has been presented by the author. His definition of this factor is based on the theory of chance and implies a statistical meaning of the safety factor.

In Eq. 2 the factor of safety is defined as the ratio of the minimum resistance to the maximum strain. The terms maximum strain and minimum resistance represent average value plus or minus the maximum range of fluctuations. Although the validity of this statement can scarcely be disputed, another aspect seems to affect the definition of the factor of safety.

Suppose that the resistance is known to such a degree that the probability of its correct value is unity; suppose also that the same assumption is true of the applied load. Then, taking the simplest case of a cable composed of 100 straight wires and subject to tensile force, by definition, the factor of safety $\zeta = \frac{s_{r0}}{s_{a0}}$.

Since each wire is taut to the same degree, the factor of safety of a single wire will be also the factor of safety for the entire cable. On the other hand, consider the same cable under bending. Then the stress in each individual wire will vary according to a linear, or some other, law.

If both the resistance and the strain are known as accurately as in the preceding case, the now variable factor of safety of an individual wire will be that previously expressed. However, the factor of safety of the entire cable will have some other value. Since the summation of all the individual factors of safety does not have any practical application, the next usable value will be the average of the individual factors of safety taken for the entire cross section of the cable. This condition will exist in a majority of cases of structural or mechanical engineering and will be especially true for structures of large dimensions with wide variations in stresses. Good examples of the latter case are gravity dams in which the stresses of any one of the sections vary not only in magnitude but also in sign.

[41] Civ. and Structural Engr., El Cerrito, Calif.

Therefore, the definition of the factor of safety should also include the degree of variation, from the average, of strains within the structure. There are also other qualifying factors pertaining to the factor of safety: (1) The necessity of analogy between the type of the strain and that of the resistance—pure shear, pure tension, combined stress, availability of lateral support, etc.; and (2) the statement of the limit against which the factor of safety is judged.

Thus, for a certain structure, elastic limit may be a criterion since plastic deformations may be not permissible; or, in another case, the ultimate strength may be a criterion, if plastic deformations are permissible. In still other cases, the deflection limit may or may not be a criterion, depending on the functional purpose of the structures. In addition, stability (such as sliding or overturning) may become a criterion.

In all these and numerous other cases, not noted herein, there will be individual and average over-all factors of safety. It is the opinion of the writer that an average over-all factor of safety should be used for cases of variable stresses in which the values of both resistance and strains are known to such a degree that they may be taken as correct values, with deviations being considered below the general precision of calculations. In concluding, the writer wishes to congratulate the author on presenting such a scientific treatment of this widely interpreted subject.

M. Hirschthal,[42] M. ASCE.—Publication of this paper is a laudable attempt to effect economies in design by reducing the "uncertainties," thus effecting a saving in the use of materials of construction by designing for the minimum required for safety. The author's thesis is the reduction of uncertainties, both in the strength of materials and external forces, by the application of the theory of probabilities to each of the factors entering into the design of a structure, both external and internal. The profession is certainly indebted to him for the thorough treatment of the subject and the painstaking analysis of the factors involved.

All engineers are agreed that the method now being used to obtain safety with a "factor" applied to the ultimate strength or elastic limit of a material is wasteful to some extent; but they have not yet found a satisfactory substitute, and the writer fears that the present paper will not provide the "perfect answer" even with complete quality control of all materials of construetion. It is to be feared that a "crystal ball" would be required to look into the future for assurance that designers were making proper provision for future conditions, such as loadings and action of materials under long time loading and reversal of stress, despite the fact that marked progress has been made in the latter field.

Consider, for example, the case of railroad structures: At the turn of the century bridges carrying railroad traffic were being designed for class E40, or class E45, Cooper engine loads, and in a few cases for class E50 loads; yet in 1935 the standard American Railway Engineering Association design loading was set at E72. These loadings are now being exceeded on some of the railroads of the United States. In addition, the increase in locomotive tender loadings has been even more marked, so that 63,000-lb axle loads for tenders as compared with the 26,000-lb axle load in the class E40 loading are not at all un-

[42] Concrete Engr., D. L. & W. R. R. Hoboken, N. J.

usual. Cars of 40-ton capacity of 40 years ago, are supplanted by cars up to 100 tons (and more) capacity.

Inasmuch as the life of a steel structure is set (by the Interstate Commerce Commission) at 60 years, and concrete structures have been accorded a life of 100 years, it is apparent that well within the life of the structure there has been an increase of 80% from E40 to E72 in loads on the driving axles and of 142% (from 26,000 lb to 63,000 lb) in engine tender loads over those of the original design. Therefore, it seems advisable to proceed slowly in making radical changes in the method of design based on safety factors since, had the structures of 1900 been designed by the proposed method, they would have been recommended for retirement before this.

Although it is not recommended that engineers design for such a contingency, there is still a feeling of satisfaction that the impact of the bomber that struck the tower of the Empire State Building in New York, N. Y., did not result in its demolition. Moreover, one never knows when a "tremor" or more severe earthquake will strike a locality never before struck, as has been declared possible by experts.

Various other methods of applying different factors of safety to dead loads and live loads have been proposed on the basis of the fact that there is very little likelihood of a major variation in the dead load of a structure (both A. J. Boase and Shortridge Hardesty,[43,44] Members, ASCE, made such proposals in connection with wartime conservation of materials), but as a matter of fact railroad bridges were designed under this theory and the practice was discarded. (Open-floor bridges have been provided with solid ballasted decks within their serviceable life.) Another factor in this connection is the variation of the ratio of live load to dead load within the same structure. Consider the case of slab beam-girder construction: The live load is a far greater proportion of the total load of the slab than is the load on the beam; the girder has a still smaller proportionate live load than the beam; and so on to the column or pier. A similar condition obtains in the case of an arch bridge with open spandrel construction where the live load on the arch ring is a much smaller proportion of the total load than is the load on the spandrel arches (or floor slab) or the load of the piers or columns that transmit the loads to the arch ring.

The theory of probabilities will give satisfactory results when determining maximum design factors for a condition of known loads or a combination of loads. However, in the case of railroad structures particularly, the factors of safety must also include allowances for an anticipated increase of loads; and the foregoing example is not encouraging.

Another complication arises in considering resistance or internal stresses. Recent research on the subject has revealed that "fatigue" influences a riveted or welded connection to a different extent than it does the main member, and that it varies with different types of connections. Nevertheless, designers are not yet in a position to assign quantitative results to these tests.

Attempts have been made to take account of plastic flow in concrete for long-time application of loads, but these attempts have been sporadic and

[43] "Saving Reinforcing Steel By Rationalizing Safety Factors," by A. J. Boase, *Engineering News-Record*, May 7, 1942, p. 81.

[44] "Steel Bridge Design to Conserve Material," by Shortridge Hardesty, *Civil Engineering*, August, 1942, p. 431.

without general acceptance. In addition, reinforced concrete is looked upon as two distinct materials of construction: One with the ultimate strength and elastic limit at the same point of the stress-strain relationship, the other with a distinct elastic limit somewhere between one half to two thirds of the ultimate strength. Moreover, the modulus of elasticity of concrete varies with age. Nevertheless, in observations of tests of reinforced concrete members the action is somewhere between that of each component material. Deflections of reinforced concrete beams rarely reach the values obtained theoretically from the conditions of loading assumed. Refinement in the analysis of redundant (or rigid frame) structures will not necessarily result in a more accurate solution when the assumptions contain inaccuracies to degrees far from minute. All theories, after all, are based on assumptions, whether applying to flexure, elasticity, applications to reinforced concrete, or to suspension bridges.

The answer to all this is research, and more research, to provide a firm basis for the theoretical formula that will eventually solve the problem of safety, combined with economy.

Alfred M. Freudenthal,[45] Assoc. M. ASCE.—Discussers of this paper have been handicapped by the brevity of the published version, which is a wartime, paper-saving condensation of a considerably longer manuscript, that has been filed for reference in the Engineering Societies Library in New York, N. Y. Part 2, dealing with " Analysis of Particular Influences" has been cut most severely, whereas not much condensation was possible in Part 1, the general and mathematical treatment. The result has been a slight distortion of perspective by the emphasis on the statistical and mathematical aspects of the problem rather than on the engineering aspects.

The impression appears to have been created that the writer had tried to put forward the claim that the theory of probability and statistical methods could be expected to provide the "perfect answer" to a problem as complex as that of the safety of structures. Actually, the purpose of the paper was to draw attention to the fact that, by the application of the theory of probability (probably the most efficient tool of modern scientific thought) the concept of safety can be rationalized, and to develop a method for the evaluation of the minimum safety factor on the basis of the available objective evidence instead of the usual procedure of arbitrary selection. Not only is it evident that the successful application of the method depends on the extent and reliability of the evidence, but that a certain "residue" of unknown and subjective factors will always be present, requiring appraisal on a level beyond that of statistical inference and prediction from the objective analysis of recorded past experience. That rationally unpredictable "residue" can be isolated by a rational analysis of all statistically predictable influences. Reliable data for this analysis, however, can only be obtained by following Mr. Hirschthal's call for "research and more research."

In his thoughtful comments, Mr. Frankland has raised the important point of the effect on the safety of structures of the distribution of elastic stresses through inelastic behavior. There is no doubt that "some of the generally accepted underlying concepts of structural design are inadequate." It is really

[45] Lecturer in Bridge Eng., Hebrew Inst. of Tech., Haifa, Palestine.

paradoxical that one's ability to analyze structures should depend on the assumption that structures are perfectly elastic, whereas the only real safeguard insuring satisfactory performance in service is the extent to which structures are inelastic. This inelastic behavior, by producing a certain redistribution of stresses, necessarily affects the safety. However, by devising an appropriate "mechanism of resistance" and establishing its range of uncertainty, that effect can easily be considered in the evaluation of the safety factor.

It is too frequently forgotten, however, that the resistance mechanism essentially depends on the rate of application of stress. This is shown by the variation of the stress-deformation diagrams of concrete (Fig. 10(*a*)) and of steel

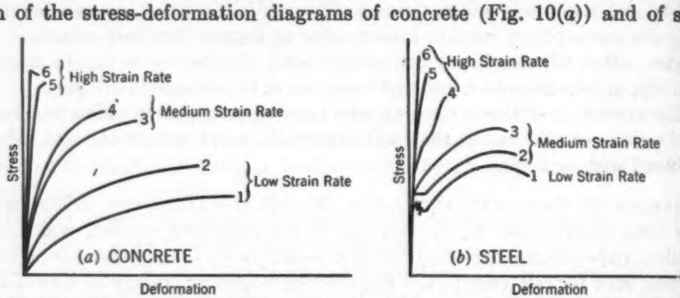

FIG. 10.—INFLUENCE OF THE RATE OF DEFORMATION ON DEFORMABILITY AND STRENGTH

(Fig. 10(*b*)). The structural member or connection in a steel frame which accommodates itself to slowly applied overstress by plastic redistribution of elastic peak stresses may fail without redistribution by cracking in a brittle manner if the same stresses are applied rapidly. This fact alone would contradict Mr. Frankland's assumption that "* * * the theory of limit design will explain the capacity of a structural material to sustain occasional overstrain without damage to the ultimate endurance limit * * *." This theory which, under the name of "Classical Theory of Plasticity"[46] has been studied very extensively in prewar Europe since the late 1920's, is certainly not applicable to conditions of repeated, rapidly moving loads which are implied in the term "endurance limit"; it has been applied, in general, to structures subjected to steady or to slowly moving loads only. However, even for this type of load values of the resistance or the carrying capacity are obtained which might be considered theoretical extremes never attainable in practice. The real values should be somewhere between that extreme and the minimum value, defined by the state of elastic stress immediately preceding the occurrence of the first plastic strain in the most highly stressed section. Such a concept is borne out by the results of experimental investigations between 1930 and 1936[47] which have led to the replacement of the rather crude "classical" concept of plastic redistribution of stress by the so-called "New Theory of Plasticity."[48]

According to the classical theory of plasticity, the upper resistance limit of a steel section in simple bending is defined by a fully plastic rectangular stress

[46] *Preliminary and Final Reports*, 2d Cong. of the International Assn. for Bridge and Structural Eng., Berlin, 1936, question I.

[47] "Test Results, Their Interpretation and Application," by H. Meier-Leibnitz, *Preliminary Report*, 2d Cong. of the International Assn. for Bridge and Structural Eng., Berlin, 1936, pp. 103–137.

[48] "Fundamental Principles of the Theory of Plasticity," by I. Fritsche, *ibid.*, pp. 15–41; and "Suggestions," question I, pp. 933–934.

distribution. The lower limit is reached when the extreme fiber stress of the triangular (elastic) stress distribution attains the yield limit s_y. Since the scarcity of the available experimental evidence does not justify a statistical interpretation of the results, this is an example of the midpoint value between known extremes, being the most reasonable tentative assumption for the design value; and this value is subject to fluctuations within the range delimited by the extremes. Let S denote the elastic section modulus; T, the plastic section modulus (which is the sum of the static moments of the section elements about the neutral axis); the design value of the resisting moment can be expressed as:

$$\bar{M}_R = \tfrac{1}{2} S\, s_y\, (1 + T/S) = \tfrac{1}{2} \bar{M}_{RO}\, (1 + T/S) \qquad (34)$$

Eq. 34 is subject to fluctuations within a range of $\pm [(T - S)/(T + S)]$.

As the resisting moment of an individual section is subject to chance fluctuations within the foregoing range, the range of fluctuations of the carrying capacity of an n-fold statically indeterminate girder, being a function of the resisting moments of its $n + 1$ critical sections, increases with an increasing number of such sections.

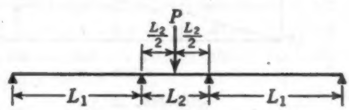

FIG. 11

As an example, consider the continuous beam shown in Fig. 11 under the loading conditions indicated. The capacity load, P_{El}, under the conventional assumptions of the elastic theory can be expressed by

$$P_{El} = \frac{4\, S_m\, s_y}{L_2\,(1 - \alpha)} \qquad (35)$$

in which S_m denotes the section modulus at the point of load application and

$$\alpha = \frac{3\, L_2}{4\, L_1 + 6\, L_2} \qquad (36)$$

For a freely supported central span, $L_1 = \infty$ and $\alpha = 0$ and the capacity load,

$$P_o = \frac{4\, S_m\, s_y}{L_2} \qquad (37)$$

The ratio—

$$\frac{P_{El}}{P_o} = \frac{1}{1 - \alpha} \qquad (38)$$

—varies between 1.0 for the freely supported central span and 2.0 for a central span with perfectly fixed ends defined by $L_1 = 0$ and $\alpha = 0.5$.

According to the theory of limit design, the capacity load, P_{LD}, of the structure is reached with the formation of three (that is, $n + 1$) plastic hinges over the supports and at the midspan of the central span. Therefore, it is independent of α and can be expressed by

$$P_{LD} = \frac{4\,(T_m + T_s)\, s_y}{L_2} \qquad (39)$$

in which T_m and T_s denote the plastic section modulus at the midspan of the central span and over the supports, respectively. For a girder with constant sections, $T_m = T_s = T$:

$$P_{LD} = \frac{8\, s_y\, T}{L_2} \qquad (40a)$$

and

$$\frac{P_{LD}}{P_e} = \frac{2\,T}{S} \qquad \text{(40b)}$$

Under the assumption that the most probable value $\bar{P}$ of the capacity load is the mean of the elastic and the limit-design values:

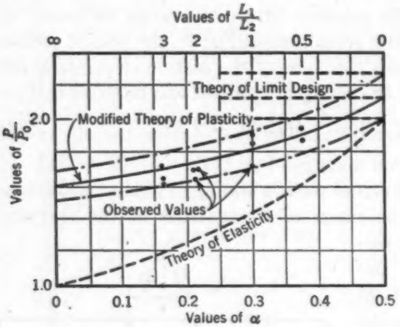

Fig. 12

$$\bar{P} = \frac{2\,\bar{M}_R}{L_2} \times \frac{3 - 2\,\alpha}{1 - \alpha} \qquad \text{(41a)}$$

and

$$\frac{\bar{P}}{P_e} = \frac{1}{4}\left(1 + \frac{T}{S}\right)\frac{3 - 2\,\alpha}{1 - \alpha} \qquad \text{(41b)}$$

The mechanism of resistance of the girder defined by the "design" load $\bar{P}$ is subject to fluctuations between the extremes within a specific range of $\pm \frac{1 - 2\,\alpha}{3 - 2\,\alpha}$, as well as to fluctuations due to the uncertainty in the individual resistance mechanism of every one of the three critical sections. Hence, the capacity load is:

$$P = \bar{P}\left[1 \pm \sqrt{\left(\frac{1 - 2\,\alpha}{3 - 2\,\alpha}\right)^2 + 3\left(\frac{T - S}{T + S}\right)^2}\,\right] \qquad \text{(42)}$$

Comparison of Eq. 42 with the results of tests performed by F. Stuessi and G. F. Kollbrunner[49] and H. Meier-Leibnitz[50] has been presented in Fig. 12; the experimental values are scattered within a comparatively narrow range about the expected or "design" value $\bar{P}$ computed with the aid of Eq. 41a, the actual range of variation being much narrower than the range between the extremes as expressed by Eq. 42.

The foregoing example illustrates that a design based on the assumption of perfect elasticity is frequently inadequate; it also shows that a design based on a somewhat crude concept of plastic behavior, as expressed by the classical theory of limit design, may be less adequate. However, the real, rather complex behavior can be fairly well approximated by a simple assumption. This serves to support the writer's assertion (see heading, "Part II. Analysis of Particular Influences: Uncertainty and Inaccuracy of the Mechanism of Resistance") that

> "* * * it is hardly possible to conceive such a mechanism [of resistance] that will effectively reproduce the actual phenomenon and which is at the same time simple enough to be suitable for practical design. Every devised mechanism, therefore, is fictitious to a certain degree * * * Its suitability is to be judged by the simplicity of the concept, by the closeness with which

[49] "Beitrag zum Traglastverfahren," by F. Stuessi and G. F. Kollbrunner, *Bautechnik*, Berlin, 1935, Vol. 13, p. 264.

[50] "Relations in Girders Continuous Over Three Spans," by H. Meier-Leibnitz, *Final Report*, 2d Cong. of the International Assn. for Bridge and Structural Eng., Berlin, 1936, p. 70.

experimental results are reproduced, and by the narrowness of the range of dispersion of such results about the 'theoretical' course."

The writer regrets (certainly not less than Lt.-Comdr. Elliott B. Roberts) the lack of a discussion of earthquake factors, and he agrees fully with the assertion that although "Evaluation of the [earthquake] risk in a specific location may introduce a delicate problem; it should never be ignored completely." A short comment on the principal aspects of this problem is included in the complete manuscript.

Although it is true that "no one could safely state that any place is perfectly free from the danger of destructive earthquakes," the frequency of occurrence of seismic forces at one location is hardly of an order of magnitude comparable to that of the occurrence of primary design loads (service loads or impact) and of secondary effects (wind or temperature changes). Even in the principal seismic areas of the world, earthquake shocks occur rather less frequently than maximum loads or extreme wind velocities. Therefore, their effects should reasonably be considered on the same level as those extreme conditions—that is, as a source of stress fluctuation of appropriate range about the stresses produced in the structure by the design values of primary loads and secondary effects. Because of the relative infrequency of earthquakes of any intensity there is hardly any justification for introducing even a small seismic acceleration force as "design value." There is even less justification for considering the stresses produced in the structure by acceleration forces which result from severe shocks (from 0.10 g to 0.15 g) similar in character to the stresses produced by the design service loads, and to compare them with the conventional values of permissible stresses.

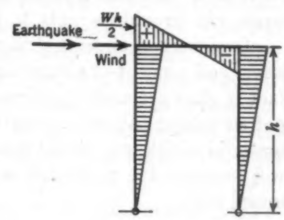

FIG. 13

A procedure recommended for use in the design for seismic forces can be illustrated by reference to the portal frame shown in Fig. 13, which represents the pier of a viaduct. Both the wind forces on the structure and the seismic acceleration force acting at its center of gravity are transmitted into the frame at its top corner. If it is assumed that (a) the extreme wind force P_w exceeds the "design" force W_o by 100%, (b) the maximum seismic force P_E is of the order of magnitude of the design wind force, and (c) the maximum range of fluctuations in the resistance value s_r is $\Delta s_r = 0.2\, s_{ro}$, then the corners of the portal bracing strut should be proportioned for the bending moment $M = \frac{1}{2} W_o h$ with a safety factor (see Eqs. 5 and 18):

$$\zeta = \frac{1 + \sqrt{\left(\frac{\Delta W}{W_o}\right)^2 + \left(\frac{P_E}{W_o}\right)^2}}{1 - \frac{\Delta s_r}{s_{ro}}} = \frac{1 + \sqrt{1 + 1}}{0.8} \cong 3 \ldots\ldots (43)$$

Eq. 43 provides for the stresses occasionally produced by seismic forces of the assumed magnitude. If earthquake effects were not considered in the design, the strut would be proportioned for the same bending moment but with a

safety factor:

$$\zeta = \frac{1 + \dfrac{\Delta W}{W_e}}{1 - \dfrac{\Delta s_r}{s_{r0}}} \qquad \text{.........................(44)}$$

From which $\zeta = \dfrac{1+1}{0.8} = 2.5$. For the strut under consideration a 17% reduction in the permissible stress, therefore, would be sufficient to provide for the effects of an earthquake force of the magnitude of the design-wind force. In this example, the absence of vertical loads tends to intensify the effect of the seismic forces.

The conventional procedure of earthquake design—in which the effects of horizontal acceleration forces ($= 0.1\,g$) are simply added to those of vertical loads and of secondary influences—undoubtedly provides an excessive safety reserve. Nevertheless, the acceleration to be used in the proposed procedure may possibly have to exceed $0.10\,g$ since it should reproduce extreme earthquake effects. Only very careful and extensive statistically interpretable observations, and analysis of seismic vibrations both of the ground and of structures, can provide a reply to this last question.

Designers of aircraft structures operate with the aid of a considerably more advanced concept of safety than is generally applied in civil engineering. This fact is shown clearly by Professor Pugsley's stimulating comments; and it is not surprising, since in aircraft design any reduction in the weight of structural material which may result from an advanced approach to the problem of safety will improve the performance of the aircraft and effect a direct saving in the initial cost.

Efficiency and economy are of such immediate concern to the air transport industry as to justify unusually large appropriations for research, particularly in wartime. The principal object of such research must be to evaluate the cumulative fatigue effects of repeated stress cycles of varying amplitude, in relation to the capacity of the material to sustain "damage by overstrain" (see heading, "Part 2. Analysis of Particular Influences: Uncertainty and Variation of Resistance Limits of Structural Materials"). In a number of excellent papers Professor Pugsley[51,52] and others have analyzed this difficult problem thoroughly and have presented important results. It appears, however, that even in the aeronautical field the results from experiment and observation are rather erratic, the correlation between the principal factors being far from satisfactory. What is probably needed is not only research on a large scale, but an entirely new approach to the problem of fatigue. The writer has attempted to provide such an approach[53] by establishing the statistical character of fatigue as an expression, on a macroscopic scale, of the progressive destruction of cohesive bonds. Fatigue is the result of the repetitive action of an external load and has the typical features of a mass phenomenon, both the cohesive bonds and the load repetitions being collectives in a statistical

sense. By combining the probabilities of bond destruction for various amplitudes and numbers of stress cycles the cumulative damage effect can be evaluated and predicted.

The distinction between "absolute" and "economic" safety admittedly presents a very delicate problem; and it is evident that the approach to this problem will be affected by the character of the structure and the seriousness of the consequences of failure. For military aircraft Professor Pugsley's recommendation that strength factors should be chosen so that "structural accident rates shall be as small as possible consistent with efficient production and operation" is probably adequate. Civil engineering structures, on the other hand, must be designed sufficiently safe to make the chance of one single occurrence of a critical or of an undesirable condition negligible. It should be recognized, however, that "absolute" safety is unattainable and that the admission of a finite (however small) probability of failure is inherent in the statistical approach.

The writer very much regrets that by using the word "strain" in a sense which differs from the established meaning of "specific deformation" the intelligibility of the paper should have suffered—a remark made by both Mr. Perry and Mr. Gray. In favor of such use the writer would like to point out that, in contrast with other languages (French or German), the English technical language lacks a term expressing the general effect produced in a structure by loads and other influences (French: *Effort and sollicitation;* German: *Beanspruchung*). The common use of the word "stress" in this general sense is still more confusing than the writer's use of "strain"; "stress" is an abstract concept implying the action of a mechanical force per unit area, whereas "strain," even in the established meaning, is the observable effect on the structure, or part of it, of influences which are not necessarily forces. Direct correlation between strain and failure has been established reliably. Although fracture does not occur unless some strain is present, the action of a force is not essential. Furthermore, the meaning of the word "strain" in nontechnical language represents, very well, the meaning proposed by the writer.

Mr. Perry's comments on the fundamental difference between the economic aspect of structural safety prevailing in the United States and in prewar Europe are very much to the point. This difference is the result not only of the substantial difference in the ratio of the cost of material and labor but also of the relative importance of standardization of production and organization of work in a country the size of the United States. The implication is unjustified, however, that because of the comparatively low cost of materials there is no need to rationalize the fundamentals of design and that the "experienced designing engineer" can be relied upon to provide all the answers by pure intuition. Such an approach to engineering denies the value of research as an instrument of progress and leads logically to "trial and error" as the only method of making engineering progress, and "apprenticeship" as the only appropriate system of engineering education.

Although it may be perfectly obvious that "money can be saved by decreasing the load or by increasing the allowable unit stress" this statement contributes nothing toward the rational appraisal of the effect of load reduction or of a unit stress increase on the real value of the safety factor. Nine out of ten

"experienced designing engineers" will not be able correctly to evaluate this effect; nor will they be able to justify, by rational argument, a definite numerical value for the safety factor. The engineer's client is generally the least qualified person to specify the loading and the allowable stresses. To specify the actual loads to be carried by the structure at present and expected in the future is the best he can be expected to do; but he generally lacks the knowledge necessary to translate these data into a workable loading specification and to select the rational safety factor pertaining to this specification.

Failures of well-designed structures have almost never been caused by simple overloading except in cases of gross neglect. They have mostly resulted from too much reliance on the past experience of the designer, and on his failure to recognize the emergence of new factors in the design.[54]

The crash of a truck into an end post of a bridge, or of a ship's mast into a truss chord of a bridge, should be prevented by the specification of adequate width of curbs and of ample clearances; it has nothing to do with the factor of structural safety, not even in "academic discussion."

Although it should provide an adequate leeway for the guidance of a very careful designer, the writer's proposal to provide for a 10% fluctuation of dead load is tentative, and does not appear to be as ample as Mr. Perry assumes. It is significant in this connection that the dead load of the original Quebec Bridge, computed after its collapse, exceeded the design load by some 20% to 30%.[55] An investigation conducted during the erection of a 48-story building[56] on eight of its main columns furnished the following ratios between the observed dead load stresses and those computed on the basis of the completed drawings: 1.20, 1.31, 1.23, 1.29, 1.27, 1.26, 1.22, and 1.30—an average of 1.26.

The fact that structures designed for a wind load of 30 lb per sq ft have given satisfactory service is hardly surprising, since such a wind load represents the pressure exerted by a storm of the infrequent velocity of about 85 miles per hr. This value is derived from the known formula,

$$p = \frac{c\,q\,v^2}{2\,g} = 0.00256\,c\,V^2 \qquad (45)$$

in which V denotes the wind velocity in miles per hour and c is an empirical factor of shape, which for structural shapes varies between 1.3 and 1.9.[57]

Wind velocities fluctuate within a wide range; wind records taken at a number of stations at New York, N. Y.,[58] reporting maximum velocities and covering several years, show that not more than one observation out of every ten recorded velocities in excess of 46 miles per hr at about 500 ft above ground level and 65 miles per hr at 1,250 ft above ground level. The maximum velocities at these heights were 71 miles per hr and 102 miles per hr, respectively. A design load of 20 lb per sq ft corresponding to a wind velocity of 60 miles per hr should be more than adequate under normal climatic conditions. An

occasional increase to as much as 40 lb per sq ft ($V = 100$ miles per hr) would have to be covered by the safety factor. Such reduction of the design wind load would not controvert the fact that a number of serious accidents have occurred as a result of wind action (Tacoma-Narrows Bridge in the State of Washington, and Chester Bridge in Chester, Ill.). These accidents were not caused by excessive wind load but by the failure to provide adequately for the accompanying dynamic effects, and for uplift.

The lack of uniformity in the properties of structural materials is an important source of fluctuation of structural resistance. For steel, the range of fluctuation inherent in the individual manufacturing process is further increased in the structure by the fact that structural shapes in one framework may originate not only from the top or the bottom of ingots of the same heat or from ingots of different heats in the same manufacturing process, but from entirely different processes and mills. Moreover, the properties are affected by the rolling, and they differ for different shapes and thicknesses. The frequency distributions drawn in Fig. 3 represent the yield limit and tensile strength of an alloy steel in which all those sources of nonhomogeneity have been present. Nevertheless, the fluctuations are enclosed within a range of from 15% to 20% above and below the mean value. Even for concrete produced on the site, the manufacturing process of which is considerably less controlled than that of steel, the range of fluctuation of the compressive strength about its modal value seldom exceeds ± 35%. This is shown in Fig. 14 which represents the results of an investigation involving more than 1,000 samples.[59] It is interesting to compare the foregoing value (± 35%) with the range of fluctuation of the compressive strength of concrete manufactured under laboratory conditions which, normally, does not exceed ± 15%.

The writer heartily endorses Mr. Gray's comments. The lack of interest in fundamentals among engineers is really surprising. The number of discussers of a paper concerned with methods of elastic stress calculation, for instance, is generally a multiple of those taking part in the discussion of paper concerned with basic principles.

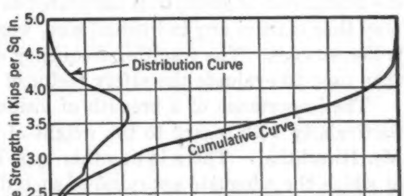

Fig. 14.—Frequency Distribution of the Cylinder Strength of Concrete (Modal Strength Approximately 3,600 Lb per Sq In.)

With regard to the safety of main cables of suspension bridges there can be no doubt that here is a structural element which probably requires an exceptionally low safety factor. If the frequency distribution of the strength of individual wires is narrow, that of the cable is still narrower, since the standard deviation of the strength of a cable consisting of m wires would be $\frac{\sigma}{\sqrt{m}}$ if σ denotes the standard deviation for the individual wire.

[59] *Ibid.*, Vol. 96, 1932, pp. 1367–1371.

As correctly stated by Mr. Gray, the uncertainty regarding the loading is also exceptionally small. However, the writer is not so sure about the reliability of the computed stress, particularly with regard to the uniformity of the distribution of stress over the individual wires. Since the capacity of the hard wire to secure inelastic relief of local overstress is rather small, the initial uniformity of stress distribution appears to be the principal question that needs careful study before designers can undertake the probably justified substantial reduction of the safety factor for suspension bridge cables.

Mr. Nelidov comments on the difference in the treatment of homogeneous and nonhomogeneous states of stress. This is a rather complex problem which, in most engineering applications, is best solved by the introduction of an adequate "mechanism of resistance"; this mechanism is an empiric function of the geometrical dimensions and the observable elementary physical properties. The variability of the resistance which determines the safety factor can be either directly evaluated from test results or computed by applying Eqs. 16 or 18 to the results of tests concerned with the observation of the constituent properties.

In a more scientific approach to this problem the probability of failure at every point of the stress field could be expressed as a function of the coordinates, considering both the variable stress intensity and the frequency distribution of the strength of an element. This approach leads to rather involved statistical computations; but it must be applied if no reasonable "resistance mechanism" can be devised a priori.

The essential difference between both approaches can be illustrated by considering the case of simple bending of a section composed of wires. The "resistance mechanism" of the section expresses the resisting moment in terms of the geometrical dimensions and the tensile strength of the material, the assumption being that failure is always initiated in the extreme fiber of the section. In contrast to this assumption, in the strict statistical approach, a definite probability of failure in relation to the distance from the neutral axis and to the fluctuation of strength is attributed to every wire of the section. Fracture may thus start in any individual wire, whatever its stress, if its actual strength is low enough. The resulting frequency distribution of sectional resistance is then used to evaluate the safety factor of the entire section.

The importance of a breadth of vision in predicting future developments, particularly with regard to the weight of railroad traffic is rightly stressed by Mr. Hirschthal. There is no other type of structure for the economic design of which the adequate appraisal of such development is as essential as for the railroad bridge. Here this aspect tends to overshadow all other aspects of the design; therefore, rational analysis and evaluation of the initial safety factor loses much of its practical value.

The difficulties of design for repeated stress cycles, to which Mr. Hirschthal refers, have been dealt with in the paper and the available quantitative results presented in Figs. 6 and 7. Admittedly, these results do not as yet fully account even for the most elementary conditions encountered in the design of structures subject to dynamic loads.

The writer greatly appreciates the stimulating and constructive comments of those who have discussed the paper and wishes to convey to them his thanks for their contributions.

FOREWORD

The Brooklyn Bridge is a suspension structure that crosses the East River between the Borough of Manhattan and the Borough of Brooklyn, in New York, N. Y. In 1943, when an examination of its physical condition and load-bearing capacity became desirable, it was 60 years old.

This investigation, which is described in the Symposium, was conducted by the Department of Public Works, City of New York, of which Irving V. A. Huie, M. ASCE, was then commissioner. Homer R. Seely, M. ASCE (author of the first paper), had general charge of the investigation for the Department, which was made under the guidance of a Board of Consultants comprising in addition to O. H. Ammann, M. ASCE (author of the second paper), the late Holton D. Robinson and the late Leon S. Moisseiff, Members, ASCE. The so-called technical survey was implemented by members of the engineering staff of the Department under the direction of Isidore Delson, M. ASCE, with Nomer Gray, Assoc. M. ASCE (author of the third paper), in charge of the work in the field. The tests described in the fourth and last paper were made under the direction of Harold E. Wessman, M. ASCE (author of the fourth paper).

HISTORICAL FEATURES OF CONSTRUCTION AND OPERATION

By Homer R. Seely,[1] M. ASCE

Preliminary Studies

While describing the anchorages of the Brooklyn Bridge across the East River between Brooklyn and New York, N. Y., in his progress report of 1876, Col. Washington A. Roebling made the following statement:

> "In European suspension bridges, the chains are usually carried in tunnels open to access, which are confidingly left to the care of future generations, and this trust is not betrayed. This, however, is contrary to the genius of the American people, with whom everything has to look out for and take care of itself; hence, in the arrangement of this anchorage, the chains are inaccessibly preserved and are not intrusted to the neglect of posterity."

In May, 1945, the Brooklyn Bridge had withstood the ravages of time and use for 62 years. How well the bridge has survived the "neglect of posterity" and how well it can serve the traffic of the future is the subject of this Symposium. This paper is devoted to a brief history of the bridge and a review of some of the more interesting features of its construction and operation.

The Brooklyn Bridge (or New York and Brooklyn Bridge as it was officially called in those days), like all undertakings of great magnitude, had been agitated, on occasion, since the early years of the nineteenth century. However, it remained for the action of three men—Henry C. Murphy, then a New York State Senator, William C. Kingsley, F. ASCE, and Alexander McCue, who met on December 21, 1866, in the City of Brooklyn—to reach an agreement resulting in the passage of an act by the New York State Legislature on April 16, 1867, incorporating the New York Bridge Company for the purpose of building and maintaining such a bridge. This action was undoubtedly aided by the unusually severe weather that winter, which caused the East River to freeze. As a result, it was possible to travel from Albany to New York by railroad in less time than it took the business man living in Brooklyn to reach his office in downtown Manhattan.

The corporators of the New York Bridge Company first met on May 13, 1867, and on May 23 retained John A. Roebling, M. ASCE, as their chief engineer. Mr. Roebling was admirably fitted for this assignment—ten years previously he had accomplished the proclaimed "impossible" by constructing a railway suspension bridge over the Niagara gorge at Niagara Falls, N. Y., and earlier that same year (1867) had completed the Cincinnati (Ohio)-Covington (Ky.) Bridge over the Ohio River with a record span of 1,057 ft.

Mr. Roebling immediately proceeded with the necessary surveys, preliminary plans, and estimates of cost and submitted his initial report on September 1, 1867. He investigated three locations, recommending the south

[1] Deputy Commr., Dept. of Public Works, New York, N. Y.

or City Hall Park location which was ultimately adopted (see Fig. 1). The river crossing required a clear span of approximately 1,600 ft. In his report, Mr. Roebling[2] stated:

> "Any span inside of 3,000 feet is practicable. With the best quality of steel wire, even greater spans may be made secure for all kinds of traffic; but, of course, the cost of such works increases with the length of span."

His implicit faith in the safety of a bridge of this magnitude, however, was not shared by a large number of the citizens. Therefore, he requested and re-

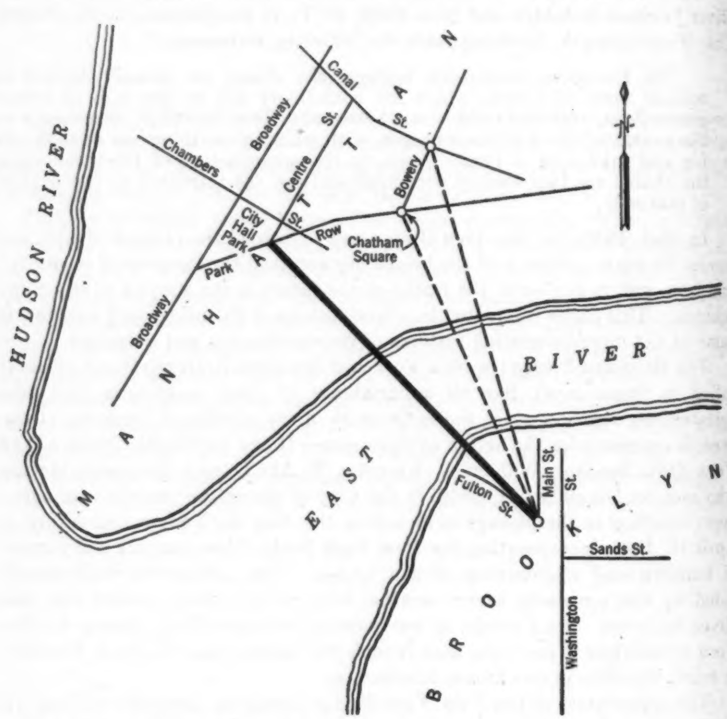

FIG. 1.—ALTERNATE AND ADOPTED LOCATIONS OF THE BROOKLYN BRIDGE

ceived the counsel of a Board of Consulting Engineers (Horatio Allen and Julius W. Adams, Past-Presidents and Hon. Members, ASCE; James P. Kirkwood, Past-President, ASCE; Benjamin H. Latrobe; William J. McAlpin; John J. Serrell; and J. Dutton Steele), who, after several months of intensive review and study, unanimously agreed in May, 1869:[3]

[2] "Report of John A. Roebling, C. E., to the President and Directors of the New York Bridge Company on the Proposed East River Bridge," Eagle Book and Job Printing Dept., Brooklyn, N. Y., 1867, p. 8.

[3] "Brooklyn Bridge 1883–1933," Dept. of Plant and Structures, New York, N. Y., 1933, p. 8.

"It is beyond doubt entirely practical to erect a steel wire suspension bridge of 1,600 feet span, 135 feet elevation, across the East River, in accordance with the plans of Mr. Roebling, and that such a structure will have all the strength and durability that should attend the permanent connection by a bridge of the Cities of New York and Brooklyn."

An Act of Congress (Public No. 53), approved on March 3, 1869, legalized the bridge as a post road for the conveyance of mails of the United States provided that it was constructed so as to not "obstruct, impair or injuriously modify the navigation of the river," and, to secure compliance with these conditions, the act stipulated that the plans of the bridge be submitted for the approval of the Secretary of War. A commission of three U. S. Army Engineers (Lt.-Col. H. G. Wright and Lt.-Col. John Newton, Hon. Members, ASCE, and Capt. W. R. King) was designated to report on the structure. After an exhaustive investigation, it was recommended that the bridge (with an underclearance of 130 ft) be approved, as planned. The recommendation was also endorsed by Brig.-Gen. A. A. Humphreys, Hon. M. ASCE, then Chief of Engineers, U. S. Army. However, in granting his approval on June 21, 1869, John A. Rawlins, then Secretary of War, acceded to the navigation interests and stipulated that the clear height of the bridge at the center of the main span be not less than 135 ft above "mean high water of the spring tides." It was recognized that even at this height it would be necessary for some of the larger merchant vessels, in order to sail under the bridge, to "send down or house their royals, and in some cases, their top gallant masts." Even so, for many years after the bridge was completed, the annual reports state that several ships were deprived of their topmasts each year.

Final surveys for constructing the bridge were started in June, 1869, but fate decreed that its master was not to build the bridge, as, on June 28, John A. Roebling, while standing on a fender rack, had his right foot crushed by a ferryboat approaching its slip. Tetanus developed and he died on July 22. Fortunately, associated with him on the work was his son, Col. Washington A. Roebling. In 1865, when only twenty-eight Colonel Roebling had resigned his commission in the Union Army to assist his father in completing the Cincinnati Bridge, taking practically complete charge of the construction. Obviously, in spite of his age, he was the logical successor to the position of chief engineer, and he was so appointed on August 3, 1869.

The trials and tribulations which confronted Colonel Roebling and his associates in the construction of the bridge were enough to exhaust the patience of ordinary men. The problems which arose in the sinking of the pneumatic caisson for the Brooklyn tower alone would furnish sufficient interesting material for a paper.

Foundation Problems

Actual construction started in January, 1870, at the site of the Brooklyn tower. The site selected for the tower fell upon a glacial deposit which proved to be a mass of boulders cemented together with decomposed fragments of green serpentine rock, making them almost impossible to dislodge. These boulders ranged in size from 1 cu ft to larger than 300 cu ft. A collection of the various

kinds of boulders encountered during the sinking of the caisson included all the varieties of rock found for a hundred miles north and northeast of Brooklyn; 90% of the boulders were of traprock, most likely originating in the Palisades.

Of course, it was necessary to break up the larger boulders in order to remove them from the working chamber. At first, this was done by plug and feather, but some more expedient method soon became necessary. Blasting had been considered from the beginning, but it was feared that, in addition to rupturing the eardrums of the workmen, a violent explosion in the compressed air of the working chamber would cause disastrous results to the caisson. After experimenting at first with a pistol, using successively heavier charges and then still larger charges fired by fuse, it was found that blasting caused no harmful effects. The powder smoke was quite a nuisance, however, as it would fill the working chamber for a half hour or more and obscure the lights. The sulfur odor did not matter as the sense of smell practically disappears in compressed air.

Illumination of the working chambers was a difficult problem. The general illumination was furnished by calcium lights. Care had to be taken, however, to prevent explosions caused by leaking gas or carelessness in turning off the burners. One explosion did take place, which, according to Colonel Roebling was "sufficient to singe off whiskers and create some alarm." Candles were used for special work where extra light was necessary. Incomplete combustion of the candles resulted in an intolerable amount of smoke in spite of all precautions, such as reducing the size of wick as well as soaking the wick in vinegar and mixing alum with the tallow. The smoke was very injurious to the lungs of the workmen; six months after the caisson work was completed, the workmen still coughed up sputa streaked with carbon black.

In the Brooklyn caisson the men worked in 8-hr tours, including 1 hour for meals, which they usually ate in the working chamber. Their wages were $2.00 a day, which was increased to $2.25 when the caisson had reached a depth of 28 ft. On the New York side, because of the greater depth and correspondingly greater pressure, the daily working hours were gradually reduced from two 4-hr tours to two 2-hr tours. The wage scale was also increased to $2.75 a day.

As one might expect, caisson disease, or the "bends," presented an acute problem, particularly on the New York side. According to Colonel Roebling, "scarcely any man escaped without being somewhat affected by intense pain in his limbs or bones or by a temporary paralysis of arms or legs." Full advantage was taken of all prior experience and knowledge of the subject—Colonel Roebling having previously made a special trip to Europe to learn of new developments in the use of pneumatic caissons. In addition, Andrew H. Smith, M.D., was retained to attend those afflicted and to conduct research. In his report Dr. Smith stated that, during his employment on the work, there were 110 cases that required treatment, of which three proved fatal. Colonel Roebling, himself, was a victim, being permanently crippled and confined to his home, from which point he continued to direct the work through his loyal and capable assistants. Some question was raised as to his ability to continue in charge of the work. A resolution introduced by Seth Low, then Mayor of

Brooklyn, to the Board of Trustees proposed that he be appointed as consulting engineer because:

> "In the judgment of this Board the absence of the Chief Engineer from the post of active supervision is necessarily, in many ways, a source of delay * * *."

Colonel Roebling positively refused to consider such an appointment and requested: "* * * that the vote of the board be taken simply as to whether or not I am to remain chief engineer." After a prolonged and heated debate, the resolution failed to be adopted by a vote of 10 to 7. In his defense Colonel Roebling also prepared a paper which Mrs. Roebling read before a meeting of the Society. There is no record, however, that the Society took any official action in his behalf. The ire of some of the Trustees was undoubtedly aroused by Colonel Roebling's inability to comply with the Board's request to attend one of its meetings when he telegraphed curtly: "Cannot meet the Trustees today." To their repeated requests, he wrote:

> "I am not well enough to attend the meetings of the Board as I can talk for only a few moments at a time and cannot listen to conversation if it is continued very long. * * * I did not telegraph you before the last meeting that I was sick and could not come, because everyone knows I am sick and they must be as tired as I am of hearing my health discussed in the newspapers."

Colonel Roebling resigned from the position of chief engineer on June 30, 1883, shortly after the bridge was opened to traffic.

The caissons were constructed of yellow pine with 2-ft-square oak sills resting on a semicircular casting, forming the cutting edge. The caissons were 102 ft wide and approximately 170 ft long—by far the largest pneumatic caissons ever constructed to that time.

The manways and supply shafts to the working chambers were equipped with air locks (see Fig. 2). The relative position of the air locks on the manway shafts became the subject of a suit for infringement of patent by Capt. James B. Eads, M. and F. ASCE, builder of the well-known Eads Bridge at St. Louis, Mo. In writing about this subject in the technical press,[4] Captain Eads stated:

> "I trust I shall not be understood as finding fault with Colonel Roebling for copying my plans in his New York caisson. * * * Colonel Roebling's failure for the past three years to credit me with the plans appropriated by him was not deemed of sufficient moment to cause me to trouble the public with the matter but having frequent occasion myself for them when designing foundations of other works, his omission being now coupled with an effort to deprive me of all merit of originality in them, compels me most reluctantly to correct his statements and show my right to use my own property."

In rebuttal, Colonel Roebling wrote:[5]

> "Captain Eads virtually makes the broad claim that any device which has been used in a pneumatic cylinder can be made the subject of a new

[4] *Engineering* (London), Vol. 15, May 16, 1873, p. 337.

[5] *Ibid.*, June 27, 1873, p. 458.

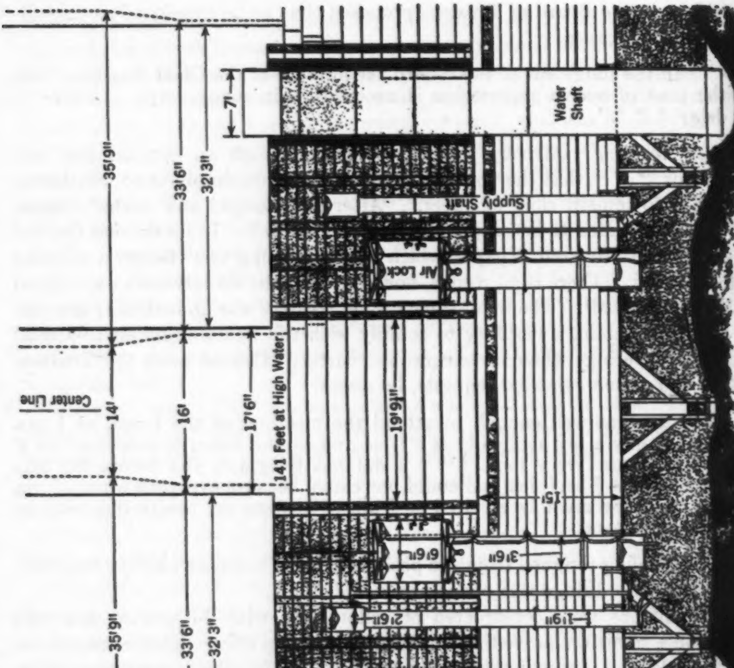

FIG. 2.—LONGITUDINAL SECTION, BROOKLYN TOWER CAISSON

patent when applied to a 'masonry caisson' and in that spirit has had several patents granted. I choose to differ with him on that point and before paying the round sum with which he proposes to tax the engineering world for the next fifteen years, I have preferred to leave the matter to the decision of the court at law where it is now being tried."

A resolution adopted in 1876 by the Board of Trustees of the bridge indicates that the suit was settled in favor of Captain Eads.

"Water shafts" (see Fig. 3) were used for removing the excavated material. There were two shafts, entirely open from top to bottom, with the lower ends submerged in pools of water. The air pressure in the working chamber was balanced by columns of water extending up the shafts. The men in the working chambers excavated the material and deposited it in the pools of water where it was picked up and hoisted up the shafts by a clamshell bucket, which was apparently a patented device in those days and called a "Grapnel" bucket.

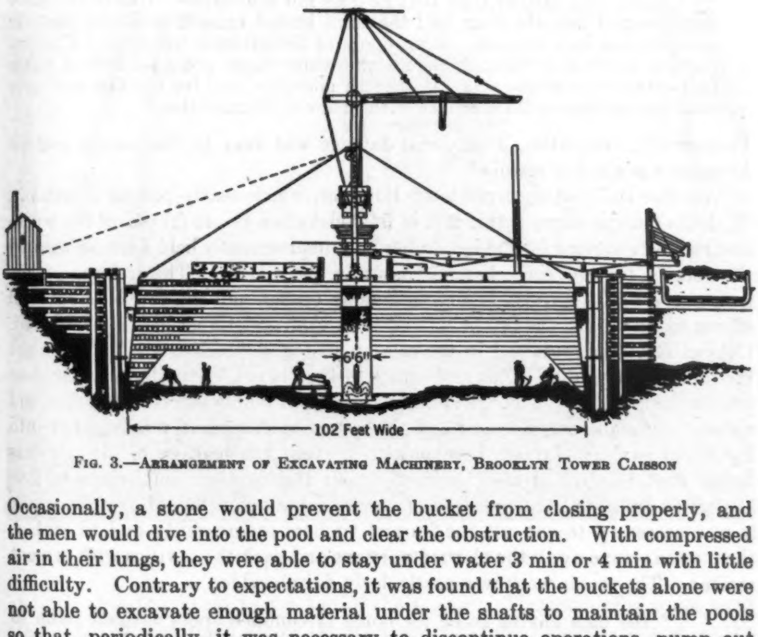

Fig. 3.—Arrangement of Excavating Machinery, Brooklyn Tower Caisson

Occasionally, a stone would prevent the bucket from closing properly, and the men would dive into the pool and clear the obstruction. With compressed air in their lungs, they were able to stay under water 3 min or 4 min with little difficulty. Contrary to expectations, it was found that the buckets alone were not able to excavate enough material under the shafts to maintain the pools so that, periodically, it was necessary to discontinue operations, pump out the pools, and excavate the material by hand. To maintain the air pressure, a cover was bolted on the shaft, loaded with rock to balance the air pressure, and the water in the shaft was released by admitting compressed air into the top of the shaft. One or two days were lost each time this operation became necessary.

During the sinking of the Brooklyn caisson, an incident occurred which Colonel Roebling refused to admit was an accident; but, rather,

"* * * simply the legitimate result of carelessness brought about by an over-confidence in supposing that matters would take care of themselves."

Early one Sunday morning, one of the earth dams retaining the water in the pools under the water shafts was washed away, allowing the air to escape through the shaft. The incident was recorded in Col. Washington Roebling's report as follows:[6]

"Eye-witnesses outside state that a dense column of water, fog, mud and stones was thrown up five hundred feet into the air, accompanied by a terrific roar and a shower of falling fragments, covering the houses for squares around. This column was seen a mile off. The noise was so frightful that the whole neighborhood was stampeded and made a rush up Fulton Street. Even the toll-collectors at the ferry abandoned their tills. There were three men on the caisson at the time, including the watchman. He reports that the current of air rushing toward the blowing water shaft was so strong as to knock him down; while down, he was hit on the back by a stone, and further than that he does not remember. One of the other men jumped into the river and the third buried himself in a coal pile. It was all over in a minute. Both doors of the air-lock fell open. The dry bottom was visible through the air and water shaft; not a particle of water had entered under the shoe into the air chamber, and for the first and only time the caisson could dispense with artificial illumination."

Fortunately, very little, if any, real damage was done to the caisson and air pressure was quickly restored.

Another incident occurred later, however, which nearly proved disastrous. With the cutting edges within 2 ft of final elevation (− 45 ft) one of the workmen, while retrieving his hidden dinner pail, inadvertently held a candle against the roof of the working chamber, igniting the timber. The leakage of air, acting as a draft, carried the fire zigzagging up through the caisson roof. All efforts to extinguish the fire failed and the working chamber had to be flooded. Colonel Roebling remained in the caisson all night directing the fight against the fire, which resulted in his first attack of the "bends"—an illness destined to cripple him for life. The fire spread laterally to points some 50 ft apart and upward through several courses of timber. Cement grout was injected into the burnt cavities through boreholes to prevent the leakage of air. It was hoped that this might also serve to repair the damage; but, since further inspection indicated the presence of considerable quantities of charred wood, it was necessary to cut out the burned timbers progressively and to replace them or to scrape away the charred portions and pack the cavities with cement mortar. The repair work was particularly disagreeable:

"* * * the men having to lie for hours in confined spots without room to turn, and breathing a foul mixture of candle smoke and cement dust, combined with powdered charcoal * * *."

The New York tower caisson, although founded at nearly twice the depth of the Brooklyn tower (− 78 ft) was sunk in 20% less time. This was largely because the material excavated was principally sand, which was blown to the surface through pipes with the compressed air in the working chamber. Some

[6] "Report of the Chief Engineer and General Superintendent to the Board of Directors of the New York Bridge Company," Eagle Book and Job Printing Dept., Brooklyn, N. Y., 1871, p. 20.

difficulty was encountered in finding a material that would deflect the sand at the top—otherwise the sand would have shot some 400 ft into the air. Wrought-iron and cast-iron elbows, used at first, would last only 1 hour or 2 hours. The elbows were finally discarded and heavy blocks of granite were hung over the pipes. The pebbles discharged with the sand, however, proved quite a hazard—a boatman on the river had a finger shot off and one of the laborers working on the caisson was shot through the arm. Comparatively little material was excavated through the "water shafts"; in fact, they were capped and not used at all during the last 10 ft of excavation.

Cable Spinning

The masonry towers and anchorages were completed sufficiently to start cable construction in August, 1876. One of the traveling or "hauling" ropes and a "carrier" rope were erected by first laying them on the bed of the river

Fig. 4.—Main Cables Under Construction

and then hoisting them to the top of the towers. The remaining ropes were erected by hauling them across the river supported on hangers running on the carrier rope. Only one footbridge, 3.5 ft wide (see Fig. 4), was used to give access to the different parts of the work. At three points in the main span and the midpoint of each land span, "cradles" or crosswalks were erected to give access from the footbridge to the wire adjusting platforms. The cable strands were spun approximately 60 ft above their final position at the center of the main span to insure the wire being pulled straight under the correspondingly higher tension. Also, the greater underclearance of the temporary ropes

offered less interference to navigation for a considerable added length of time. Hanging platforms were erected for adjusting the strands which were reached by ladders from the wire adjusting platforms.

The cable wire was spun basically the same as for modern bridges. However, only one strand for each cable was spun at a time, so that the spinning wheels returned empty each trip. Eighteen months were required to spin the cables, the last wires being placed on October 5, 1878. Based on his experience at Cincinnati, Colonel Roebling had estimated that it would take at least 2.5 years to 3 years to spin the cables. Only one major mishap occurred on this phase of the work. While one of the strands was being slacked off to adjust it to the proper sag, the strand broke loose at the New York anchorage and slipped over the tower until it came to rest on the bed of the river. Fortunately, no boat happened to be under the bridge or it might have been cut in half; but, unfortunately, the strand shoe did strike and kill two of the men working on the anchorage.

Difficulties of Material Inspection

Galvanized steel wire was used for the main cables instead of iron wire which had been used for all previous parallel wire bridge cables. The specifications established limitations as to unit weight, strength, elastic limit, and modulus of elasticity. However, no restrictions were included on the process of manufacturing the steel or the wire even though at the time it was generally believed that open hearth or Bessemer steel would not produce acceptable wire. All parties expecting to submit a bid were requested to furnish samples of the wire they proposed to supply. Colonel Roebling realized that this was no assurance that all the wire would conform to the sample, but (he indicated) it would serve to acquaint each bidder with all the problems involved in producing the wire and convince him that there were no unjust or arbitrary conditions in the specifications, that would be impossible to fulfil. The samples submitted by prospective bidders soon indicated:[7]

> "* * * that both Open Hearth and Bessemer steels could be so manipulated as to meet the requirements in every respect, giving *uniformity* equal to and even superior to any brand of cast-steel * * *."

John A. Roebling's Sons Company submitted alternative bids for wire of crucible cast steel and of Bessemer steel. The Executive Committee recommended the award of the contract to the Roebling Company on the basis of their low bid for Bessemer steel wire. Nevertheless, a strong vote of the Board of Trustees in favor of crucible cast-steel wire caused the contract finally to be awarded to the firm submitting the low bid for such wire. The contract price was 8.7¢ a lb—nearly 2¢ a lb more than the Roebling bid. The bids were taken at so much per pound, gold, to eliminate all questions of probable changes in the value of currency during the life of the contract.

The successful bidder was a local Brooklyn company and everything apparently went well until inspectors noticed that the stock of rejected wire,

[7] "Report of the Chief Engineer of the New York and Brooklyn Bridge, January 1, 1877," Eagle Book and Job Printing Dept., Brooklyn, N. Y., 1877, p. 21.

instead of growing larger, was gradually growing smaller. It was determined that the contractor was substituting rejected wire for all approved wire which happened to remain at the plant overnight and then, of course, on the following morning, carted it to the bridge without further inspection. When this skulduggery was discovered, the contractor conceived the idea of having each wagonload of wire driven to a building en route where the approved wire was replaced with an equal weight of rejected wire. The approved wire was then returned to the plant and resubmitted to the inspector as new wire. Colonel Roebling, upon learning this, assigned a man on horseback to accompany each wagonload, and in reporting the matter to the president of the Board stated (letter from the chief engineer to the president of Board of Trustees, New York and Brooklyn Bridge, dated July 9, 1878):

> "I owe it to myself to protect my reputation in this matter and in case a want of strength shall in the future be found in the cables, I wish the responsibility to rest where it belongs, with the Board of Trustees."

When asked to explain this statement, Colonel Roebling replied that the old Board of Trustees must be held responsible because,

> "They awarded so important a contract as the cable wire to a man who had no standing commercially or otherwise, and the same responsibility must be assumed by the present Board if they fail to at once put an end to [his] * * * contract, now that he has been detected in fraud. * * * I further recommend that you call for new bids for the wrapping wire as [his] * * * bid is below the cost of production and he must be intending to furnish something else than the material called for."

Colonel Roebling's bitterness was probably aggravated by a previous action of the Board of Trustees in voting to prohibit acceptance of bids from any firm or company in which any trustee, officer, or engineer of the bridge was interested, thus forcing him to sever all connection with the John A. Roebling's Sons Company. Although the Trustees did not cancel the cable wire contract, as urged by Colonel Roebling, they did reaward the contract for the wrapping wire.

It was estimated that about 221 tons of rejected wire had been spun into the cables. To compensate, 14.25 tons of wire, or, roughly, 1.7% was added to each cable. To have fully compensated for the estimated loss in strength would have required 22 tons of wire per cable, which would have made the cables too large to accommodate the cable bands.

Suspended Structure

The floor structure, as originally planned, consisted of six stiffening trusses of uniform depth when the floor beams framed at the neutral axis of the trusses. Between the outer pairs of trusses, provision was made for a sidewalk and a roadway for one lane of vehicles. An elevated promenade for the use of people of leisure and invalids was included between the inner pair of trusses in the plane of the top chords. The two intermediate spaces were designated for railway cars. To provide the additional underclearance required by the Secretary of War, the stiffening trusses were raised in relation to the floor beams. thus making it unnecessary to change the profile of the roadway. The

sidewalks were also eliminated, and the bridge was widened to provide roadways for two lanes of vehicles—a most fortunate decision, considering the needs of present-day motor traffic. At the same time, the inner trusses were made deeper to serve as railings for the promenade. The floor structure was to be constructed mainly of wrought iron. The design remained in this status until May, 1878, when, in spite of repeated objections by Colonel Roebling, the Board of Trustees voted that the bridge should be constructed to accommodate standard-gage "palace" or sleeping cars in order to make possible continuous transit between the two cities without transfer to bridge cars. Colonel Roebling had previously determined that provision should be made for a lighter weight passenger car with not less than 6-ft gages to insure steadiness in high winds.

The Board of Trustees believed its action would not cause a serious change in the plans (which had been completed); and, accordingly, bids for furnishing the ironwork were taken in June, 1878. The president was authorized by the Board to award the contract; but the cash on hand at the time was only $2,582.06, and, with liabilities of more than $157,000, no award was made. In the meantime, Colonel Roebling investigated the possibility of using steel and reported that (letter from the chief engineer to the president of Board of Trustees, New York and Brooklyn Bridge, dated April 2, 1879):

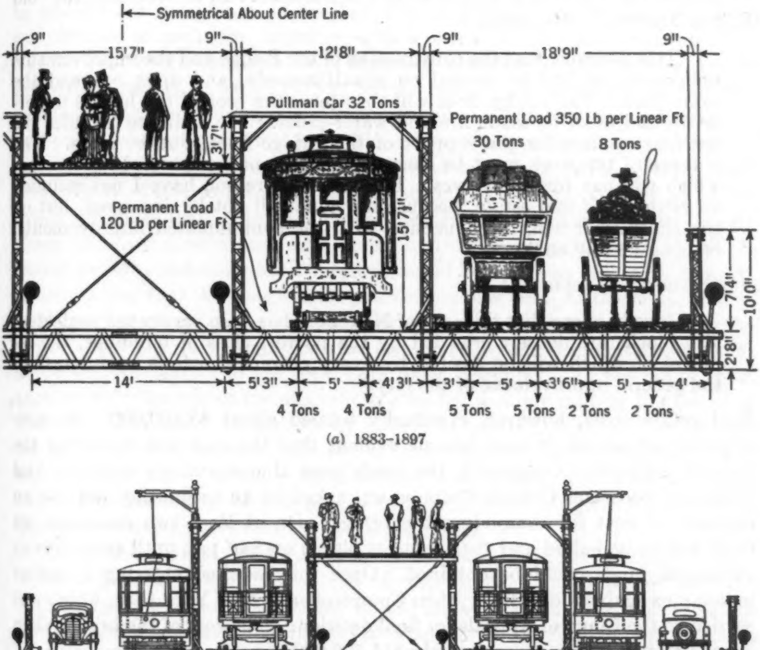
> "There will be nothing experimental, therefore, now on our part in the use of steel, as manufacturers have proved satisfactorily that a mild grade of steel in every way suited to bridge construction can be produced."

In April, 1879, the Board ordered that revised plans and specifications be prepared on the basis of using principally steel in place of wrought iron. Bids on this basis were to have been received on May 1 but were delayed until May 27, pending the outcome of an investigation of a charge against the engineers that they released advance information of the steel specifications for a consideration of $10,000. A committee of Trustees, after investigating, stated: "It is unnecessary to say that there is not the slightest evidence to sustain the charge."

The contract was finally consummated on August 6, 1879, with the Edge Moor Iron Company, calling for the delivery of not more than 500 tons of steel during the remainder of that year. For financial reasons, no deliveries were to be made between January 1 and May 1, 1880, and the Board reserved the right, until May 1, to order the remainder of the steel called for in the contract. Progress was slow. Revised drawings were not completed until January, 1880. The unprecedented size of the channel sections made it necessary for the mill to design and construct new shears to cut the blooms and new rolls to form the channels. The engineers had also assumed that it would be possible to fabricate the eyebar stiffening-truss diagonals by the same procedure that had been used to make iron eyebars; but, when made in this way, the diagonals would not meet the specifications. Four months of constant and costly experimentation were required to develop a satisfactory method. It was not surprising, therefore, that the contract price increased from 4.35¢ a lb to 8.50¢ a lb for subsequent orders of steel not covered by the original contract. The

first shipment was made in November, 1880, and field erection was begun in January, 1881.

The original contract called for approximately 5,500 tons of steel. When the change from iron to steel was made, it was estimated that there would be a saving in tonnage of from 12% to 15%. As the work progressed, it was discovered that some additional 1,100 tons would be required. This was due partly to an increase in the depth of the four inner trusses (see Fig. 5(*a*)) and other strength-



(*a*) 1883–1897

(*b*) After 1897 (Trolley Cars Rerouted over Railway Tracks, December 15, 1944)

FIG. 5.—CROSS SECTION AT MIDDLE OF RIVER SPAN

ening necessary to accommodate the Pullman cars, but largely because the steel could not be rolled as thin as iron. Considerable concern was expressed by the Trustees regarding the resulting margin of safety of the bridge, to which Colonel Roebling replied: "The margin of safety in this bridge is still over four, which I consider safe." He added, however, that perhaps an error of judgment had been committed in using a design stress of 15,000 lb per sq in. in place of 20,000 lb per sq in., although, even at the lower unit stress, some of the sections were deliberately made thicker to compensate for corrosion, which he probably visualized would result from "neglect of posterity."

Financial and Political Difficulties

Engineering and construction problems were not the only difficulties that confronted Colonel Roebling and his associates. In the preparation of the original design of the bridge, his father had estimated the cost of the structure at $7,000,000. This estimate, intentionally, did not make any allowance for real estate. John Roebling visualized approach structures supported on small masonry pillars and iron columns in such a way that the property beneath could be utilized for commercial purposes such as a market hall to supersede the "old Fulton Market." He stated:[3]

> "It is desirable that the construction of the Bridge and the improvements underneath should be carried on simultaneously, and upon one and the same plan. The Bridge floor will thus form the roof of the houses underneath and must be made fire and water-proof. My estimate includes the necessary pillars for the support of the Bridge floor, but no more. The balance of the work must be charged to the improvements of the ground, which will pay for themselves. For this same reason have I not included an estimate of real estate, because its value will not be destroyed, but on the contrary it will, in connection with the contemplated improvements, be considerably enhanced."

Furthermore, he reported:

> "It so happens that this part of New York has been very much neglected. The blocks are densely crowded by the poorest class of buildings, the removal of which will be desired by every citizen who feels an interest in the general improvement of the city."

Real estate costs, however, eventually totaled about $3,800,000. As construction advanced, it soon became evident that the cost was exceeding the original estimate. Frequently, the funds were almost entirely depleted, and upon such occasions Colonel Roebling was asked for an accounting and also an estimate of cost for completing the bridge. On at least two occasions, all work had to be halted and the engineers placed on half pay until such time as additional funds could be obtained. Once this required entering a suit of mandamus against John Kelly, then Comptroller of New York City, which was carried to the Court of Appeals for final decision. The cost of the bridge when opened to traffic was approximately $15,500,000.

It was not surprising, therefore, that suspicions were aroused as to the proper expenditure of the funds, and the records of the day are filled with insinuations and accusations which quite often led to investigations.

As organized by the Act of 1867 (Chapter 399), the New York Bridge Company was a private corporation with an authorized capital stock of $5,000,000. Of this sum, $3,000,000 was subscribed by the City of Brooklyn, $1,500,000 by the City of New York, and $500,000 by individual investors. The act was amended in 1869 (Chapter 26) to provide for representation of the cities on the Board of Directors; but, as these directors had no vote in the election of others, the control of the Board remained entirely in the hands of the private stockholders. Decisions on all business matters were made by an Executive Committee, it being ordered by the president of the company at the very beginning that: "* * * the Chief Engineer should have nothing to

do with the making of any contracts or purchase of any supplies." The action of this committee in appointing the majority stockholder as "general superintendent" on a 15% fee basis (including the cost of real estate) for supervising the construction of the tower foundations to high-water level, was, for a time, the subject of much bitter debate and an investigation which resulted in a considerable downward adjustment of the fee finally paid.

In June, 1874, the New York State Legislature again amended the Act of 1867 to provide for the purchase of the stock held by the private investors and to transfer the completion of the bridge to the direction of the mayors and comptrollers of each city, together with a Board of Directors appointed by them. The reorganization on this basis was modified by still another Act of Legislature passed in May, 1875 (Chapter 300), which provided for the dissolution of the New York Bridge Company and the establishment of the bridge as a public work of the two cities. The first meeting of the Board of Trustees appointed under authority of the act was held on June 9, 1875. This change seemed only to add to the suspicions of the general public. In 1876 an application for an injunction to halt further construction was made to the Circuit Court of the United States; and again, in 1879, upon petition of D. Willis James and others stating that the bridge would be unsafe as well as an obstruction to traffic, that it would reduce property values, and, furthermore, that it would cost in excess of the cost fixed by law, a complete investigation of the project from the very beginning was conducted by the Committee on Commerce and Navigation of the New York State Assembly. In the fall of 1882, another investigation of the affairs of the bridge was initiated by the Board of Trustees, following charges made by a daily newspaper, the *New York World*, accusing the Trustees of malfeasance in office, neglect of duty, conspiracy, and misappropriation of funds. All that this investigation disclosed, however, after more than a year of search, was an overpayment of $9,578.67 to some of the material contractors because of clerical errors.

Then, there were problems, such as the case of widow Delaney, whose husband had the misfortune to fall off the bridge. The Trustees paid the funeral expenses, amounting to $51.12 and already donated the sum of $25 to Mrs. Delaney; but she sought further assistance. It was decided that, although she had no legal claim on the Trustees and any donation granted her would be simply an act of charity, a sum not to exceed $100 was to be paid to her in instalments, at the discretion of the vice-president.

Opening Ceremonies

The bridge was finally completed and opened to the public on May 24, 1883. The opening ceremonies were of national importance, being attended by the President of the United States, the governors of several states, and the mayors of nearly all the cities in the vicinity.

It was a gala holiday and excursions were run by the railroads from the neighboring cities and towns. As President Chester A. Arthur, Governor Grover Cleveland, and Mayor Franklin Edson of New York City, walked over the bridge, escorted by regiments of the National Guard, salutes were fired from the Navy Yard and from the forts in the harbor, joined by five naval ships

anchored below the bridge. Whistles were blown and the chimes of Trinity Church in New York City rang out.

After the exercises, which were held on the Brooklyn side, the President, the Governor, and the Trustees were driven to the near-by home of Colonel Roebling to offer him their felicitations as he was unable even to attend the ceremonies. In the evening, the bridge was cleared for an elaborate display of fireworks.

The joys of opening day, however, were dampened a week later on Memorial Day when a skeptic yelling that the bridge was falling created a panic and caused the death of thirteen people on the promenade stairway at the New York anchorage.

Traffic

After considerable discussion and voting, the following toll rates were established by the Board of Trustees:

Traffic	Cents
Pedestrians	1
Railroad fare	5
One horse or horse and man	5
One horse vehicle	10
Two horse vehicle	20
Additional horses, each	5
Sheep and hogs, each	2
Neat cattle, each	5

In later years these rates were modified from time to time and, except for the railroad fare, were finally abolished in 1911.

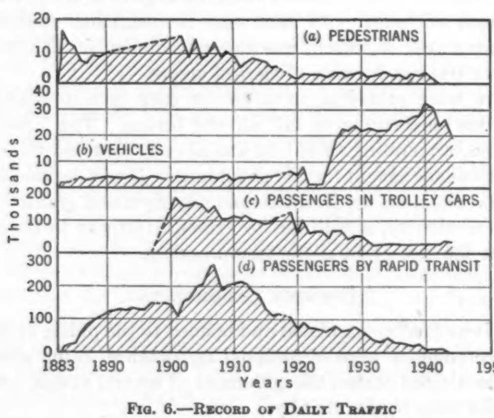


Fig. 6.—Record of Daily Traffic

Pedestrian traffic was particularly heavy at first and on Sundays and holidays one of the roadways was usually closed to vehicle traffic and made available for pedestrians to Brooklyn, the promenade being restricted to those crossing to New York. In the first year pedestrian traffic averaged about 16,600 daily (see Fig. 6) with morning and evening hourly peaks of more than

2,000. The fad of walking over the bridge apparently ended about 1910, because since then traffic has gradually decreased to about 3,000 people a day. By order of the Navy Department, the bridge was closed to pedestrian traffic on July 27, 1942, for the duration of World War II.

Railway traffic over the bridge began on September 24, 1883. This facility probably received more thought and planning than any other feature. John A. Roebling visualized multiple-car, rope-driven trains running alternately back and forth over each track. In 1878 Colonel Roebling still recommended this system, making the following pertinent comment in regard to the circulating system (letter from the chief engineer to the president of Board of Trustees, New York and Brooklyn Bridge, dated February 25, 1878):

> "Imagine for a moment that at 6 o'clock P.M., a single car on the circulating system with a carrying capacity of fifty passengers has arrived. A crowd of two hundred is waiting to get in! Who will enter it? Why the strong men and active boys. In a minute-and-a-half or probably two minutes, another car arrives. By this time a fresh relay of strong men and active boys is at hand, and the performance is repeated. It may thus happen that ladies and timid persons will have to wait a whole hour before they can cross."

It was finally suggested, however, to use circulating multiple-car trains stopping at elevated platforms on each end of the bridge and, on this basis, Colonel Roebling agreed that the circulating system was preferable and recommended its adoption. He also proposed the installation of tracks on the roadways for horsecar transportation, but this facility was later abandoned by action of the Board of Trustees.

Traffic using the rapid transit trains increased from approximately 25,000 passengers a day in 1883 to a maximum of about 266,000 a day in 1907, with a peak hour count of more than 46,000—nearly 82% more than the most optimistic forecast of such traffic made in 1879. Early in 1908, the first subway to Brooklyn was placed in operation and two years later the Manhattan Bridge was opened to traffic. Passenger traffic over the Brooklyn Bridge, accordingly, went on the decline and on March 5, 1944, when the service was discontinued, there were only about 7,800 passengers using the trains each day.

Single cars were used at the beginning, increasing in number as the traffic demanded. Steam locomotives were used to switch the cars at either end and to haul them over the bridge during the slack hours. On foggy days, flagmen were stationed at frequent intervals along the tracks to guard against rear-end collisions, until a satisfactory automatic block signal system became available in 1908. Oil lamps in the cars were replaced in 1895 with electric lights served by overhead trolleys. The locomotives were replaced by electric motor-driven cars in 1897, but use of the rope or cable power continued until 1908. The trains increased in length until six-car trains operating on a 1-min headway were used during the peak hours. Through trains from Brooklyn started running over the bridge in 1898 (the year that New York and Brooklyn were consolidated and the bridge was placed under the jurisdiction of the Department of Bridges of the City of New York).

By 1901 traffic facilities at the Manhattan terminal had become so overtaxed that the condition was brought to the attention of the New York County

Grand Jury by the District Attorney. During the next decade continual effort was made to alleviate the congestion. Legislation was passed and numerous plans were projected for a new station. Elevated lines to disperse the traffic to several stations were proposed and lines connecting with the Williamsburg and Manhattan bridges, then under construction, were also urged; but, except for acquiring property for a new station, nothing was ever accomplished because of the stolid inaction on the part of the city officials in the face of certain injunctions to any construction which might have been attempted. However, after repeated applications, approval was granted to the extension of the head house first to the west side of Park Row and later to the west side of Centre Street (see Fig. 1), thus providing for six-car trains starting in January, 1908. This construction was regarded as temporary until a new station could be built but it remained in place until 1935.

The property acquired for the station was finally used as a site for the Municipal Building. In one last effort to connect the rapid transit tracks with those of the other two bridges, connections were constructed from the bridge approach passing under Park Row to a subway station beneath the Municipal Building. At this point the tracks were intended to connect with those of the Centre Street subway which was opened to traffic in 1913. The construction of the connections, except for the installation of the tracks, was completed in 1914, but these connections were never used because the operating company refused to enter into an agreement with the city.

Tracks for trolley cars were installed on the bridge roadways in 1897 (see Fig. 5(*b*)) and within a few years the trolleys were transporting approximately 169,000 passengers a day. This traffic has also decreased to about 38,000 passengers a day. Work has been completed which on December 15, 1944, enabled the rerouting of the trolley cars over the tracks formerly used by the trains. The stations, which had long since become an eyesore as well as a maintenance headache, have also been demolished.

Vehicular traffic over the bridge increased, roughly, from 1,700 vehicles a day in 1883 to approximately 30,000 a day in 1940. This seems to be about the limit of capacity, however, when compared with the traffic trends of the other East River bridges.

Pneumatic mail-tube service over the bridge was initiated in August, 1898, reducing the time of transporting mail between Manhattan and Brooklyn from 25 min to 3 min.

Interruptions of Traffic

During its existence, the Brooklyn Bridge has not always operated without interruption. On July 29, 1898, a horse died on the south roadway near the Brooklyn tower, completely blocking all Brooklyn-bound vehicular and trolley traffic. The entire river span was soon jammed, causing a shifting of the cable saddles riverward and a readjustment of stresses in the overfloor stays. Some of these stays, being attached directly to the tower tops rather than to the saddles, picked up more than their share of the load, thus causing a severe lateral distortion of the stiffening trusses described in the records as a "buckling" of the bottom chords. No mention was recorded of what repairs,

if any, were necessary; nor is there any physical evidence of any having been made. The condition partly corrected itself with the dispersion of the live load and the saddles slowly returned to their former position.

Again, on July 24, 1901, nine consecutive suspenders at the center of the river span along the north cable were found broken, requiring the cessation of all rail traffic for 36 hours. These suspenders are short, solid, round rods connected to the floor system through trunnions to permit longitudinal movement. The discovery attracted the attention of Eugene Philbin, then District Attorney for New York County who retained Edwin Duryea, Jr., and Joseph Mayer, Members, ASCE, consulting engineers, to

> "* * * make an examination of the bridge * * * with a view of ascertaining whether or not the capacity of the bridge is overtaxed * * * and as to whether or not the bridge has been allowed to deteriorate because of improper supervision, inspection and repair."

These engineers submitted a lengthy report severely criticizing the men entrusted with the care of the bridge and also certain features of the design of the structure. A careful review of the report made by Richard S. Buck, M. ASCE, chief engineer and Henry A. LaChicotte, assistant engineer of the Manhattan and Queensborough bridges at the request of Charles C. Martin, M. ASCE, chief engineer of the Brooklyn Bridge, not only refuted all accusations of lax supervision, inspection, and maintenance, but also showed basic fallacies in the Duryea-Mayer analysis of the design. Wilhelm Hildenbrand M. ASCE, who, with Mr. Martin, had been associated with Colonel Roebling on the design and construction of the bridge also refuted the Duryea-Mayer report. No official action was taken by the District Attorney.

Motor vehicles were barred from the bridge on July 6, 1922, following a riverward shifting of the northerly two cable saddles over the Manhattan tower. From a study of saddle movements, it appears that these movements were simply the readjustment of cable stresses consistent with the condition existing in the other two cables. The ban against motor vehicles was lifted to passenger cars on May 12, 1925.

The Eighth Wonder of the World

The completion of the Brooklyn Bridge was without question a milestone in the science of suspension bridge construction. Its span held the record for 20 years and was not materially exceeded until 1925, when the Philadelphia (Pa.)-Camden (N. J.) Bridge across the Delaware River was opened to traffic. It also marked an advance of 51% in length of span which was not surpassed until the completion of the George Washington Bridge across the Hudson River between New York City and Fort Lee, N. J., in 1931, which increased span length 89%.

Considering the manifold unprecedented problems which confronted its builders, and the limited means with which to solve them, the Brooklyn Bridge truly stands as, so frequently described, "The Eighth Wonder of the World."

References

Many references were consulted in the preparation of the Symposium, some of them probably available only in the files of the Department of Public Works of the City of New York. An exceedingly comprehensive bibliography on the Brooklyn Bridge may be found in **"A History of Suspension Bridges in Bibliographical Form,"** by A. A. Jakkula, U. S. Public Roads Administration and the Agricultural and Mechanical College of Texas, College Station, 1941, pp. 198-236. The following references proved to be the most productive of useful information:

DESIGN AND STRESS CONDITION

By O. H. Ammann,[8] M. ASCE

Introduction

The Brooklyn Bridge is a structure of momentous interest in the history of bridge building. The bridge furnishes a wealth of information on the safety and useful life of a structure of its kind and on the merits and shortcomings of its design, as viewed from present-day experience and advanced knowledge.

Its construction was the culmination of a series of splendid records in suspension bridge building in the nineteenth century. Remarkable progress in suspension bridge building began with the achievements of English and French engineers in the early part of that century. In 1826 Thomas Telford completed the famous Menai Bridge in Wales with the then unprecedented span of 576 ft; and, in 1834 the French engineer, M. Chaley, built an 870-ft span at Fribourg, Switzerland.

In the second half of the nineteenth century attention was focused on the United States because of new achievements in the field of suspension bridges and advances in the art of building wire cables to new records of span. John A. Roebling, who planned and initiated the building of the Brooklyn Bridge, himself had created a number of outstanding bridges of this type, among them the unique Railway Suspension Bridge across the Niagara River in 1855 and the bridge across the Ohio River at Cincinnati in 1867. With its span of 1,057 ft, the Ohio Bridge was at that time the longest suspension bridge and served as a close model for the Brooklyn Bridge.

The latter, however, outranked its predecessor because of a 50% longer span (1,595 ft), exceptionally long side spans (933 ft), and more than 100% greater carrying capacity. The Brooklyn Bridge is also distinguished by the first introduction of steel wire in place of the wrought-iron wire previously used for cables. Cable wire was increased in strength from 90 kips per sq in. to 160 kips per sq in., and thus much longer and heavier spans were possible. For the first time, also, the cable wire received a galvanized zinc coating, instead of a film of grease, which contributed to increased life.

Together with the Eads Bridge in St. Louis, which was under construction at the same time, the Brooklyn Bridge has the distinction of being one of the first large bridges in which pneumatic caissons were used in building great foundations.

Conception of the Original Design

Although the design of the Brooklyn Bridge reflects general practice in the nineteenth century, in many respects it reflects the individual conceptions of John A. Roebling. The most conspicuous features are the massive masonry towers, which were common in early suspension bridges (Fig. 7). Mr. Roebling properly remarked that "in a work of such magnitude, located between two

[8] Cons. Engr., New York, N. Y.

great cities, good architectural proportions should be observed." He stated:[9]

> "The great towers will serve as landmarks to the adjoining cities, and they will be entitled to be ranked as national monuments. As a great work of art, and as a successful specimen of advanced bridge engineering, the Brooklyn Bridge will forever testify to the energy, enterprise and wealth of that community which shall secure its erection."

The graceful cable curve with its small sag (one thirteenth of the span, which is characteristic of older suspension bridges) also contributes to good

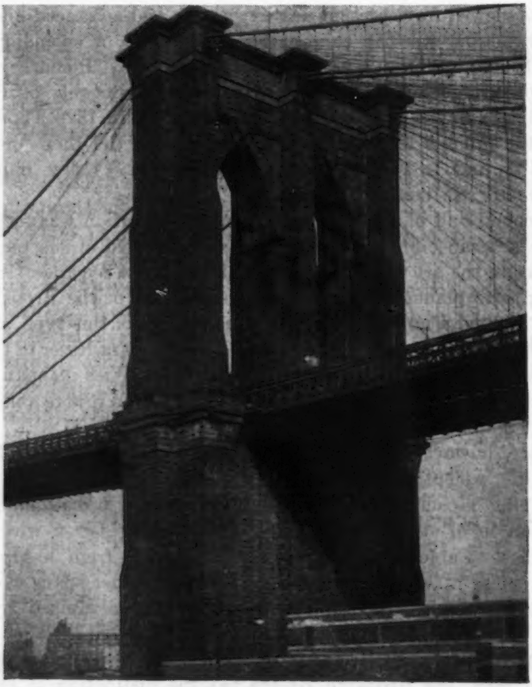

FIG. 7.—"THE MOST CONSPICUOUS FEATURES ARE THE MASSIVE MASONRY TOWERS"

appearance. The relatively shallow parallel-chord stiffening trusses along the floor, although considerably deeper than those originally conceived by Mr. Roebling, do not detract from the elegance of the structure. The inclined stay ropes add to the unique appearance.

At the time of the conception of the Brooklyn Bridge, suspension bridge building had already been highly developed as an art, but proportioning had not yet reached the stage of refined modern science. The theory of the suspended

[9] "Report of John A. Roebling, C. E., to the President and Directors of the New York Bridge Company on the Proposed East River Bridge," Eagle Book and Job Printing Dept., Brooklyn, N. Y., 1867, p. 3.

cable was well known, as was also the common theory of elastic structures; but the designers of the Brooklyn Bridge were not familiar with more refined methods which would have aided in the analysis of the highly indeterminate structure. The so-called deflection method of calculating stresses, which is now commonly applied to suspension bridges, was developed only in the early years of the twentieth century. Whatever records remain of the stress calculations used in designing the Brooklyn Bridge indicate a very crude conception and analysis of the stress action in the stiffening system.

Nevertheless, Mr. Roebling had a keen practical understanding of the suspension system and the functions of the component parts. He appreciated the merits inherent in the simple unstiffened cable suspended from the towers. Experience had amply demonstrated that the cable had to be stiffened against objectionable or destructive oscillatory motions incited by moving loads or wind; but Mr. Roebling realized that such stiffening must be kept to a rational limit. Contrary to this wise view, in the early part of the twentieth century, there was a fallacious tendency to make a virtue of rigidity, which resulted in many excessively rigid, economically wasteful, and clumsy looking suspension bridges.

Previous developments had led to two essentially different methods of stiffening, one by a system of inclined stay ropes and the other by stiffening girders or trusses along the floor. Mr. Roebling believed that he could obtain greatest effectiveness by a combination of the two. He assigned to the trusses the principal task of stiffening the cables vertically in the center of the center span and in the anchorage portion of the side spans, where the stays cannot be effective. He also considered the trusses essential in resisting dynamic wind action, for he stated:[10]

> "* * * to guard against vertical and horizontal oscillations, and to insure that degree of stiffness in the flooring which is absolutely necessary to meet the effects of violent gales in such an exposed situation, I have provided six lines of iron trusses, which run the whole length of the suspended floor from anchor wall to anchor wall * * *. Those parts of the trusses which extend below the floorbeams, afford an excellent means for lateral trussing and bracing."

According to Mr. Roebling's original plans, all six trusses were to be 12 ft deep, or only one one hundred and thirtieth of the center span. For the traffic then contemplated these flexible trusses would have been adequate, but (see Mr. Seely's paper) it appears that, during construction of the bridge, Col. Washington A. Roebling (who became chief engineer after his father's death) was induced by the directors of the Bridge Company to provide for the possibility that heavy Pullman cars might eventually be moved over the bridge. This called for stiffer trusses near the tracks and thus the four inner trusses were increased in height to 17 ft.

John A. Roebling assigned to the stay system the principal task of reducing the motions of the cable saddles under unbalanced loads on center and side spans. The stays, in combination with the stiffening trusses, fixed at the

[10] "Report of John A. Roebling, C. E., to the President and Directors of the New York Bridge Company on the Proposed East River Bridge," Eagle Book and Job Printing Dept., Brooklyn, N. Y., 1867, p. 17.

towers, form a cantilever system that relieves the cables of a substantial part of the vertical load. This stay system is so strong (John A. Roebling stated), that:[11]

> "The supporting power of the stays alone will be ample to hold up the floor. If the cables were removed, the Bridge would sink in the center, but would not fall."

Col. Washington A. Roebling disclosed that he was aware that the stays do not act in perfect harmony with the cables and that for a single span he would not advocate their use; yet in this case, on account of interaction between center span and the long side spans, he considered them indispensable and he maintained that the "want of harmony between stays and cables is less in reality than in theory."

It is not clear from the records why unusually long side spans were adopted—very likely to reduce the height of the anchorages and thus to minimize their cost. John A. Roebling realized the resulting difficulties, especially in maintaining "the balance of spans," as he called it. Originally, he considered anchoring down the cables of the side spans halfway between the towers and the anchorages—an idea which was advanced in subsequent years by several engineers who reviewed the design. Mr. Roebling abandoned this feature, however, as not being very effective, and he decided that the motions of the cable saddles were most effectively checked by the stay system.

The bridge was originally built to accommodate (on two tracks) passenger trains composed of cars attached to an endless rope propelled by a stationary engine. Two 2-lane roadways were to serve horse-drawn vehicles, and a pedestrian promenade was provided on a central elevated platform (see Fig. 5).

The live load corresponding to this traffic capacity was estimated at 1,800 lb per ft of bridge and, with an estimated dead load of 8,750 lb, brought the total load to be carried by the bridge to 10,550 lb.

In course of time a trolley track was placed on each roadway, the inner tracks were used by heavier electric trains, and certain additions were made to the floor structure, so that for a period of time the bridge carried as much as 40% more load than was originally intended.

Review of Design in Light of Present Knowledge

In 1943, on the eve of transforming the Brooklyn Bridge from a structure principally for passenger traffic in electric trains and trolley cars into a structure for modern highway traffic, it appeared advisable to review its design with a complete calculation of the stresses and to undertake an examination of its physical condition.

The completed investigation aimed first at determining the limitations of capacity without major alterations and second at exploring the possibilities of major reconstruction to create an up-to-date link in the highway system.

The Main Carrying System: Cables, Stiffening Trusses, and Stays.—Study of the original design and changes made in course of time reveal a stress condition

[11] "Report of John A. Roebling, C. E., to the President and Directors of the New York Bridge Company on the Proposed East River Bridge," Eagle Book and Job Printing Dept., Brooklyn, N. Y., 1867, pp. 18 and 19.

that is far more complex, statically indeterminate, and uncertain than would appear from a superficial examination of the geometry of the system.

Fortunately, however, the uncertainty of stress action does not apply to any great extent to the carrying members upon which the safety of the structure depends—the cables, towers, and anchorages. Uncertainty as to stress action is confined to the vertical and lateral stiffening systems, damage to which does not necessarily endanger the safety of the structure.

As in most suspension bridges the four cables are continuous from anchorage to anchorage and form natural catenaries under the loads transmitted to them by the suspenders (Fig. 8). On top of the towers the cables rest on cast-iron

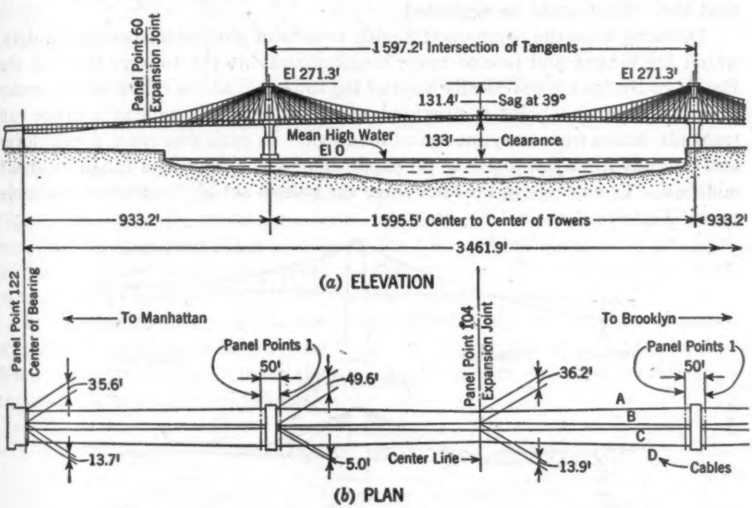

FIG. 8.—GENERAL PLAN AND ELEVATION, THE BROOKLYN BRIDGE

saddles and these in turn bear on nests of rollers designed to permit longitudinal motions of the cables under temperature changes and unbalanced loads. These rollers are very small (only 3.5 in. in diameter); and in course of time collection of dirt and rust, and in some cases dislocation of the rollers, increased the friction to such an extent that under most ordinary conditions no motion took place. Only on a few rare occasions of severe loadings was a "slipping" of the saddles observed. For future highway traffic, the existing roller nests may be considered frozen, and any unequal cable pull can be assumed transmitted to the rigid towers.

The bridge thus acts as three independent suspension spans, and this condition was assumed for the calculation of stresses in the first phase of conversion, in which the cable saddles would be left as they were. This realistic assumption simplified the stress calculations. On the other hand, the inaction of the roller nests has introduced uncertain stresses because it is not known under what temperature and live loads the rollers did become frozen. The floor is

suspended from the cables by the customary wire-rope suspenders at the floor beams.

Six stiffening trusses are placed along the floor (see Fig. 5); four of them are close to the four cables and the two intermediate trusses are placed between the outer and inner cables. The four inner trusses were made 17 ft deep, whereas the outer trusses are only 8.75 ft deep. This cross-sectional arrangement is one source of indeterminateness, although not a major one since the continuous and closely spaced floor beams are sufficiently rigid to assure a fairly even deformation of the six trusses. Furthermore, the moment of inertia of the two outer trusses is only about one eighth of that of the four inner ones, so that their effect could be neglected.

Differing from the common stiffening trusses of modern suspension bridges, which are hinged and free to move longitudinally at the towers, those of the Brooklyn Bridge are practically fixed at the towers. At the center of the center span, an expansion joint is provided which, although it acts as a hinge can transmit shears from unsymmetrical loadings. In each side span, a cantilever arm extends from the tower to an expansion joint acting as a hinge at about midspan. From there to the anchorage the trusses act by themselves as simple spans (Fig. 9).

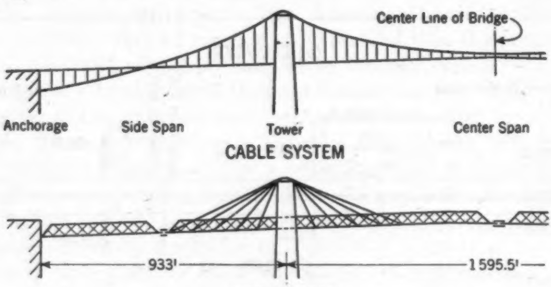

Fig. 9.—Cable and Stay Systems, Brooklyn Bridge

The four stiffening trusses near the cables are supplemented by a system of diagonal stays which run from the tops of the towers to the bottom chords of the trusses (Fig. 8). Because the trusses are fixed longitudinally at the towers they form (together with the stays) a complete cantilever system superimposed upon the cable system. Thus, there are two distinct, but interacting, vertical carrying systems, which form a highly indeterminate compound system. Although the interaction between the two systems for temperature, live load, and any additional dead load can be calculated fairly reliably on the basis of the elastic properties of the component members, the stresses under the original dead load are by no means determinable with any degree of accuracy.

The lower chords of the stiffening trusses must resist the horizontal components of the stay tensions in addition to the flexural stresses caused by the bending of the trusses. These direct stresses become cumulative and very large toward the towers and have been the reason for overstress in the bottom chords.

The web system of the four deep stiffening trusses is formed by vertical posts at the floor beams and a quadruple system of diagonals composed of forged bars (Fig. 10). Half the diagonals (the so-called "counters") are adjustable in length. In course of time many of the counters have been tightened far beyond a nominal initial stress, thus inducing appreciable uncertain stresses.

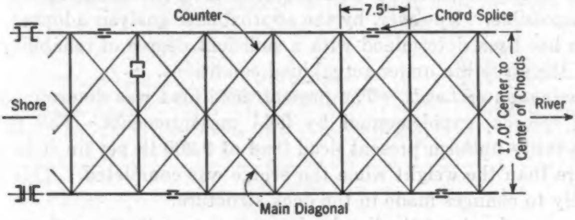

FIG. 10.—INNER AND INTERMEDIATE (HIGH) STIFFENING TRUSSES

The top chords of the trusses were provided with a number of construction joints, three in each half of the center span, which created zero moments at those points. These joints were later bolted tightly; but, since there is no record of the stress condition existing at the time of the bolting or of the final riveting of other truss connections, another uncertainty is introduced with respect to the stresses from the original dead load.

In addition to these complications and uncertainties affecting the primary or axial stresses, secondary stresses are caused by faulty or crude design details or lack of proper maintenance. In fact, such defects have led to a number of local structural failures in the past.

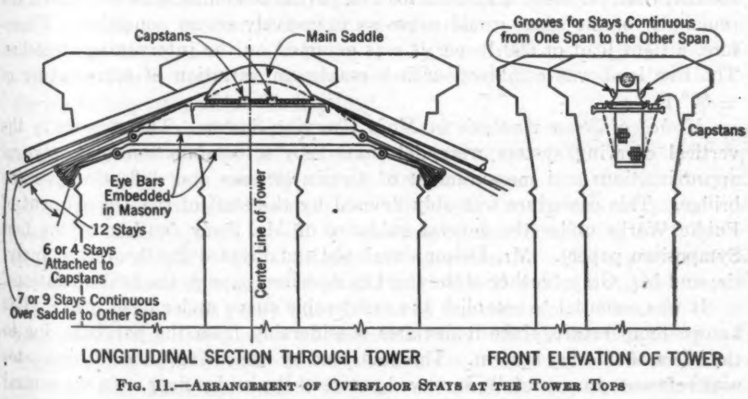

FIG. 11.—ARRANGEMENT OF OVERFLOOR STAYS AT THE TOWER TOPS

One of the most incongruous details is the attachment of the stay ropes at the tops of the towers (Fig. 11). The stay ropes nearest the towers are connected to wrought-iron bars anchored in the tower masonry. Others are fixed to the saddle bed plates and some pass over the saddles. As a result, the latter group moved longitudinally with the saddles, while the others remained fixed.

Such motions must at times have caused appreciable redistribution of the stresses between the various stays and between the stays and the main cables. It would seem that on one occasion excessive strain put on certain stays caused excessive compression, with resulting bending or initial buckling, in the bottom chords of the stiffening trusses to which the stays are attached.

Under these conditions an accurate stress calculation throughout the structure is impossible. However, by the approximate analysis adopted, the stress condition has been determined with a sufficient degree of reliability to assure safety of the structure under actual load conditions.

Determination of Loads.—The present dead load was determined from the available records, supplemented by field measurements. The field survey showed a fairly uniform present dead load of 9,200 lb per lin ft or 800 lb per lin ft more than the weight when the bridge was completed. This increase is due largely to changes made in the deck structure.

When an estimate of the live load was being made, it was known that the elevated trains would be abandoned. They have since been removed, permitting the use of the tracks between the inner stiffening trusses by the trolley cars and leaving the two 17-ft roadways free for vehicular traffic.

Preliminary calculations indicated that a live load corresponding to unrestricted vehicular traffic on the two roadways would cause excessive stresses; and for this reason, as well as on account of the narrowness of the roadways, it was concluded that the vehicular traffic should be restricted to passenger automobiles as, in fact, it has been since 1925. On this assumption, the live load used for the calculations of the stresses in the existing structure was estimated at 2,400 lb per ft of bridge.

When applying this live load in the design of the stiffening system, it was realized that, imposing maximum load on partial stretches, with no load on the remainder of the span, would cause an excessively severe condition. Therefore, a light load of 600 lb per ft was assumed on the intervening stretches. The live load was combined with a maximum variation of temperature of $\pm 50°$ F.

Method of Stress Analysis in Main Carrying System.—The stresses in the vertical carrying system were determined by a combination of analytical approximations and measurement of certain stresses and deflections on the bridge. This procedure was ably devised by the staff of the Department of Public Works under the general guidance of Mr. Seely (author of the first Symposium paper). Mr. Delson developed and directed the theoretical analysis; and Mr. Gray (author of the third Symposium paper), the field operations.

It was essential to establish the exact cable curve under dead load and at known temperature, since it deviates considerably from the parabola due to the effect of the stay system. This was done by measuring the cable ordinates with reference to a carefully surveyed profile of the bridge floor. In the central section, outside the stay attachments to the floor, the cable curve was found to be a parabola, as expected; but it flattens considerably toward the towers, indicating the increasing absorption of the floor panel loads by the stay system. The maximum deviation from the parabola under dead load at 39° F is 4.75 ft in the center span and 5.3 ft in the side span (Fig. 12).

It was also essential to determine directly the dead-load tensions in the stay ropes. This was done by measuring the sag of certain selected stays and calculating the tension which produces that sag—proper adjustment being made for temperature differences.

From the dead-load concentrations and the stay tensions thus found, it was possible to determine the distribution of the dead load between cables and

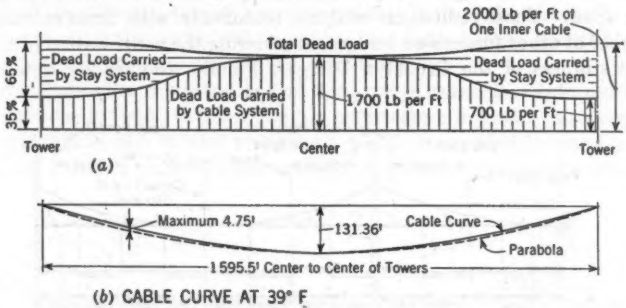

FIG. 12.—DISTRIBUTION OF DEAD LOAD IN THE CENTER SPAN

stays, to check the form of the cable curve, and to calculate the dead-load stresses in the cables.

Since there was no record of the erection procedure with respect to the stiffening trusses, it appeared reasonable to assume that, as is done in modern practice, the bolted construction joints in the top chords remained untightened and free to move and also that the other truss connections remained unriveted, until at least the greater part of the dead weight was in place. Under this assumption the trusses would be practically free from the original dead-load stresses. The stresses from subsequently added dead load were calculated by the method developed for the live load.

The stresses from live load and temperature were calculated first by a so-called elastic theory—that is, the relieving effect of the deflections was ignored. Since there are fifty stays in the center span, with twenty five near each end, in addition to the unknown cable pull, for any unsymmetrical live load, the elastic system would be statically indeterminate in the fifty-first degree. To simplify the laborious and unnecessarily refined procedure involved, the stays were assumed to act in groups of several adjacent stays of equal tension and each group was replaced by one resultant. Thus, the center-span system was simplified to a system statically indeterminate in the seventh degree for unsymmetrical loads. For symmetrical loads in the center span and for each side span the system became indeterminate in the fourth degree, requiring the solution, respectively, of seven and four elastic equations for each separate loading.

A further simplification was introduced by dividing the spans into approximately equal individual live-load lengths and assuming only full-load lengths for any load position. The moments and shears were calculated separately for

each load length and the results were combined for maximum values (Fig.13). The chord stresses so found were then reduced to allow for the effect of the deflections caused by the live load. The reduction was determined by measuring the deflections and certain chord stresses under an experimental elevated train placed on the bridge and then comparing the stresses with those calculated by the elastic theory for that loading. This procedure led to stress reductions of from 15% to 25% in the side span and from zero to 20% in the center span. These reductions compare reasonably with those calculated for a number of other suspension bridges, considering the contribution of the stays to the stiffness of the Brooklyn Bridge. Finally, the readily determinable

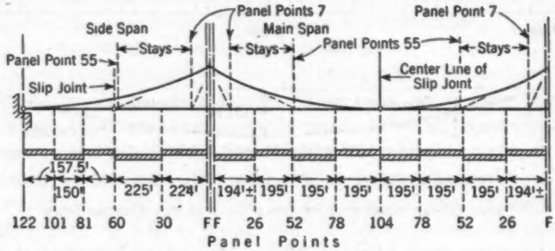

FIG. 13.—ASSUMED LOAD LENGTHS

direct compression stresses in the bottom chords were added to the flexural stresses, so reduced, as horizontal components of the stay-rope tensions.

The Make-Up and Strength of the Principal Members and Their Safety Under the Assumed Loads.—The stress investigations were supplemented by a program of tests to determine the present strength and other physical characteristics of the more important members, cables, anchorage chains, stay ropes, chords, and web members of the stiffening trusses. These tests are described more fully in the third and fourth papers of this Symposium.

Each of the four cables has a diameter of 15.75 in. and is composed of nineteen strands of wires which vary considerably in size, some being No. 7 gage and some No. 8 gage. The aggregate net area has been estimated at 144.8 sq in. Specimen tests on sixty wires cut from the cables show an ultimate strength ranging from 146,000 lb per sq in. to 192,000 lb per sq in., with an average of 162,600 lb per sq in. Other properties, although indicating a fairly hard steel, give assurance of an acceptable condition of the wire, with no apparent deterioration since it was erected.

The maximum axial stress in the cable, under the live load of 2,400 lb per sq in., is calculated at 44,600 lb per sq in.—less than 30% of the average strength of the wire. The physical qualities of the wire would justify a cable stress of 60,000 lb and therefore permit an increase in cable stress of as much as 33% in case of an eventual reconstruction of the floor structure. In such reconstruction, if the stay system is eliminated, thus throwing the entire load on the cables, the margin for additional load would be only about 18%.

The stays are steel wire ropes 1.75 in., 1.875 in., and 2 in. in diameter.

A full-size test of a rope disclosed an ultimate strength of 147,000 lb per sq in. The calculated live-load stress of 23,000 lb added to the dead-load stress of 21,000 lb derived from the sag measurements gives a maximum stress of 44,000 lb per sq in., which is only 30% of the ultimate strength of the rope. Therefore, the stays are also capable of sustaining a considerable increase in live load.

The stress calculations and measurements disclosed that the chords and web members of the stiffening trusses were the weakest parts of the structure. This is corroborated by the many web members that have broken and the chords that have been bent under severe load conditions.

A typical chord is composed of two 9-in. rolled channels, reinforced in the heavier sections by web plates. The top chords were originally also provided with a cover plate, and in later years cover plates were added to many bottom chords (Fig. 14). In place of efficient latticing, the two channels are connected

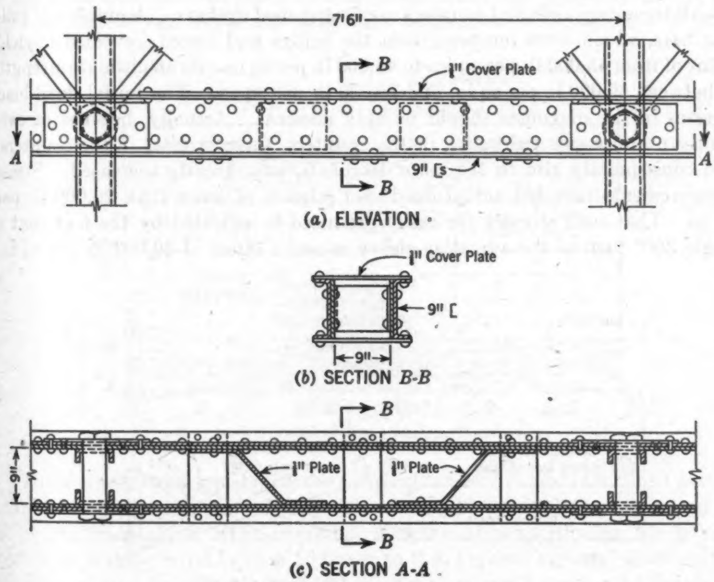

Fig. 14.—Typical Panel, Bottom Chord

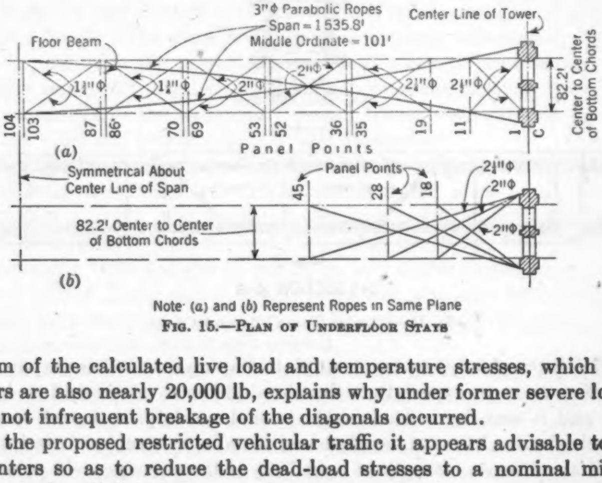
(in each 7.5-ft panel only) by two bent plate diaphragms. This very inefficient detail gave reason to expect that the chords have a relatively low buckling strength and it was deemed advisable to make a full-size model test. The model chord, built without cover plate and of ordinary structural steel, actually developed an ultimate strength of only 78% of the average yield point of the material.

The actual chords are made of high carbon steel. Specimen tests cut from the chords revealed an average yield point of 48,700 lb per sq in.—as high as

that for present-day silicon steel. Application of the 78% ratio to this yield point gave an estimated buckling strength of 38,800 lb per sq in. for the chord members without cover plates. With allowance for the cover plates, where added in later years, the strength was estimated at between 40,000 lb per sq in. and 42,000 lb per sq in. of the original section.

Compared to these strength figures, the calculations indicate compression stresses in some bottom chord members of more than 40,000 lb per sq in. and in a large number of more than 30,000 lb per sq in. In view of these large calculated stresses, it is not surprising that, in the region of the most highly stressed chord members, the latter sustained permanent deformations. On the other hand, although the chords were never straightened, no more serious consequences resulted thereafter, demonstrating that relatively high working stresses in the stiffening trusses of suspension bridges can be permitted. Nevertheless, it is advisable to reinforce the overstressed chord members in the Brooklyn Bridge.

All truss diagonals and counters are forged steel eyebars. A number of full-size bars, which were removed from the bridge and tested, revealed a yield point of from 43,000 lb per sq in. to 46,000 lb per sq in. and an ultimate strength of between 69,000 lb per sq in. and 76,000 lb per sq in. The initial dead-load stresses in the diagonals should be only nominal. Actually, because of evidently promiscuous tightening of the counters, these stresses in the counters, and consequently also in the main diagonals, were greatly increased. Stress measurements revealed actual dead-load stresses of more than 20,000 lb per sq in. That such stresses are easily produced is indicated by the fact that a single 360° turn of the adjusting sleeve causes a stress of 30,000 lb per sq in.



Note (a) and (b) Represent Ropes in Same Plane

FIG. 15.—PLAN OF UNDERFLOOR STAYS

The sum of the calculated live load and temperature stresses, which in some members are also nearly 20,000 lb, explains why under former severe load conditions not infrequent breakage of the diagonals occurred.

For the proposed restricted vehicular traffic it appears advisable to adjust all counters so as to reduce the dead-load stresses to a nominal minimum. The diagonals will then have enough spare strength for such traffic.

The Lateral System.—The system designed to resist wind and other lateral forces is also one of great complexity (Fig. 15). It is composed in part of a

lateral truss whose chords are the lower chords of the outer stiffening trusses. The web system is formed by the floor beams and double wire-rope diagonals. Additional diagonal ropes are connected directly to the towers. Thus, in each half of the center span, and between the tower and the hinge in the side span this lateral truss acts as a cantilever arm fixed at the towers.

The truss system is supplemented by a pair of parabolic wire-rope cables, 3 in. in diameter, which, in the center span, stretch from tower to tower with a central sag somewhat greater than the width of the floor. In spite of the relatively wide floor (one nineteenth of the main span), the lateral truss is very flexible on account of the extensibility of the wire-rope diagonals. The very flexible parabolic wind cables likewise offer little resistance to lateral deflection. Consequently, the floor deflects easily and transmits a substantial part of the wind force to the main cables, which thus become the third important element resisting the lateral forces. Fig. 16 shows the calculated distribution of the wind load between lateral truss, wind cables, and main cables. Area ABC in Fig. 16 represents the wind load transferred from the deck to the cables.

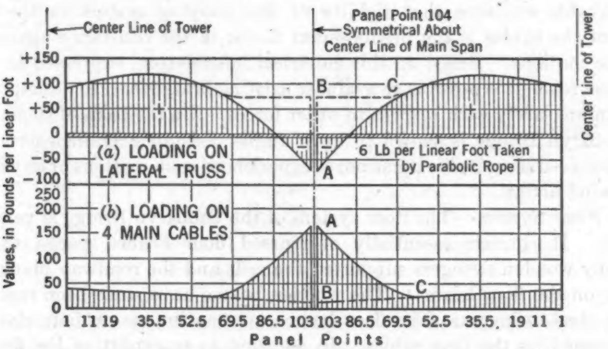


FIG. 16.—WIND-LOAD DISTRIBUTION, MAIN SPAN

To enhance lateral resistance, the main cables were placed in inclined planes as in many earlier bridges. Today this cradling of the cables is recognized to be of negligible effect. The prevailing practice of proportioning the lateral system for a static wind force of 30 lb per sq ft of exposed surface (which corresponds to a wind velocity of about 100 miles per hr) would require the Brooklyn Bridge to be adequate for a wind force of about 950 lb per ft of bridge. This force would deflect the bridge laterally at the center 6.5 ft, or by one two hundred and fiftieths of the span, and would cause wind stresses of about 30,000 lb per sq in. in the truss chords. Such stresses in possible combination with the high live-load stresses must be considered excessive.

Such a condition, however, appeared unrealistic. Observations showed maximum deflections, under a quartering wind of 35 miles per hr, of only 2 in.—or a fraction of the theoretical deflection corresponding to this wind velocity. This great difference between actual and theoretical deflections must be due

in large part to the fact that the static wind pressures acting on large suspension bridges are far lower than the theoretical ones assumed in modern design. This is confirmed by observations on a number of other large suspension bridges.

On the basis of observed deflections it was concluded that under severest wind velocity the Brooklyn Bridge would probably not deflect more than 1 ft at the center. This assumption was made in computing the wind stresses, which were found to be very moderate, both in the trusses and in the parabolic wind cables. The latter are probably rarely under stress.

In view of the fact that the lateral flexibility of the Brooklyn Bridge is within the range of that of several longer and much narrower suspension bridges which have experienced oscillations in wind, it seems pertinent to inquire what resistance the Brooklyn Bridge offers to such motions, which were disastrous to the Tacoma Narrows Bridge in the State of Washington.

Contrary to widespread belief, evidence shows that within practical limits lateral flexibility has little or no influence on oscillations in wind. The behavior of many suspension bridges during the 120 years since about 1825 furnishes unmistakable evidence that rigidity of the carrying system in the vertical planes of the cables is the predominant factor in the resistance against aerodynamic motions. Based on this empirical information, expressed in rational analytical form, it is possible to evaluate existing bridges and to design new ones for optimum safety with respect to other forces. On the basis of such analysis, the Brooklyn Bridge is shown to have ample resistance against aerodynamic oscillations—during its life it has never experienced such motions or any ill effects under wind action.

The Floor System.—The floor system of the Brooklyn Bridge is very simple (Fig. 5). It consists essentially of trussed floor beams spaced at 7.5 ft. Originally wooden stringers supported the rails and the roadway planks rested directly on the floor beams. The wooden beams have since been replaced by shallow steel stringers. The floor beams are continuous on four elastic supports formed by the four cables. In addition to transmitting the floor loads to the cables, the floor beams must distribute the proper share in resisting bending to the intermediate stiffening trusses.

Under former severe traffic conditions, coupled with high secondary stresses due to faulty details, the floor beams must have been subjected to high stresses, and consequently suffered local fractures of the chords on several occasions. Under restricted vehicular traffic, even allowing for an occasional 10-ton truck, the stresses are well within permissible limits, so that, except for local corrections, strengthening of the floor beams is not necessary.

The Towers.—The towers below the floor are massive, but partly hollow masonry pillars, mostly of granite (Fig. 17). Above the floor they consist of three masonry shafts joined at the top by Gothic arches. The towers are 271 ft above high water, 140 ft long, and 59 ft wide at the water line. Through a spreading base, mostly of limestone, each tower rests on a concrete-filled timber caisson about 170 ft long and 102 ft wide. As previously mentioned, these caissons were sunk by the pneumatic process. They were launched in 1870 and 1871 and were then of unprecedented size.

The New York caisson rests, at a depth of 78 ft, on a shallow layer of hard compact material overlying the bedrock of gneiss. The Brooklyn caisson is founded on a compact formation of sand, gravel, and boulders at a depth of 45 ft.

Because of the immovability of the cable saddles, any unbalanced horizonta cable pull must be resisted by the towers in bending. The calculations indicate resulting compression stresses in the masonry, at the floor level, of more than 700 lb per sq in.—about 50% of which is due to bending. In view of the excellent condition of the masonry, these stresses may be considered per-

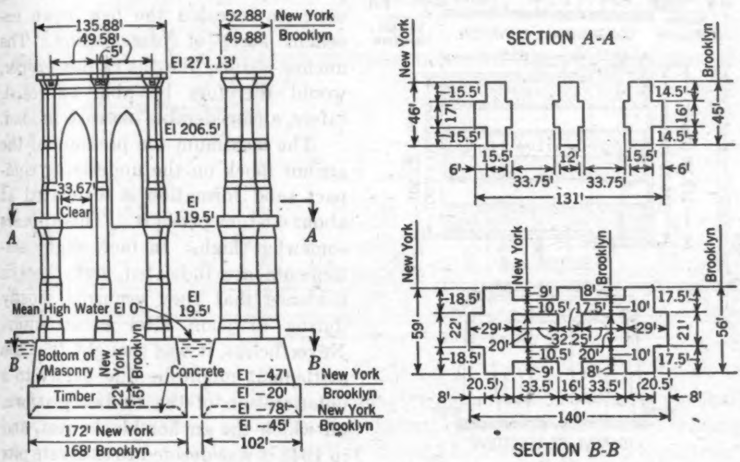

FIG. 17.—THE TOWERS

missible, but in any major reconstruction they should not be allowed to increase. Such an increase can be prevented by reconstructing the cable saddles to assure longitudinal motion and thus avoid bending the towers.

The pressure at the bottom of the New York tower foundation, under balanced cable pull, is calculated at 5.5 tons per sq ft; and the maximum edge pressure under unbalanced cable pull, at 9 tons. The pressures under the Brooklyn tower are somewhat less. There is no evidence that any settlements have occurred; but, like the stresses in the masonry, the foundation pressures should not be increased.

The Anchorages.—The anchorages form massive limestone masonry blocks about 90 ft high (Fig. 18). They rest on shallow timber grillages about 130 ft long and 120 ft wide, originally placed entirely below the ground-water level. The anchor chains, from their attachment to the cables at the top of the anchorage, pass through the anchor block with a right-angle arc. At the bottom they are attached to cast-iron anchor plates. The anchor chains are composed of forged wrought-iron bars and, except for a short piece at the upper end, are completely embedded in the masonry. The cable stress be-

comes gradually dissipated by friction in the masonry and the partly exposed upper links of the chain may be considered the most critical ones.

The anchorage bars had been made for a specified strength of 50,000 lb per sq in., and a test coupon cut from a similar forged erection bar which had been left in place showed a strength of 48,000 lb per sq in., whereas the maximum stress in the anchor bars under a live load of 2,400 lb per ft is only 12,000 lb per sq in. A piece exposed by removing the surrounding concrete revealed the bar in an excellent state of preservation. The anchor chains, like the cables proper, would therefore be able to resist, safely, a considerable increase in load.

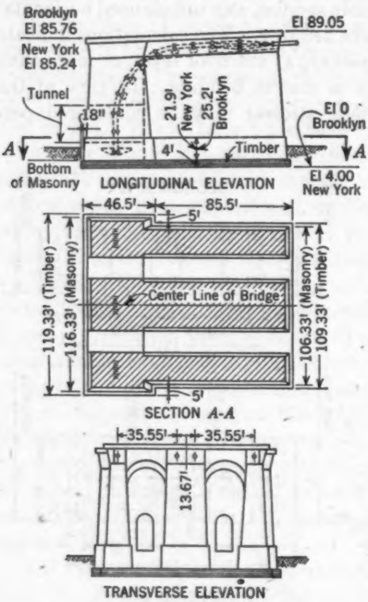

FIG. 18.—THE ANCHORAGES

The maximum toe pressure of the anchor block on the underlying compact sand formation is estimated at about 6.5 tons per sq ft. This appears somewhat high. In fact, slight settlements are indicated, but there is evidence that they occurred mostly during or soon after construction. Nevertheless, it was thought that the settlement might be due partly to a deterioration of the timber platform on which the anchor blocks rest, and in 1943 it was decided to excavate pits to the bottom of the base to permit examination of the timber. Although the ground water was lowered, so that on the New York side the timber platform is partly, and on the Brooklyn side entirely, above the present water level, the condition of the timber was perfectly sound. The masonry likewise is in excellent condition so that there is sufficient cause for confidence that even a moderate increase in pressure would not result in further settlements or in any way endanger the stability of the anchorages.

Possibilities for Reconstruction to Serve Six-Lane Highway Traffic

A simple plan of alteration has been developed by which the bridge can accommodate two 3-lane roadways for passenger automobiles and buses when the surface car tracks are removed (Fig. 19). The scheme involves the removal of the top chord and web members of the two intermediate trusses and their re-erection in place of the two shallow outer trusses. The top chords of each remaining pair of trusses are to be connected by knee-braced struts. The trolley tracks and the present wooden roadway flooring would be replaced by a light open-grid steel floor over the full width of each 3-lane roadway.

The cost involved in this alteration is very moderate and the changed condition is expected to be adequate for many years, especially since the present approaches and street connections make continued exclusion of truck

traffic advisable. It is estimated that the present capacity volume of vehicular traffic would be more than doubled.

A tentative study also indicates that it will be feasible to reconstruct the bridge for 6-lane unrestricted highway traffic, corresponding to a live load of 3,000 lb per ft of bridge. By the use of a light floor, the increased load would be resisted safely by the cables, towers, and anchorages, provided the cable saddles on top of the towers are rebuilt to assure longitudinal motion under live load and temperature changes. It is questionable whether this can be done at the same time making the necessary floor alterations economically

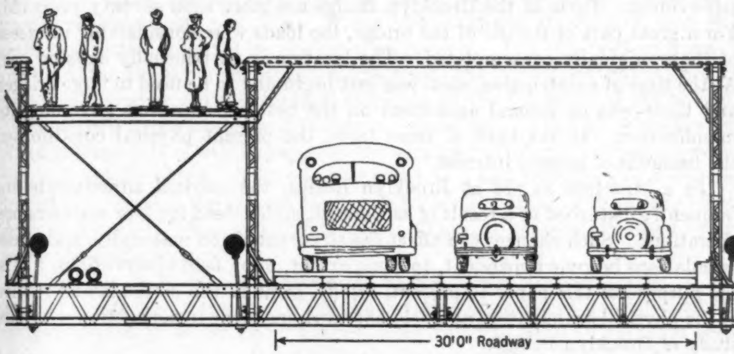

FIG. 19

while the cables remain in place. It may be found more economical to rebuild the cables completely. Whether the diagonal stays would be retained is largely a question of possible sentiment in favor of preserving the characteristic appearance of the bridge.

On account of excessive stresses in the stiffening trusses and floor system, complete reconstruction of the suspended structure would be necessary.

CONCLUSION

Despite the crudeness of the theories employed in its design, the incongruities of some of the design features, primitive structural details, and consequent defects which developed during the life of the Brooklyn Bridge, this structure has given greater service than was originally anticipated.

Its behavior is a testimony to the fundamental soundness and safety of its design and that of the suspension type of bridge in general. The bridge as it exists today cannot be considered serviceable for unrestricted modern highway traffic, with two tracks for electric surface cars; but with moderate structural changes it can be reconditioned to serve a greatly increased volume of automobile traffic for many years.

A complete reconstruction of the suspended structure, with retention of the towers and anchorages, and possibly even the cables, to transform it into a modern 6-lane highway bridge for unrestricted traffic is feasible and can be accomplished without altering the general appearance of this magnificent structure, which has become world renowned and a cherished landmark of the City of New York.

PHYSICAL EXAMINATION AND FIELD OBSERVATIONS

By Nomer Gray,[12] Assoc. M. ASCE

Introduction

The need for a physical examination in an investigation of this kind is self-evident. Parts of the Brooklyn Bridge are more than seventy years old. For a great part of the life of the bridge, the loads were considerably in excess of those originally contemplated. The location is an unusually exposed one. At the time of construction, steel was just beginning to be used in large bridges and there was no general agreement on the best specifications governing its manufacture. In the light of these facts, the present physical condition of the bridge is of general interest.

In a structure as old as Brooklyn Bridge, the original adjustments are frequently disturbed as a result of settlement, added dead load, or maintenance operations. Such changes can affect the stress condition materially, and stress calculations become dependent, to some extent, upon field observations. It is the purpose of this paper to present, briefly, some of the methods and results of the physical examination and field observations made in connection with this study of Brooklyn Bridge.

The datum originally used in the construction of the bridge was mean high water at the site, as established by tide gage observations made by the bridge engineers. It was considered advisable to refer the 1943 surveys to this original datum. Unfortunately, no records of old bench marks were found, and many discrepancies arose in attempting to reconcile old plan elevations with the 1943 level runs. This problem was solved satisfactorily by reference to a very comprehensive set of precise levels[13] made about 1910 by the City of New York for the purpose of establishing one datum for all city departments. Library records of this excellent work provided ties with the datum planes used by the borough governments. The recorded relationship between the datum planes of Brooklyn Bridge and those of the Borough of Brooklyn and of the Borough of Manhattan controlled the level surveys. The first levels taken were for anchorage settlement.

Settlement Observations

The two anchorages are of limestone masonry, laid with joints of Rosendale cement mortar. Their construction is identical, except that the base of the masonry of the Manhattan anchorage is 4 ft lower than the base of the masonry of the Brooklyn anchorage. Both are supported on timber grillages 4 ft thick which, in turn, rest upon well-compacted sand. Close examination of the masonry does not reveal any cracks or spalls, and the original mortar of the

[12] Civ. Engr., Dept. of Public Works, City of New York, New York, N. Y.

[13] "Precise Levelling in New York City," by Frederick W. Koop, City of New York Board of Estimate and Apportionment, Office of the Chf. Engr., New York, N. Y., 1915.

exterior joints is in excellent condition after 70 years. A level check of a bed joint near the ground surface at the Brooklyn anchorage showed an extreme variation in elevation of 3 in. and an average settlement, from plan elevation, of 5 in.

In the absence of exact information regarding allowances made, during construction, for anticipated initial settlement, a comparison between lower-course elevations and plan elevations can be misleading. A level check with the top course is more dependable, since corrections in the estimated settlement during construction will have been made to bring the upper courses closer to plan grade. The average settlement of the Brooklyn anchorage based upon top-course elevations was 3 in. From this evidence it appears that the anchorage settled about 2 in. during construction. The observed settlement and tilt of the Brooklyn anchorage, coupled with the knowledge that the bridge rested on a timber grillage, aroused suspicion of the condition of the timber. Old construction records showed the ground-water level to be just below the top of the grillage. It is well known that the ground-water level has been lowered materially in Brooklyn. This was confirmed by a test boring which showed a drop of 13 ft, placing the present ground-water level 11 ft below the grillage and, incidentally, 11 ft below mean high water. Thus, it became necessary to examine the grillage.

A test pit 26 ft deep was excavated at the face of this anchorage, at the point of greatest settlement. When the concrete encasement was stripped off, the yellow pine 12-in. by 12-in. timbers were found to be in an excellent state of preservation, except for the first inch penetrated. It had been intended to take horizontal cores from the timber grillage, using a standard test boring rig placed in the bottom of the test pit, but great difficulty was encountered because of numerous drift bolts in the timber. Hand-operated auger borings, 5 ft deep, were made, without revealing any change in the quality of the chips. The auger holes may be seen in the exposed timbers in Fig. 20.

Conditions at the New York anchorage were better. The settlement (5 in.) was uniform judging by the lower-course elevations, and only 1.5 in. as measured by the top-course elevations. The present ground-water level is about 8 in. below the top of the grillage, which (as nearly as could be observed) is kept completely wet by capillary action. Auger borings showed sound wood in the accessible upper courses of the grillage. There is additional evidence that most of the settlement in both anchorages occurred during construction or shortly thereafter.

Physical Condition of Structural Members

The exposed ends of the wrought-iron eyebars in the anchorage galleries showed no sign of corrosion. At the point where the eyebars enter the wall, concrete was removed for a depth of several inches. The original coating of red-lead paint on the bars was found to be intact. The massiveness of the masonry towers (Fig. 7) contrasts strongly with the relative slenderness and flexibility of modern steel towers. Some conception of the size of the towers may be gained from the fact that the respective weights are 93,000 tons and 108,000 tons, each being considerably heavier than the 60,000-ton anchorages.

The combined weight is about twelve times that of the suspended superstructure.

The tower masonry is almost entirely of granite. Although subjected in places to appreciable stresses, there is no apparent sign of distress in the masonry. With the exception of one or two places where the stone has been exposed to an unusual amount of wetting and drying, the mortar of the original joints is in excellent condition.

As in the case of the anchorages, the two towers rest upon heavy timber grillages 15 ft and 22 ft thick, respectively. Their great thickness is explained

FIG. 20.—EDGE OF A TIMBER CRIB UNDER THE BROOKLYN ANCHORAGE

by the fact that they originally formed the tops of the compressed air caissons used in construction, and as such were designed as slabs to bear tremendous loads. Immediately below the grillage there is a mass of concrete, from 6 ft to 7 ft thick, filling what was formerly the working chamber of the caisson.

At the site of the Brooklyn tower, rock lies more than 90 ft deep. The difficulty of excavating and the fact that the material encountered gave evidence of a bearing capacity greater than 20 tons per sq ft led Washington A. Roebling to found the Brooklyn tower on compact sand, gravel, and boulders at El. − 45.

The Manhattan tower is generally regarded as resting on rock. Old reports indicate that the rock surface under the tower varies from El. − 75 to El. − 90. The caisson cutting edge is at El. − 78 and the concrete fill bears upon rock

projections and hardpan, filling the depressions in the rock. The direct bearing pressure of about 7 tons is conservative for these materials.

The situation at the Manhattan anchorage with respect to the tower grillages differs materially from that at the Brooklyn anchorage. The tops of the grillages are, respectively, 20.0 ft and 46.5 ft below mean high water. Soundings indicate that the river bottom adjacent to the towers is 20 ft and 34 ft above the respective grillages. At these depths, the timber, which is completely encased in concrete, should be entirely safe from attack by marine organisms.

Surveys to determine plumbness and settlement of the towers confirm this judgment of the state of the grillages. No settlement or tilting was detected in either tower. The towers, which are higher than 300 ft (Fig. 17), are plumb within 0.5 in.

Movement of Cable Saddles

The cable saddles at the tower tops each rest upon about forty cylindrical rollers, 3.5 in. in diameter. This design had been adopted principally to provide for saddle movement during erection. The base plates were placed 12 in. shoreward and the saddles were originally an additional 6 in. shoreward from the transverse center line of tower. The positions of the saddles at various times are given in Table 1.

TABLE 1.—Riverward Movement of Cable Saddles A, B, C, and D, Fig. 8, from Their Original Positions[a]

June, 1943	7-12	7-8	8-8	8-0	5-14	6-12	6-12	6-10	7-3	3-10

[a] The original position of each saddle was 18 in. shoreward from the transverse center line of the tower. Dimensions are in inches and sixteenths—for example, "3-11" denotes 3 $\frac{11}{16}$ in. [b] The column of totals gives the average total movements from the beginning of construction to the date indicated. The column marked "operation" gives the average total movements during the time the bridge has been in operation. [c] Two days before the bridge was opened. [d] The first year that trolley cars were operated on the roadways. [e] Immediately after the bottom chords buckled.

Col. Washington A. Roebling stated[14] that the sensitiveness of the saddles under unequal loading, during the erection of the superstructure was quite marked but that the saddle movement in the completed structure, under ordinary traffic, would be very small indeed. This proved to be the case, although under increasing dead loads and live loads the saddles moved very gradually toward the river.

[14] "Report of the Chief Engineer on the Strength of the Cables and Suspended Superstructure of the Bridge to the Board of Trustees, January 9, 1882," Eagle Book and Job Printing Dept., Brooklyn, N. Y., 1882.

During erection of the cables and superstructure, the saddles moved an average of $3\frac{3}{16}$ in. toward the river. After the bridge was opened their movement, to June, 1943, has amounted to an additional $3\frac{5}{8}$ in. Until 1887 movements of the saddles under seasonal temperature changes were observable and amounted to from $\frac{3}{8}$ in. to 0, indicating a variation in rolling friction for the various saddles.

Since 1902 the saddle movement has been small and very gradual except in 1922 when two saddles moved suddenly under heavy vehicular traffic and high temperature. Although records of the exact movements since 1915 are lacking, an examination of the saddles indicates that they have not moved for years. The likelihood of movement is dependent, of course, upon the magnitude of unbalanced side and main span cable pulls. The friction is now very great as a result of a skewing of some of the rollers and an accumulation of rust and dirt, the rollers being practically inaccessible. No movement occurred under a fairly heavy unbalanced test load.

Live loads and temperature changes tend to produce unbalanced cable pulls which, in modern flexible steel towers, are compensated for by movements of the tower tops. This is not so, however, in the masonry towers of the Brooklyn Bridge. As a result of saddle friction and failure of the massive towers to yield easily, the unbalanced cable pulls induce appreciable bending stresses in the towers. The determination of the magnitude of these stresses depends to some extent upon the movement of the tower tops. Analytically, this is a complex problem. It was a relatively simple matter, however, to measure the movement by observations on a full-scale model which, in effect, is what the investigators had in this case. A transit was set at the base of the tower on the prolongation of the transverse center line. Empty elevated trains weighing a total of 600 tons, centrally placed on one span at a time, were used. Movements of the Brooklyn tower top of approximately $1\frac{1}{4}$ in. and $1\frac{1}{2}$ in., respectively, were observed for the load on the main and side spans. Further transit observations revealed that the elastic line of the tower, with the top so deflected, was practically a straight line—a significant phenomenon, as it indicates that the tower rotates principally as a rigid body, about the base. This angular yielding of the base reduces the bending stresses in the masonry.

The towers, generally, were found to be in excellent condition, testifying to the soundness of their construction and the durability of good stone masonry.

The Main Cables

The main cables are the principal supporting members and, as such, merit careful examination. These cables, four in number, are $15\frac{3}{4}$ in. in diameter under the wire wrapping. The exact net area of the cables is not known; but, taking the best estimate as 144.8 sq in., the percentage of voids is 24%. This may be compared with from 19% to 21% of voids in modern cable construction.

To examine the cables in detail, it was necessary to remove the wire wrapping at a number of places. On this bridge, the cable bands were placed over the wrapping, which is continuous from anchorage to anchorage, except through the towers. The wrapping, which originally had been placed by hand, was found to be tight and generally well painted. The watertightness of the

painted wrapping is indicated by the fact that the interior of the cables is dry at the low points. In the worst case after several days of rain, a slight moisture was detected in one cable at the midpoint of the main span.

The wrapping wire was removed from the cables for lengths of from 7 ft to 10 ft at twenty-four points; twelve cable wires were removed at each point—or 0.2% of the cross section of the cable. In each case, a length of new wire was spliced in to replace the wire removed for test. It was possible to remove and

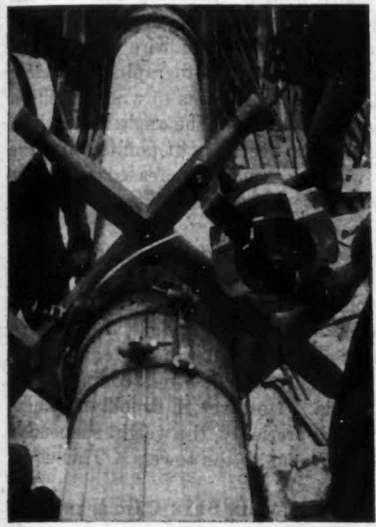

Fig. 21.—Device for Rewrapping the Cable by Hand

Fig. 22.—Long Overfloor Stay Ropes from the Center Line of the Bridge

splice in surface wires within 1 ft of the end of the wrapping. An effort was made to achieve approximately the original tension in each spliced wire by screwing up the threaded sleeve splice. The method of obtaining the correct tension (admittedly not exact) was to approximate the force required to deflect the wire from its straight alinement.

Under the wrapping wire, a loose, dry, chalky substance (which was probably the white lead of the paint applied to the wrapping) appeared between the surface cable wires. When this was brushed away, the cable wires were found to be almost entirely free from rust. At a few points, notably near the center of the main span, some of the surface wires were rusted just under the cable band. This condition rarely extended to a depth, into the cable, of more than two wires. The writer attributes the rusting at these points to two factors: (1) The very short suspender rods, at these points of maximum truss expansion, cause some "working" of the cable bands which tends to abrade the surface wires; and (2) canvas fillers under the cable bands at these points undoubtedly contribute to the retention of moisture and consequent promotion of rust.

For some distance out from the anchorages the deck is supported on top of the cables by short posts. Because of the greater rigidity of this connection between cable and deck, the "working" of the cable bands has caused the wrapping wires to wear ridges into the top surface wires of the main cables and in some cases to break a few of them. The cables have been inspected regularly at these points and the broken wires repaired.

The cables were wedged open to a depth of about 4 in. to permit visual examination of the interior wires at many points. In every instance the interior wires appeared as clean as, and generally cleaner than, the surface wires.

The hand-wrapping frame for replacing the wrapping wire is shown in Fig. 21. Its operation will be self-evident from the photograph. For close contact between adjacent wires the practice, of course, was to wrap uphill—a fact which is not apparent in the photograph because of the angle from which it was taken. The clamps around the cable were necessary at points where the cable had been wedged open, as the wedging usually increased the cable diameter slightly. The wrapping frame was used wherever sufficient clearance permitted its use.

The physical characteristics of the cable wire, as determined from many tests, are the subject of the fourth and final paper in the Symposium.

The shape of the cable curve was a matter of interest, differing as it does from the conventional form. In most modern suspension bridges, the approximately uniformly distributed suspended weight results in an equilibrium polygon very close to a true parabola. Actually, in the stress computations for a truss it is commonly treated as a parabola. However, in Brooklyn Bridge, the effect of the overfloor stays is to reduce, appreciably, the weight suspended from the main cables in the quarter span adjacent to the towers. This effect

TABLE 2.—Ordinate Measurements to the Main Span Cable, in Feet

Description	Panel Points									
	T	6	18	30	42	54	66	78	90	104

of nonuniform distribution of cable load was so marked that a survey of the cable curves became necessary.

Two factors tended to complicate the cable-curve survey: (*a*) The curve changes from minute to minute under passing train loads; and (*b*) there is the usual uncertainty regarding the true cable temperature during the daylight

hours. By making the survey at night, both these difficulties could be overcome, because the train service could be discontinued. However, the difficulty of measuring cable ordinates accurately, in total darkness, will be readily appreciated. The solution of the problem was to make a profile survey of the more accessible top chord of the truss between midnight and dawn, with the train service stopped. With the profile of the top chord as a reference line, it was an easy matter to measure the vertical distances from the cable center line to the top chord at any convenient time, even with trains running. The resulting cable curve, of course, would be that which existed at the time the chord profile survey was made. It may be of interest to record that passing trains produced a deflection at the center of the main span in excess of 1 ft. Their observed effect in elongating suspenders did not exceed $\frac{3}{16}$ in.

Referring to Table 2, the effect of the stays in distorting the curve from parabolic form is clearly discernible. The parabola used for comparison is that which would contain the points of intersection of the tangents at the towers and the low point of the midspan. The measured ordinates were used in the truss stress analysis.

Stiffening Effect of Stay Ropes

One of the distinguishing features of Brooklyn Bridge is the use of overfloor stays to stiffen the suspended structure. These are wire ropes, from 1.75 in. to 2 in. in diameter, which radiate from the tower tops to connect with the trusses at two-panel intervals in the quarter span adjacent to the towers. A view of the stays looking along the center line of bridge is given in Fig. 22. The stays are clipped to the suspenders at every intersection. The flatness of the catenaries of the long stays emphasizes more clearly than figures the high tensions of the stays.

The present condition of the ropes is fair considering their long service in an extremely exposed location and the constantly varying tensions under passing loads. Care has been taken to prevent loss of section by the use of metal sleeves or leather spacers at points of contact with other surfaces. A tensile test was made on a single $1\frac{7}{8}$-in. stay rope, removed from the bridge for this purpose. This stay rope, which had been in service for 60 years, developed an ultimate strength of 147,000 lb per sq in. The modulus of elasticity was approximately 20,000,000 lb per sq in.

The tensions in the stays were set at from 15 tons to 17 tons each in the original design. Knowledge of the present stay tensions was necessary to determine the thrust induced in the bottom chords of the trusses to which they are attached. The cumulative effect of these stay tensions is surprisingly large, being of the order of 500,000 lb in a single bottom chord.

Observations were made to determine the tension in thirty two of the one hundred stays which lie under one cable. As will be appreciated by any one who has ever used a surveyor's tape, the tension in a rope is a function of the sag. The stay tensions were found by measuring the vertical sags. The method, as indicated in Fig. 23, is as follows:

A transit is set up adjacent to the lower end of the stay, the horizontal axis being on a level with a point on the stay. The telescope is directed along the

closing chord, by sighting at the upper end of the stay; and then it is clamped, fixing the vertical angle, which is recorded. Next, the transit is placed, by trial, in a new position so that the line of sight is tangent to the stay, while maintaining the original vertical angle. The method of calculating the desired vertical sag will be evident from Fig. 23. In this manner, it is possible to make all the observations without leaving the bridge floor. The entire operation was frequently completed in 20 min, using one observer and one assistant.

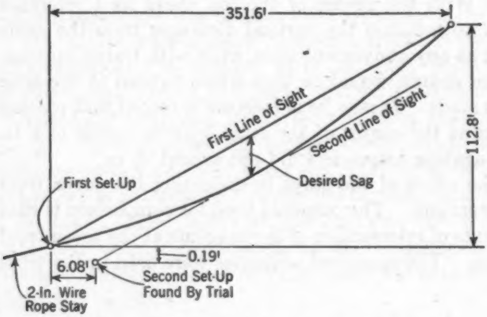

Fig. 23.—Method of Measuring Stay-Rope Stresses (Measured Sag 2.14 Ft and Computed Stress 50.8 Kips Per Sq In.)

The observations were necessarily made at temperatures which differed considerably from the basic temperature of 39° F used in the stress calculations. Therefore, corrections had to be applied to the stay tensions as calculated from the observed sags. When temperatures change, several factors influence the stay tension, as follows:

(1) The stay rope itself tends to change length;
(2) The curve of the main cable changes as the cable length changes; and
(3) The truss shortens or lengthens, thus moving the stay connection horizontally and influencing the stay tension.

The effect of factor (2) is to raise or lower the truss to which the lower end of the stay is connected, thus influencing the tension. Factors (1) and (3) can be treated analytically, but factor (2) offers great difficulty analytically because of the interaction of a number of elements. It proved fairly simple to observe the elevation of the truss at the two temperatures—namely, at 39° F and the temperature prevailing when the sag observation was made. For the long stays, the difference in elevation amounted to as much as 5 in. for a 50° F change in temperature. The increment in stay tension was as great as 23% for a 50° F rise in temperature.

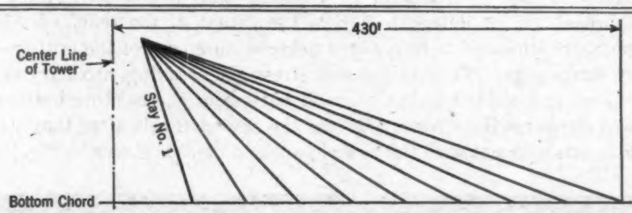
A comparison of the design tensions and the measured tensions is given in Table 3. In maintenance operations on the stays, through the years, the practice has been to turn the adjusting nuts back to their original positions, which procedure, if faithfully followed, should have preserved the initial tensions. The slightly higher present tensions are probably caused by increases in the dead load since the time of the original adjustment.

Stiffening Trusses

The stiffening trusses have tension web members, with adjustable counter diagonals pin-connected to the chords. The small size of the members, the

nature of the details, and the absence of traveling platforms combine to make painting costly. However, inspection indicates that, through most of its long life, the bridge has been well painted. There is no marked reduction in sectional area through corrosion, except at the towers. At this point, curiously enough, the chords lie partly in chases, in the granite, making access for

TABLE 3.—Tensions Measured in the Stay Ropes, in Kips



Item	Description	Stay No.: 4	7	10	13	16	19	22	25

7	Manhattan end; main span	30.2	30.8	22.6	22.4	19.8	28.4	33.9	28.8

painting impossible. Fortunately, the sectional area is greatest here and the same loss of area is not as significant as it would be elsewhere. Nevertheless, it will be necessary to strengthen the corroded sections of the bottom chords at the towers.

In years past, the deflections under live load, common to suspension bridges, have resulted in considerable pin wear. During those years, the pins have been inspected and replaced where necessary as a regular maintenance practice and, in consequence, their present condition is not bad.

During the first decade of the twentieth century, the bridge was subjected to very much heavier live loads than at present. At that time the diagonals frequently failed and the top flanges of the floor beams cracked. Since 1922 no heavy trucks have been permitted on the roadways and the elevated train service has decreased progressively until, in March, 1944, train service was discontinued. Under the prevailing light live loads, the aforementioned difficulties have practically disappeared.

Analysis showed that the chord stresses were high, and it was decided to test the physical characteristics of the chord materials. Since it was impracticable to remove a full-chord section, coupons were cut from the flanges of the channels making up the chord section at sixteen well-distributed points. They were cut out with hack saw and chisel, sufficient excess being taken to

permit machining away the material disturbed in the cutting. The results of these tests are reported in the last paper of this Symposium.

As stated, the cumulative tensions of the overfloor stays, applied to the bottom chords of the stiffening trusses, result in a large compressive force near the towers. At a point about 250 ft from the towers, the bottom chord has a low sectional area (13.72 sq in.). The compressive unit stress from the stays alone reaches a high value at this point. It was realized that other longitudinal members must participate in resisting this compressive force. The best approach to the determination of the extent of the relief afforded by other members appeared to be a direct field measurement of the bottom-chord stress by strain gage. To obtain a zero stress gage reading, auxiliary channels were riveted and welded to the top and bottom of the existing bottom chord and zero stress readings were taken on the new channels after they were in place. This arrangement with the new channels in place is shown in Fig. 24. Six gage

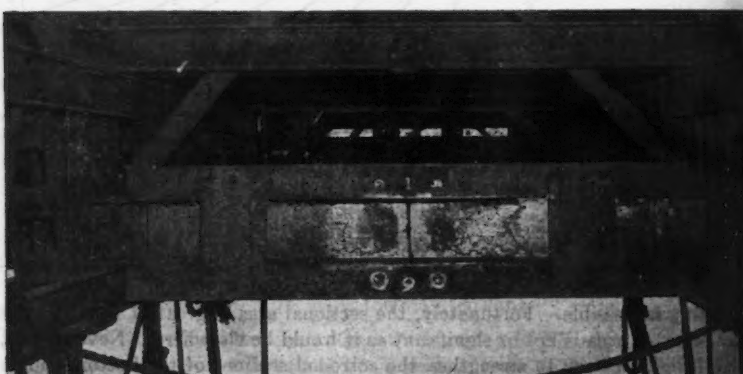

FIG. 24.—BOTTOM CHORD OF STIFFENING TRUSS WITH AUXILIARY CHANNELS IN PLACE

lines were used on each new channel, completely traversing the section in order to obtain a fair total stress.

The original chord section was then burned through at the middle of the panel, transferring the compressive stress into the new channels. In manipulating the torch care was taken to remove metal concentrically and progressively, in order to avoid high temporary eccentric stresses. The strain-gage measurements then taken on the new channels gave a unit stress of 17,000 lb per sq in. for the original chord section. This value is about 30% less than it should have been for the then existing loading condition, which indicates that other members participate in the bottom-chord stress to that extent. In this manner, it was possible to obtain a more exact knowledge of the actual bottom-chord stresses, confirming an analytical treatment of participation.

On July 30, 1898 (see Table 1), a traffic block on one roadway caused a large overload and a partial failure of the bottom chords of the stiffening trusses, resulting in considerable discussion in the technical journals of that

period. The bottom chords of four main-span trusses were bent out of line, because of the extremely high compressive stress caused by the stays. In time, the same bending was produced in the side spans. The bending referred to is

FIG. 25.—VIEW ALONG THE TRACK, SHOWING THE BEND IN THE FLOOR STRUCTURE AFTER CHORD MEMBERS HAD BUCKLED

clearly visible in the single plank walk shown in Fig. 25. Although the misalinement was never corrected, the chords were reinforced with cover plates and bottom battens about 1908.

TABLE 4.—TENSILE TESTS ON EYEBAR DIAGONALS

Item	Description	Bar 1	Bar 2	Bar 3	Bar 4
	Nominal Section, in Inches:				
1	Width	3	2	2	2
2	Thickness	0.625	0.5	0.5	0.5
3	Measured areas, in square inches	1.93	1.12	1.12	1.14
4	Yield point, in kips per square inch	44.6	42.7	44.9	46.1
5	Ultimate strength, in kips per square inch	75.8	69.2	71.8	71.3
6	Ultimate percentage elongation in 22.5 ft	13.7	9.28	13.5	14.0
7	Percentage reduction of area	46	41	46	53

In order to learn something of the physical characteristics of the web members, four eyebar diagonals were removed from the high trusses for full-size tensile tests. The results of these tests are presented in Table 4. None of the eyebars broke in the head, a considerable excess sectional area having been provided in their manufacture. This excess is made up partly by additional

thickness in the head, since there is insufficient clearance within the chords for widening the head. The additional thickness is fortunate, since corrosion is greatest in the eyebar head, which is inaccessible for painting.

Decision to remove the eyebars for test provided an opportunity to check their stresses by strain gage. Accordingly, gage points were drilled in the members to be removed, and readings were taken at a moment of extremely light live load. Theoretically, there should be only nominal dead-load stresses in a properly adjusted truss at mean temperature, and the analysis indicated small live-load stresses. Surprisingly, on measuring the no-load gage lengths after removal from the truss, the stresses in the diagonals were found to be approximately 24,000 lb per sq in.

The four eyebars were removed from points well spaced along the main span. The discovery of this high shear could not be explained satisfactorily by the general truss analysis. However, it was in agreement with the records of failures of many diagonals in past years. After some study, it became apparent that these stresses could be caused by high tensions in the adjustable counterdiagonals.

To test this hypothesis, gage holes were drilled into the main diagonals and counters of three adjacent panels at two widely separated points. The gage distances in the counters were measured before and after slacking off the

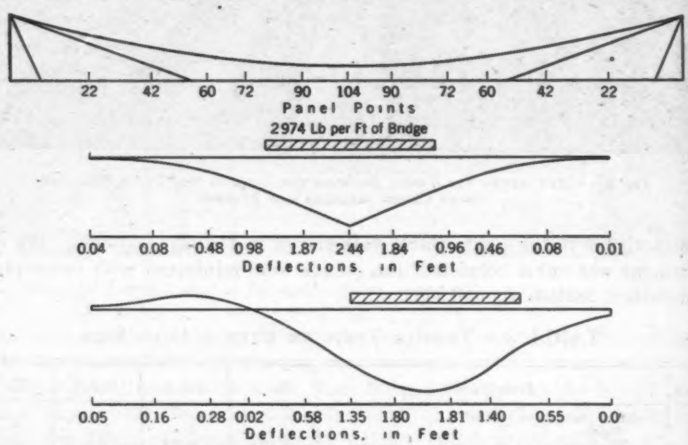

FIG. 26.—DEFLECTIONS OF THE MAIN SPAN UNDER LIVE LOAD
(One Eight-Car Train on Each Track; Total Length, 394 Ft and Total Load, 586 Tons)

adjusting sleeves to zero tension. As had been supposed, the countertensions were found to be unnecessarily high—from 12,000 lb per sq in. to 17,000 lb per sq in. Simultaneous readings on the adjacent main diagonals showed smaller changes in their tensions—suggesting that the horizontal shear produced by the over-tightened adjustable counters is resisted over long lengths by groups of diagonals rather than by the immediately adjacent main diagonal. Thus, efforts to correct this condition will require the scheduling of the adjustments and a large amount of checking and rechecking by the strain gage.

Live-Load Deflections

In the course of the analysis of truss stresses, by an adaptation of the so-called elastic theory, the need arose for a check on the deflections under live loads. Arrangements were made to place trains in predetermined positions on the main span and side spans. Profile surveys of the top chord were made before and while the trains were in position. The resulting deflections are shown in Fig. 26 and Fig. 27.

Historically, the introduction of the Melan deflection theory into the United States is associated with Brooklyn Bridge. The late Mr. Moisseiff (who is

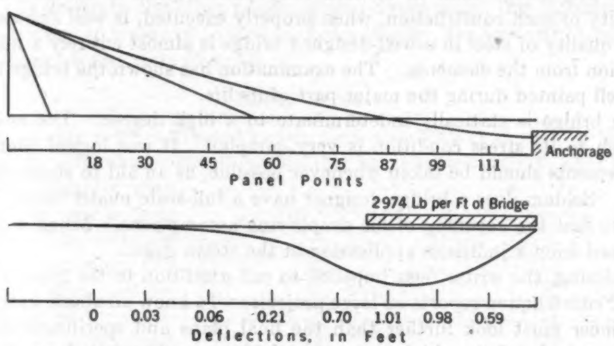

Fig. 27.—Deflections of a Side Span Under Live Load
(One Six-Car Train on Each Track; Total Length, 295 Ft and Total Load, 439 Tons)

generally credited with the first application of this theory to an actual structure) has stated that it was his study of the failure of the suspender rods of this bridge in 1901, which first drew his attention to the effect of the distributed dead load in resisting live-load deflections.

Further checks on the live-load chord stresses were made with the strain gage, using the train loads. The results are too detailed for enumeration in this paper. It may suffice to state that the strain gage showed stresses lower than those computed by the elastic theory and the measurements aided in the determination of stress reduction percentages.

The Floor System

The floor beams are continuous over the four cable supports. The solution of the floor-beam stresses is complicated by consideration of the amount these four supports yield under load. The exact calculation of the deflections of the six trusses is an extremely difficult, if not impossible, problem if approached from a purely analytical angle because of the interaction of the main cables, six trusses, the overfloor stays, and the floor beams. A more direct approach is to select that floor beam which will deflect the most, because of differential deflections of the supporting cables, and measure the deflection under a known load. This was done, using the same train loads as shown in Fig. 26. At midspan the inner cables and trusses deflected 2.5 in. more than the outer trusses, under

the centrally placed load. After the yielding of the floor-beam supports under a known load had been measured, it was possible to calculate the floor-beam stresses for the working loads used in the study.

Conclusion

The Brooklyn Bridge has had a long and extremely useful life; and, although it is customary to associate old age with decrepitude, there is nothing in the results of the physical examination to suggest that advancing age has seriously weakened any major element in the structure. Stone masonry plays a larger part in this bridge than in modern long-span suspension bridges, and the durability of such construction, when properly executed, is well known. The lasting quality of steel in a well-designed bridge is almost entirely a matter of protection from the elements. The examination has shown the bridge to have been well painted during the major part of its life.

The bridge is statically indeterminate to a high degree. The analytical approach to its stress condition is very complex. It was logical that direct measurements should be taken whenever possible, as an aid to stress determination. Seldom does a bridge designer have a full-scale model before him on which to test the accuracy of his simplifying assumptions. Much could still be learned from a judicious application of the strain gage.

In closing, the writer feels impelled to call attention to the great value of detailed construction reports on large projects. To know all about a structure, an engineer must look further than the final plans and specifications. The progress reports of the chief engineer and his several assistants on the construction of Brooklyn Bridge are veritable mines of information which are still available in technical libraries. In the course of this investigation, they helped resolve many questions; and they can be read today, with profit, by the practicing engineer as well as by the student of bridge engineering.

TESTS OF METALS REMOVED FROM CABLES AND STIFFENING TRUSSES

By Harold E. Wessman,[15] M. ASCE

Introduction

The tests reported in this paper were made on wire specimens cut from the cables and on chord specimens cut from the stiffening trusses of the Brooklyn Bridge. As stated in the other papers of this Symposium, this historic structure was opened to traffic in 1883; and, consequently, the test specimens have been in service for at least 60 years.

Cable Wire

Wire samples were cut from the top, side, and bottom of each of the four cables at six different points on each cable as indicated in Fig. 28. Of the total, sixty samples were subjected to tensile tests to failure. The ultimate strength, elongation, and reduction in area were determined for all the specimens. In addition, strain measurements over an 8-in. gage length were taken on twenty four of the sixty samples and stress-strain diagrams plotted to determine the proportional limit, yield strength, and modulus of elasticity. The wire samples when cut from the main cables tended to assume immediately the curvature of the coils in which they were delivered to the bridge site years ago. Hence, after being placed in the grips of the testing machine, the wire was subjected to an initial load of 250 lb to straighten it before the extensometer was attached.

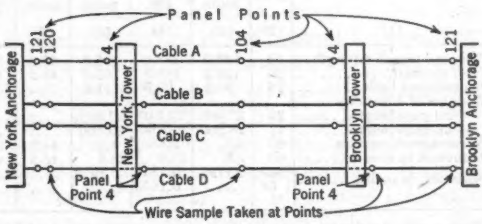

Fig. 28

Simultaneous load and strain measurements were also taken on twelve long samples using a gage length of 84 in. to obtain a more accurate value for the modulus of elasticity. In these tests, the maximum load was approximately that corresponding to the proportional limit of the material.

Values for the physical properties of the cable wire are summarized in Table 5, Cols. 2 to 5. The values in Cols. 4, 7, and 10, Table 5, are arithmetical averages. Maximum and minimum values are also tabulated in order to indicate the range of values encountered among the samples tested.

The average "ultimate tensile strength" for sixty samples is 162,600 lb per sq in. The original specifications,[16] phrased in terms of the small-diameter

[15] Cons. Engr.; Chairman, Dept. of Civ. Eng., College of Eng., New York Univ., New York, N. Y.

[16] "Specifications for Steel Cable Wire for East River Suspension Bridge," in "Report of the Chief Engineer of the New York and Brooklyn Bridge, January 1, 1877," Eagle Book and Job Printing Dept., Brooklyn, N. Y., 1877, p. 71.

wires initially contemplated for the bridge cables, specified that a single wire should sustain an ultimate load of 3,400 lb before breaking. Inasmuch as the approximate diameter of the small wires after galvanizing is 0.165 in., the specified breaking load is equivalent to a unit stress of 159,000 lb per sq in. Only a small quantity of the small-diameter wire had been used, when a change was made to a larger wire with an approximate diameter, after galvanizing, of 0.184 in.

The average unit tensile strength of the wires tested is a little greater than the unit strength indicated in the original specification; thirty-two specimens had strengths greater than 159,000 lb per sq in. whereas twenty-eight

[a] Units are in kips per square inch except where specially noted. [b] Tensile tests of chord coupons. [c] *Transactions*, ASCE, Vol. 97, 1933, Table 8, p. 364. [d] The number of samples tested is given in Col. 2. The six reported in the last line were smaller wires used in a few bottom strands of the cables.

specimens had strengths less than this value. It is of some interest to note that, in general, the bottom wires of the cables exhibited higher strengths than the side and top wires.

The average yield strength of twenty-four samples (Col. 4, Table 5) is 143,800 lb per sq in. This value is 88.4% of the average ultimate strength. The yield strength in these tests is defined as the unit stress at that point on the stress-strain diagram at which the elongation is 0.7%—in other words, the unit strain is 0.007.

The average value for the proportional limit of twenty-four samples is 99,900 lb per sq in. The proportional limit is defined as the unit stress at the point at which there is an observable deviation from the straight part of the stress-strain diagram. This point could be determined more accurately, however, from a study of the variation in increments of strain noted in the tabulated data for each test in combination with a scrutiny of the stress-strain diagram.

The average values for the proportional limit and the yield strength cannot

be compared directly with specification requirements. The original specifications state that the elastic limit (of the small-diameter wire) should be 1,600 lb. This is equivalent to a unit stress of 75,000 lb per sq in. What was meant at that time by the elastic limit is not clearly defined in the specifications.

The modulus of elasticity was found to have an average value of 28,760,000 lb per sq in. This value is based on stress-strain diagrams for eleven of the twelve tests of long samples using an 84-in. gage length. One test was discarded because the wire was badly corroded. The original specifications required that values for the modulus of elasticity should fall between 27,000,000 lb per sq in. and 29,000,000 lb per sq in. Values for E were also determined from twenty-four tests of short samples, using a gage length of 8 in. The average for this series is 29,010,000 lb per sq in. However, in one of the tests averaged, the modulus was determined as 32,300,000 lb per sq in., which was considerably "out of line" with the values for the remaining twenty-three tests. Omitting this value, the average was reduced to 28,870,000 lb per sq in. The average values for the short-gage tests and the long-gage tests show very good agreement.

The average value for ultimate elongation in 10 in., based on sixty tests, is 2.88%; twenty-five samples had elongations in the interval between 2.0% and 3.0%; and twenty four were in the interval between 3.0% and 4.0%. The original specifications (for the small-diameter wire) called for a minimum elongation of 2% in a 50-ft gage length or 3.5% in a 5-ft gage length.

A direct comparison of test values for elongation with original specified values is not possible because of the difference in gage lengths. However, the wire seems somewhat deficient in ductility. It is of some interest to compare it in this respect to modern cold-drawn suspension bridge wire. The wire for the George Washington Bridge (Cols. 9 to 11, Table 5) was required to have a minimum elongation of 4% in 10 in., but the average value of 26,274 tests[17] was 6.0%. Moreover, the average tensile strength of the cable wires in the George Washington Bridge was 234,000 lb per sq in., which is considerably higher than the average tensile strength for wire in the Brooklyn Bridge. It is important to remember that, in general, ductility decreases as ultimate strength increases.

The average value for reduction in area at the point of fracture is 15.6%. The original specifications for the small-diameter wire stated that necking at the break should be such as to give a diameter less than 0.15 in. Since the original diameter of this wire was approximately 0.165 in., this statement is equivalent to specifying a minimum reduction in area of 17.5%. The significance of "reduction in area" is a subject for considerable debate. There is no definite correlation evident in these tests between reduction in area and elongation or tensile strength.

A comparison of ultimate tensile strengths with carbon content, determined from chemical analyses of twelve samples indicates that, in general, strength increases as the carbon content increases. The carbon ranged from 0.55% to

[17] *Transactions*, ASCE, Vol. 97, 1933, p. 364.

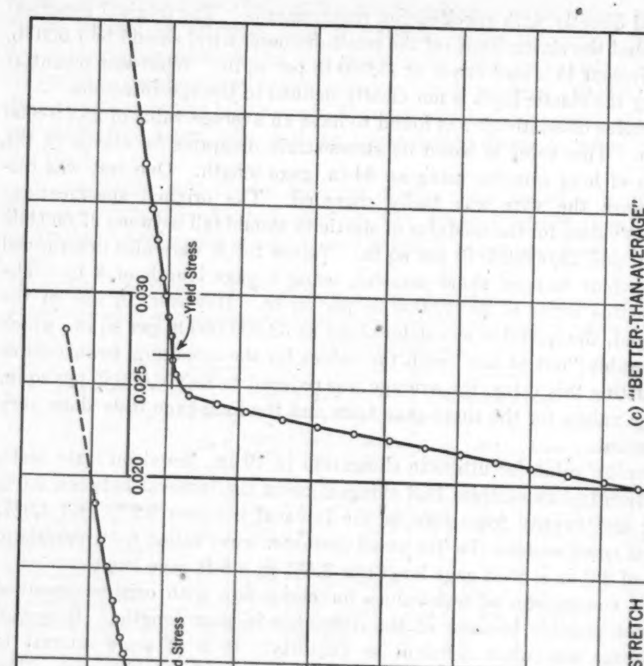

FIG. 29.—TYPICAL STRESS-STRAIN DIAGRAMS FOR CABLE WIRE (SEE TABLE 6)

0.89% whereas the tensile strength for the twelve samples ranged from 143,600 lb per sq in. to 184,000 lb per sq in., the detailed comparison being as follows:

Ultimate strength (kips per sq in.)	Carbon (%)
143.6	0.63
144.6	0.55
151.0	0.68
154.0	0.63
157.8 (Fig. 29(*c*))	0.67
162.2	0.71
166.7	0.74
167.4 (Fig. 29(*b*))	0.76
172.0	0.70
174.0	0.82
178.5	0.89
184.0	0.84

Typical stress-strain diagrams for the tensile tests are shown in Fig. 29. The physical properties accompanying these diagrams are listed in Table 6.

TABLE 6.—CHARACTERISTICS OF SPECIMENS PLOTTED IN FIG. 29

Characteristic	Fig. 29(*a*)	Fig. 29(*b*)	Fig. 29(*c*)
Ultimate tensile strength (lb per sq in.)	148,500	167,400	157,800
Yield strength (lb per sq in.)	142,500	144,800	138,000
Proportional limit (lb per sq in.)	102,900	99,000	98,000
Modulus of elasticity (lb per sq in.)	28,700,000	28,800,000	29,500,000
Percentage elongation in 10 in.	1.1	2.8	3.2
Percentage reduction in area	0	17.4	13.9

Fig. 29(*a*) pictures the data for a specimen having low elongation; Fig. 29(*b*), for one with average stretch, and Fig. 29(*c*), for one with "better-than-average" ductility. All the stress-strain curves show a flat slope above the yield point. In general, the reserve of strength between the yield stress and the ultimate strength is small. The diagrams also exhibit a sharp increase in curvature or "knee" in the transition zone from elastic to plastic behavior. Although the yield strength is a value rather arbitrarily defined in cable-wire tests, nevertheless, in these tests, it seems to coincide rather closely with what might be termed a point or region where yield begins to be pronounced.

Bend tests on samples of the wire from which the galvanizing had been removed were conducted by the New York City Department of Public Works in its own laboratory. The detailed results of those tests are not included in this paper. The results indicated that the wire was deficient in flexibility. More than one half of the samples tested could not be coiled continuously (at least one 360° turn) around a cylindrical mandrel less than 1 in. in diameter. There was practically no correlation between the results of these tests and the elongation obtained in the tensile tests. On the other hand, some correlation was evident between the bend data and the values for reduction in area. In general, the wires that broke on the large-diameter mandrels (1 in. and 1.5 in.) gave small reductions in area on the tensile tests.

FIG. 30.—WIRE SAMPLE WITH BANDED STRUCTURE

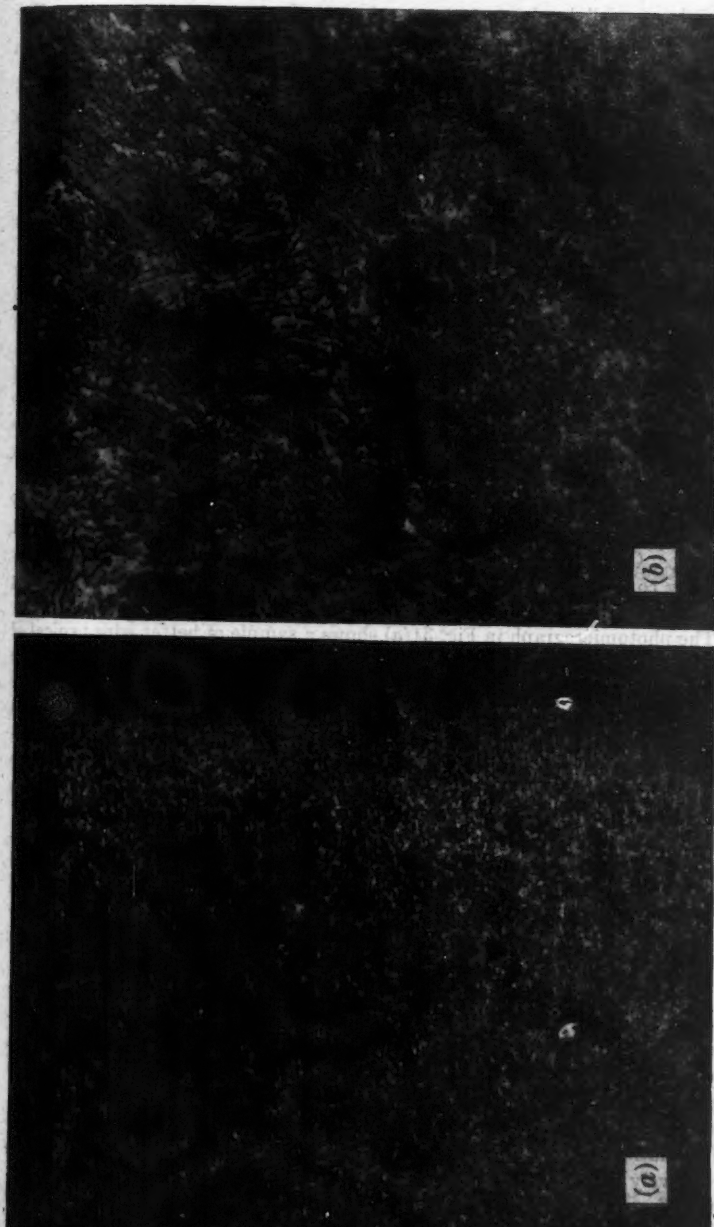

FIG. 31.—PHOTOMICROGRAPHS SHOWING PERLITE STRUCTURE
(a) MAGNIFICATION 100 ×
(b) MAGNIFICATION 600 ×

"Scleroscope" hardness tests were made on twenty-four samples. The hardness ranged from 55 to 66 except for one very soft spot on one sample. In general, as hardness increased, tensile strength increased.

The metallographic examination of twenty-four samples of cable wire showed variations and irregularities that would not be encountered in wires made more recently, under rigid, modern standards of inspection. It must be remembered that these wires were made at a time when it was the exception rather than the rule to make analyses of steels. Very few steel plants at the time were equipped with chemical laboratories, and metallographic examination was still unknown.

Most of the wires seem to be a good grade of steel, of eutectoid (0.83% *C*) composition, approximately. However, two wires were of hypereutectoid structure, five were decidedly hypoeutectoid, and three showed a banded structure like that illustrated, in Fig. 30. The same sample is shown in both Figs. 30(*a*) and 30(*b*), but Fig. 30(*a*) was originally taken at a magnification of 100 diameters; and Fig. 30(*b*), at 500 diameters. This banded structure is generally considered indicative of poor quality and low strength. The white streaks are ferrite, practically pure iron, and the dark areas are perlite, an iron-iron carbide mixture.

Phosphorus, silicon, and other elements present in steel sometimes remain segregated, even after rolling. They become elongated in the direction of hot working. Carbon is less soluble in these areas than in the regions of lower impurity content and the result is the banded structure in Fig. 30. Banding gives directional properties to steel.

The photomicrograph in Fig. 31(*a*) shows a sample of better wire typical of most of the wires, under a magnification of 100 diameters. Fig. 31(*b*) is the same sample magnified 600 diameters. This particular sample is a little higher in carbon than most of those tested but, nevertheless, illustrates the eutectoid composition. The structure is almost entirely of perlite, as evidenced by the predominance of dark areas. Fig. 31(*a*) shows, however, appreciable decarburization along the outer surface of the wire. A short sliver of steel should be noticeable at the left center extending into the zinc coating (black).

In one respect—namely, in the structure of the perlite—all the wires examined were alike and of high quality. The individual grains were small, and the laminations within the grains were fine. Both these characteristics tend to improve the strength of the wire—other factors being the same, the smaller the grain size, the greater the tensile strength. Otherwise, every feature that could be observed under the microscope varied from wire to wire.

Although some of the wires were as free of nonmetallic inclusions as wire produced today, many of the samples had far too many slag and oxide inclusions. The banded structure shown by several of the wires indicated not only hot rolling but also too high a percentage of undesirable constituents such as phosphorus, sulfur, and slag.

Several of the samples were nonuniform in the distribution of the carbon. This variation appeared in two independent forms. In one case, isolated spots of relatively carbon-free ferrite of appreciable size were scattered throughout a matrix of essentially 0.8% carbon. In the other case, which is more serious, the

wires show a widely varying amount of decarburization along the surface. This decarburization will give the wire a lower tensile strength than it would otherwise have had.

The technical press has recorded[18,19,20] that the original small-diameter wire was cold-drawn through two dies from rolled crucible rod steel, oval in section, with diameters of approximately 7/32 in. by 15/64 in. The first drawing reduced the wire to No. 7 gage and the second drawing to No. 8 gage, the latter being approximately 0.165 in. in diameter. Only a relatively little of the smaller wire had been used when the change to a diameter of about 0.184 in. was made, which was slightly less than that of No. 6 wire. Available literature offers no evidence that the larger wire was still given two drawings and that the size of the basic crucible rod steel was increased.

From the microscopic examination of the samples it would appear that only a few of the wires were given a real wire-drawing operation. This lack of wire drawing is indicated in two independent ways: (1) The longitudinal section of cold-drawn material shows the grains, especially near the surface, to be drawn out axially; and (2) wire drawing produces a smooth surface. Most of the samples showed no axial tendency at all; and, in cases where it would be observed, such a tendency was restricted to a very superficial depth. If the hole in the die is not perfectly circular, ridges extending along the wire may be produced; but, even so, the cross-sectional shape does not vary from place to place. Many of the wires examined were extremely rough, the high and low spots occurring in random order. That this was the condition of the wire at the time of manufacture is shown by the way in which the zinc coating has filled in these irregularities.

The greatest irregularities were noted in the zinc coating. Some samples showed a heavy, uniform coating; others, a very thin uniform coating; and in

TABLE 7.—Chemical Analyses of Cable Wire (Percentages)

[a] *Transactions*, ASCE, Vol. 97, 1933, Table 7, p. 362.

some the coating was extremely irregular. The irregularity may have been due, in part at least, to the flow of the zinc occurring under pressure when the individual strands were pressed into the form of the cable and then wrapped.

The results of the chemical analyses of the cable wire are compared with similar analyses for George Washington Bridge[21] in Table 7. Carbon,

[18] "East River Bridge Wire," *The Iron Age*, January 4, 1877, p. 5.
[19] "Making Wire for the Brooklyn Bridge," *ibid.*, March 1, 1877, p. 1.
[20] "Wire for the East River Bridge," *Scientific American*, March 3, 1877, pp. 127 and 130.
[21] *Transactions*, ASCE, Vol. 97, 1933, Table 7, p. 362.

phosphorus, and sulfur contents were determined in twenty-four samples, whereas manganese and silicon contents were found for four samples. The wide range of carbon content is apparent. In the cable of the George Washington Bridge, the range for 958 melts of steel was from 0.72 to 0.93, with an average of 0.81. The phosphorus and sulfur contents are considerably higher than those in modern bridge wire which generally average less than 0.04%.

It is not within the scope of this paper to recommend a working stress to be used as a basis in evaluating the Brooklyn Bridge cables under modern loading conditions. Nevertheless, it is advisable to call attention to a number of factors evident from the physical, chemical, and metallographic studies which have a bearing on this question. The stress-strain diagrams show a rather flat slope above the yield strength. There is not much difference between the yield strength and the ultimate strength. The elongation is low. Even though the ultimate strength of this wire is about 70% of that for modern bridge wire, the energy capacity is less than 50% of the energy capacity obtained today.

The carbon content exhibits a wide range. The metallographic studies corroborate this conclusion and also indicate nonuniformity in other characteristics. The galvanizing coat is quite variable in thickness. In view of all these factors, it seems wise to be conservative in establishing a limiting working stress for any revision in loading conditions.

This statement is not to be construed as indicating a belief by the writer that the wire is definitely inferior in quality. Such is not the case. It must be remembered that this wire was manufactured more than 60 years ago, when standards for insuring uniformity were not as definitely established as they are today. The cable wire has stood the test of many years of satisfactory service and its quality today is high enough to warrant the expectation of many years of added service.

Chord Samples from Stiffening Trusses

Sixteen flat coupons were machined from steel samples cut from the chords of the stiffening trusses of the Brooklyn Bridge. The results of the physical tests made on these specimens are summarized in Table 5, Cols. 6 to 8.

The average value for the ultimate strength is 79,000 lb per sq in. The average value for the yield point is 48,700 lb per sq in. These values are somewhat higher than those generally encountered today in low-carbon structural steel as defined by Specification A7–42 of the American Society for Testing Materials for bridges and buildings.

The average value for ultimate elongation for all sixteen tests is 23.2%. The average for the eight samples with 8-in. gage is 23.1% whereas the average for the eight samples with 7-in. gage length is 23.2%. These values are practically the same as values obtained today in tests of low-carbon steel.

A metallographic study and a chemical analysis were made for two of the samples, the one with lowest strength (69,800 lb per sq in.) and the one with highest strength (89,500 lb per sq in.). The low-strength sample had a carbon content of 0.17% and a manganese content of 0.68%. The high-strength specimen had a carbon content of 0.26% and a manganese content of 1.43%.

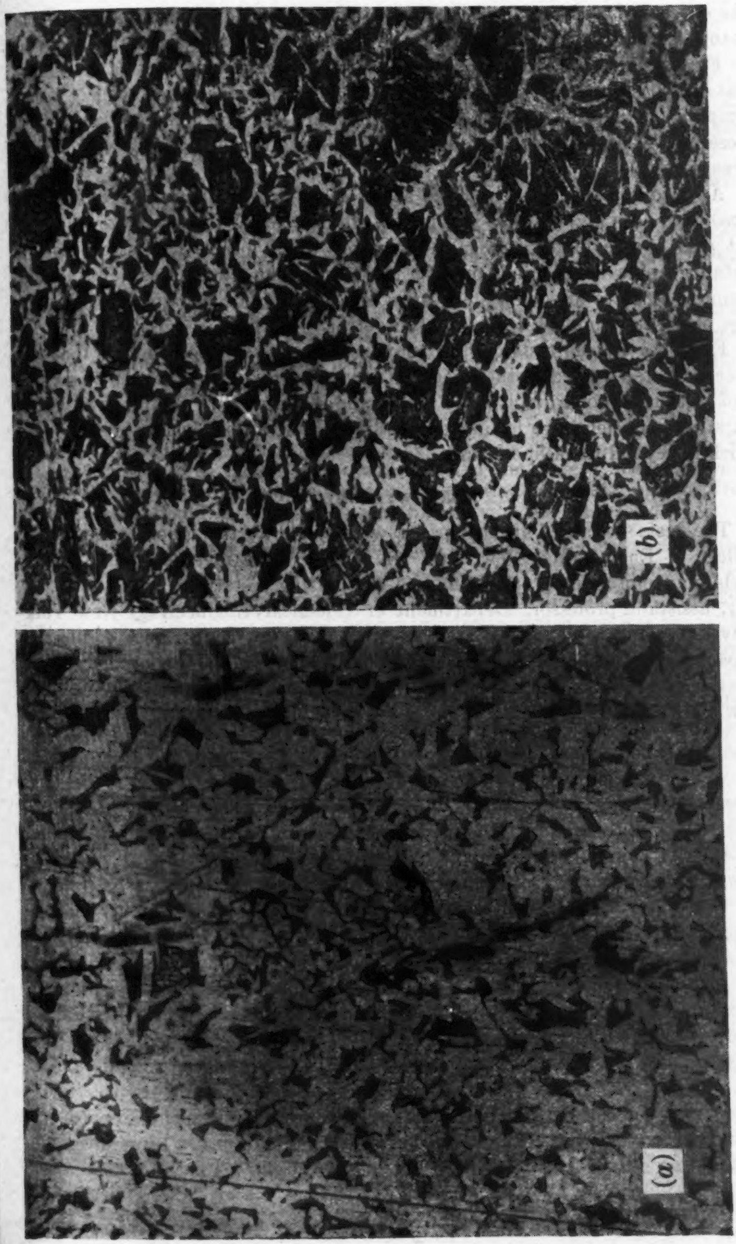

FIG. 32.—PHOTOMICROGRAPHS OF CHORD SPECIMENS
(a) LOW-STRENGTH SAMPLE AT 100 ×
(b) HIGH-STRENGTH SAMPLE AT 100 ×

The difference in the quantities of these elements undoubtedly was one of the factors accounting for the difference in ultimate strengths of the two samples.

Fig. 32(*a*) is a photomicrograph of the low-strength sample with a magnification of 100 diameters. Fig. 32(*b*) shows the high-strength specimen. When compared with Figs. 30(*a*) and 31(*a*), which are also magnified 100 diameters, these views show clearly the larger grain structure associated with lower-strength steels.

As is to be expected, Fig. 32(*b*) shows a higher proportion of perlite (dark area) than does Fig. 32(*a*). This is due, not only to the higher carbon content, but also to the higher manganese content which places this steel, from a metallographic standpoint, outside the low-carbon steel class. Without a chemical analysis of such a steel, an estimate of carbon content based on the area of perlite might be considerably in error.

From the sixteen tests of steel coupons, it seems safe to conclude that the structural steel placed in the Brooklyn Bridge trusses more than 60 years ago is of unusually good quality. Whether the sections have the most desirable shape and sufficient area for modern loadings, however, is another matter—one which is beyond the scope of this paper.

Acknowledgment

The tests described in this paper were made at the laboratories of the College of Engineering, New York University. The metallographic studies (including photomicrographs) and the galvanizing tests were made by F. C. Fair, assistant professor, Department of Chemical Engineering, New York University; and the chemical analyses were made by H. B. Hope, professor, Department of Chemical Engineering, The Cooper Union—under the general supervision of H. J. Masson, chairman, Department of Chemical Engineering, New York University.

DISCUSSION

Isidore Delson,[22] M. ASCE.—In presenting the several papers on the Brooklyn Bridge, the authors have done a fine service to the engineering profession.

Mr. Ammann's authoritative paper leaves little for discussion to one who, like the writer, has had an intimate part in the investigation of the bridge.

The writer's preoccupation with the Brooklyn Bridge dates back to 1939, when he was required to make a study of a memorandum on the reconstruction of the bridge submitted by the late Leon S. Moisseiff, M. ASCE.

As far back as 1903, Mr. Moisseiff had collaborated in a plan for reconstruction advocated by the late Gustav Lindenthal, Hon. M. ASCE, then commissioner of the old Department of Bridges of the City of New York. Ever since then Mr. Moisseiff had nurtured the hope of some day participating in such a reconstruction. In his memorandum Mr. Moisseiff stated that:

> "Thorough physical examination and surveys of the material and the structure must be made. An examination of the state of preservation of the existing cables should be made and a substantial number of wires from the cables should be tested for strength, behavior and duration."

The investigation which began four years later led to the recommendation, as stated by Mr. Ammann, that, with motor trucks excluded from the roadways, the two so-called intermediate trusses may be removed, thus providing 30-ft roadways in place of the present narrow roadways which are less than 17 ft wide. Under this plan, as noted by Mr. Ammann, the shallow outer trusses will be rebuilt to the full height of the inner trusses.

As indicated in Fig. 5 (Mr. Seely's paper), four of the six stiffening trusses are directly suspended from the cables. The two intermediate trusses are supported on the floor beams about 14.5 ft from the point of suspension of the inner trusses.

The interaction between the floor beams and the intermediate trusses is extremely indeterminate. Entirely neglecting any support given to the floor beams by these trusses, it was found that under a local loading of a 35-ton trolley car, and a 10-ton truck, the maximum stresses in any floor beam were moderate, especially in view of the high strength of the steel.

Inasmuch as the proposed removal of the intermediate trusses is predicated on the carrying capacity of the floor beams, it may not be amiss to discuss the fractures to which Mr. Ammann has referred.

Virtually all these fractures occurred in the top chords of the floor beams close to the point of attachment of the inner suspenders. It was rather baffling to find that all but one of thirty-two fractures recorded between 1929 and 1936 occurred in the side spans, nearer to the anchorages.

A reasonable explanation was suggested to the writer by the very competent bridge foreman at the time the fractures had occurred; namely, that they could have been induced by the braking of the trains approaching the terminals on the downgrades.

---

[22] Cons. Engr., Staten Island, N. Y.

Mr. Ammann's paper states the simplifying assumptions made for the analysis of the stiffening trusses. As regards the effect of the diagonal stays, actually each group of twenty-five stays was divided into three zones, in each of which the upward vertical pulls of the stays (the vertical components of the stay tensions) were assumed to be uniform, their resultant acting at the center of the zone. The stays may be conceived as furnishing points of yielding supports to the stiffening trusses.

As regards the very high unit stresses of the bottom chords found in parts of the span in the region of the stays, they were due, to a large extent, to the longitudinal components of the stay tensions, the so-called direct stresses. The original designers had made the rather naive assumption that these direct stresses would be resisted equally by all the longitudinal material on the bridge, both steel and timber. Mr. Gray's paper describes the method used for measuring, in one of the most highly stressed chords, the direct stress due the dead-load stay tension, upon the basis of which participation by the floor system was fixed at 25%. For the direct stresses due to live load, the same ratio was used, in addition to which, participation by the top chords through the web system was determined by analysis.

The revelation of these high unit stresses, in some members exceeding their yield point, was somewhat startling. The figures, of course, were the result of laborious computations based on a theoretical analysis which was set up by the aid of reasonable assumptions for simplifying the complicated structure into a calculable pattern.

Mr. Gray has described the deflection tests under predetermined train loads. At the time that these tests were made on the Brooklyn side span, Mr. Gray also took strain-gage readings on a top chord, which disclosed a stress, 75% of that computed for the particular loading. This compared closely with the result of the computation for stress reduction due to the deflection at that point. It was reassuring to find that measure of agreement between the calculated and the measured stress.

T. Kennard Thomson,[23] M. ASCE.—Under the heading, "The Main Cables," Mr. Gray states that "passing trains produced a deflection at the center of the main span in excess of 1 ft." In other words, the vertical deflection from live loads is given as about 1 ft, but of course the vertical variation caused by the expansion and contraction of the cable is much greater. For the Brooklyn Bridge the total possible deflection is 18 ft, 9 ft above and 9 ft below the mean level. For the Williamsburg Bridge the total possible variation is about 6 ft 9 in.

The writer obtained these values from the Bridge Department of New York City, N. Y., for an article that appeared in 1909.[24]

Theodore Belzner,[25] Affiliate, ASCE.—In addition to its real technical importance, this Symposium is of unusual interest and is a very valuable and

[24] "New York City Bridges," by T. K. Thomson, *The Engineering Magazine*, September and October, 1909.

[25] Insp. of Steel and Bridge Insp. in Chg., Brooklyn Bridge, Dept. of Public Works, City of New York New York, N. Y.

helpful contribution to engineering literature. Brooklyn Bridge, the oldest long-span suspension bridge, has had 62 years of extremely useful service. For years it carried much heavier loads than were originally contemplated without undergoing any major reconstruction.

The more that is known about existing long-span bridge structures, after many years of useful service, the more it is realized that they demand careful and searching study to be designed efficiently and that computation alone is no measure of efficiency. Mathematical analysis and reasoning are mental operations, and there is usually enough uncertainty about the distribution of steel in a structure (particularly a structure of long service) to make strain-gage measurements indispensable for a satisfactory knowledge of service effects. Stress-gage measurements will demonstrate the agreement between engineering theory and the actual behavior of the structure.

Very true and timely are Mr. Gray's statements (see "Conclusion") that:

> "Seldom does a bridge designer have a full-scale model before him on which to test the accuracy of his simplifying assumptions. Much could still be learned from a judicious application of the strain gage."

Also applicable is the old saying: "Anything worth doing at all is worth doing well." This applies to investigations of engineering structures, as well as to many other activities.

The time has come when large bridges, with long service (particularly those of the magnitude of the East River bridges), should be investigated for the purpose of comparing computed stresses with those measured by the strain gage.

Admitting that field stress measurements are more or less expensive, time consuming, and laborious and that they require a high order of instrumental and technical skill to be of value, the fact remains that there are many situations in practice where the results of these stress investigations would give the engineer the answer to many otherwise indeterminate stress problems.

An important instance may be mentioned in connection with a difficult erection problem, some years ago on the Williamsburg Suspension Bridge across the East River in New York, N. Y. To the writer's knowledge, the first time in the history of the New York City Department of Bridges (later the Department of Plant and Structures and still later the Department of Public Works) that extensometer investigations were ever conducted on one of its bridges, and particularly on a structure of such magnitude, was in connection with this bridge. Extensometer investigations were made during 1913 and 1914 under the direction of the late Austin Lord Bowman, M. ASCE, chief engineer, in cooperation with the National Bureau of Standards, under the auspices of the late James E. Howard, engineer physicist, in connection with strengthening the end spans of that bridge.

The writer was assigned to the extensometer investigation of the important truss members of the main towers and of the legs of the intermediate towers at the Brooklyn end. He recalls distinctly not only the difficult problems involved but also the value of the extensometer measurements. One of the

wedging operations,[26] particularly, solved a critical and perplexing erection problem, not only because of the close agreement of the computed stresses but also because of the fact that, after the removal of the pins, there were no apparent changes in the stresses of the members.

Also of the utmost importance to this or any other great bridge is its potential life as it affects capacity, maintenance, and repairs. With proper design, construction, protection, inspection, and maintenance, the life of a steel structure, under reasonable conditions, may be practically unlimited. In other words, there is no danger or deterioration from working stresses if properly provided for, and none from corrosion, if the steel is properly used and protected.

In conclusion, it can be stated without fear of contradiction that the Brooklyn Bridge, long regarded as "The Eighth Wonder of the World," is still the most famous and esthetic span in existence.

C. H. Gronquist,[27] M. ASCE.—The history of the major undertakings of the past is always engrossing, in engineering as in other fields. In that part of the Symposium on the Brooklyn Bridge concerning the practical difficulties of the construction job of the eighties, it will be seen from Mr. Seely's account that the problems of today are the problems of the past. Because of the ingenuity and capacity of the engineering pioneers of the past, the solution of that day now has become routine.

The analysis of the stresses in the stiffening trusses of the Brooklyn Bridge is complicated by the unusual conditions of fixity at the towers and hinged connections at the centers of the three spans, combined with the action of the overfloor stays in stiffening the suspended structure. The solution has been handled in a practical manner that is undoubtedly sufficiently accurate. The deflection theory correction in the simple span part of the side span can be estimated closely by the use of buckling loads,[28] but the correction in the main span and in the cantilever part of the side span is most difficult to estimate and is not constant. These corrections were approximated by the investigators with the help of the results of the test loading of the structure.

The overfloor stays are considered to add much to the esthetic appeal of the Brooklyn Bridge, and in addition they contribute greatly to the stiffness of the structure. The long side span, with the center hinge eliminated, still would be very flexible if it were without the stays. This fact should require careful consideration in the complete rebuilding of the structure.

The relative effectiveness of the outer trusses as measured by their stiffness is much less than is indicated by comparison of moment of inertia, since deflection is proportional to the total buckling load—the sum of the buckling load of the truss and the value of the cable tension.[28] The proposed replacement of the shallow outer trusses by the deep intermediate trusses, now not directly connected to the cables, is fully justified; it will decrease the total stiffness of the bridge by an entirely inappreciable percentage.

[28] Discussion by C. H. Gronquist of "Rigidity and Aerodynamic Stability of Suspension Bridges," by D. B. Steinman, *Transactions*, ASCE, Vol. 110, 1945, p. 490.

The report of the physical examination of New York's first suspension bridge more than sixty years after its completion attests to the thoroughness of the workmanship employed in its construction, and the results of the tests on the cable wire and truss metal are on the whole reassuring. The authors and their associates are to be complimented on the thoroughness and effectiveness with which they attacked the interesting problems attendant to making a technical survey of the condition of the historic Brooklyn Bridge.

BLAIR BIRDSALL,[29] ASSOC. M. ASCE.—The papers composing this Symposium represent not only an ingenious and competent study of a very complicated engineering problem but also a fitting tribute by present day engineers to the lasting genius of the creators of the Brooklyn Bridge. The subject has been well covered by the four papers but the following comments may prove of interest as footnotes to some of the statements in the Symposium.

No printed matter could appear to be more dry and uninteresting than the publication entitled, "Testimony Taken by the Committee on Commerce and Navigation of the Assembly in Relation to the New York and Brooklyn Bridge Pursuant to Resolution of the Assembly, Passed February 5, 1879."[30] However, to one who has an interest in the history of the Brooklyn Bridge or of the cities of New York and Brooklyn, this book makes reading which is exceedingly interesting if not exciting. It includes the testimony taken pursuant to the petition of D. Willis James and others mentioned by Mr. Seely under the heading, "Financial and Political Difficulties." The following excerpts from this testimony will be of considerable interest to those who have read the Symposium. It is in startling contrast with the 60 years' service record of the Brooklyn Bridge.

Edward W. Serrell, Jr., was a witness for the opposition. Incidentally, he was a nephew of the John J. Serrell who was a member of the Board of Engineers called in by the late John A. Roebling, M. ASCE, in 1869. As a part of his testimony purporting to show the insufficiency of the design of the bridge, he made the following comments:

> "* * * for 25 years past there has been discussion as to the deterioration of metals under strain and what that deterioration is has not, so far as I know, been accurately determined even for wrought iron which is the most familiar that we have now in bridge construction; now, I understand that the maximum strength in any steel wires used in these bridge cables is 160,000 lb. per sq. in.; now, I am willing to place anything I have to say in the matter on the assumption that every wire there now is capable of carrying that amount."
>
> "But that metal, such a metal as that, is a new metal; it is a metal, to be sure, we have used I don't know how long; but steel wires of such a strength as that, so far as I have been informed, have not been subjected to the test of time in such a way as to determine whether the factor of safety for a number of years can be properly found by calculating the present strength of that steel."

[29] Asst. Chf. Engr., Bridge Div., John A. Roebling's Sons Co., Trenton, N. J.

[30] "Testimony Taken by the Committee on Commerce and Navigation of the Assembly in Relation to the New York and Brooklyn Bridge Pursuant to Resolution of the Assembly, Passed February 5, 1879," Weed, Parsons and Co., Albany N. Y., 1879.

Statements submitted as evidence by William H. Webb, president of the Council of Political Reform (whose particular interest was tax reduction) included the following section headings which were supposed to be descriptive of the bridge:

"An obstruction to commerce * * *. Depreciates dock property * * *. Impracticable * * *. Inconvenient * * *. Will not accommodate passengers * * *. Illegally unsafe."

In summing up the case William H. Arnoux, who appears to have been the counsel for the opposition, makes the following statements:

"It seems to me this committee ought to report to the Legislature that this work should stop until a competent board of engineers should be appointed who should examine into this work and determine whether it is safe for the public. All other questions sink into insignificance compared with the loss of human life which would result, if, upon some occasion, the bridge should be crowded and should give way under the strain. It therefore becomes a very serious problem. And in connection with this matter, as I did not feel competent myself to discuss the engineering project in view of the testimony Mr. Serrell gave to us, I have invited him and the Council of Political Reform have asked him to come here and give to you his views upon that question of the bridge."

"Is it not preposterous, in view of all the matters that are going on day by day, to say that anybody shall construct a bridge that shall provide not only for the uses of today but for the additional uses of a period 75 years hence?"

In connection with the traffic volume mentioned by Mr. Seely under the heading, "Opening Ceremonies," it might be interesting to show the forecasts of this traffic made by both the opposition and the defendants during the investigation of 1879. Data quoted from the forecasts of 1879, in Table 8, are based on one direction of travel only. This is probably more nearly comparative to the traffic recorded for the maximum hour in 1907 as that was undoubtedly a rush hour during which most traffic would be in one direction. In any case it is very apparent that even the most sanguine hopes of those who favored the bridge in 1879 fell far below the actual potentialities of the bridge.

TABLE 8.—PREDICTED AND ACTUAL NUMBER OF PEOPLE CROSSING BROOKLYN BRIDGE (MAXIMUM HOURLY CAPACITY)

Item	Type of traffic	Trolley cars	Elevated cars	Vehicles	Total passengers	Pedestrians	Grand total
	1879 Forecast:						
1	By the opposition.........	....	6,000	Few	6,000+	8,000	14,000+
2	By the defendants.........	....	25,350	4,650	30,000	36,000	66,000
3	1907 actual...............	25,000	46,256	474	71,730	2,270	74,000

NOMER GRAY,[31] M. ASCE.—In commenting on the statement in the writer's paper that "passing trains produced a deflection at the center of the main span in excess of 1 ft," Mr. Thomson states that "the total possible de-

[31] With Ammann and Whitney, Cons. Engrs., New York, N. Y.

flection is 18 ft, 9 ft above and 9 ft below the mean level." Even as the most extreme hypothetical deflection at midspan that one could rationalize, 18 ft is much too large for Brooklyn Bridge. The maximum range of main-span deflection is about 6 ft—3 ft above and 3 ft below a mean level. This estimate is based on a temperature range of from 120° F to − 10° F, and a live load such as prevailed in the first decade of the twentieth century, when the bridge was subjected to the heaviest traffic. Elevated railway service was discontinued on March 5, 1944. With the present live load, consisting of trolley cars and passenger automobiles, the corresponding maximum range of deflection is not likely to exceed 4 ft.

The writer takes this opportunity of expressing the appreciation of the authors of the four papers comprising the Symposium for the contributions made by several discussers.

ANALYSIS OF UNSYMMETRICAL BEAMS BY THE METHOD OF SEGMENTS

By Sol Lifsitz,[1] Esq.

With Discussion by Messrs. William A. Conwell, Ralph W. Hutchinson, Thomas P. Revelise, Victor R. Bergman, A. A. Eremin, and Sol Lifsitz.

Synopsis

A considerable number of tables and diagrams are available from which fixed-end moments, stiffness, and carry-over factors may be obtained for beams with variable moments of inertia. However, most of these tables and diagrams were prepared for symmetrical beams or for beams haunched at one end only. Since the combinations of shapes for unsymmetrical beams are limitless, it is obviously impracticable to tabulate data for but a limited range of shapes. The method proposed herein enables the designer to utilize the data available for beams haunched at one end only for the purpose of determining, quickly and accurately, the end moments, the stiffness, and the carry-over factors for unsymmetrical beams of any combination of shapes. This method should prove to be shorter than any other heretofore published for this purpose, with an accuracy equal to that obtained from the so-called "exact methods."

Nomenclature

The letter symbols used in this paper are defined where they first appear, in the text or by diagrams, and are assembled alphabetically, for convenience of reference, in the Appendix. Discussers are requested to make their nomenclature conform to these symbols. In order to avoid confusion as to signs, all terms are expressed in absolute values and the directions of end moments are indicated by arrows.

Fixed-End Moments

Divide beam AB, Fig. 1, into two segments, AO and OB, by introducing a temporary support at point O, the point of minimum thickness. Values of the fixed-end moment M_F, stiffness ratio K, and carry-over factor C, for each segment, may be obtained from available data.

Note.—Published in March, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Civ. Engr., Board of County Road Commissioners, Wayne County, Detroit, Mich.

Assume a vertical settlement, y_o, at point O. Compute the fixed-end moments m_F due to y_o and determine the final end moments at all the joints by the moment-distribution method.[2] Also compute F_y, the reaction at point O which is equal to, but of opposite sign to, the force acting on beam AB at point O (see Fig. 2). The downward force is simply the sum of the reactions

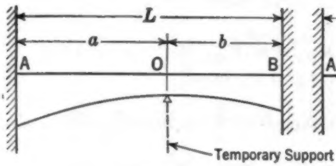

Fig. 1

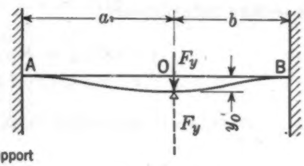

Fig. 2

at point O from the beams AO and OB resulting from the final end moments in the two beams.

Fig. 3(a) shows a beam AO, fixed at point O and hinged at end A. Apply a partial moment m'_{AO} at end A, rotating joint A through the angle θ (since θ is small, $\theta = \tan\theta = \dfrac{y_o}{a}\Big)$. This in turn will induce a moment at the fixed joint O which is equal to m'_{AO} times the carry-over factor C_{AO}. Fig. 3(b)

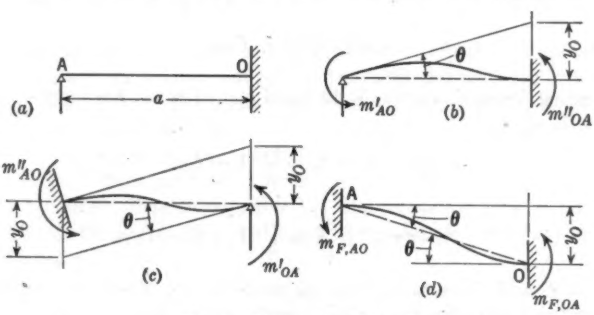

Fig. 3.—Derivation of Eqs. 1

shows the position of the beam after this rotation. The end moments at end A and end O caused by this rotation are:

$$\curvearrowleft m'_{AO} = K_{AO}\,\theta = K_{AO}\,\frac{y_o}{a} \qquad \text{(1a)}$$

and

$$\curvearrowleft m''_{OA} = m'_{AO}\,C_{AO} = K_{AO}\,C_{AO}\,\frac{y_o}{a} \qquad \text{(1b)}$$

By the principles of moment distribution:

$$K_{AO}\,C_{AO} = K_{OA}\,C_{OA} \qquad \text{(2)}$$

[2] *Transactions*, Vol. 96, 1932, p. 1.

Therefore,

$$m''_{OA} = K_{OA}\, C_{OA}\, \frac{y_o}{a} \qquad (3)$$

Lock joint A in its new position and apply a moment m'_{OA} at end O, rotating joint O through the same angle θ as shown in Fig. 3(c). The end moments from this second rotation are:

$$\curvearrowleft m'_{OA} = K_{OA}\,\theta = K_{OA}\,\frac{y_o}{a} \qquad (4a)$$

and

$$\curvearrowleft m''_{AO} = m'_{OA}\, C_{OA} = K_{OA}\, C_{OA}\, \frac{y_o}{a} = K_{AO}\, C_{AO}\, \frac{y_o}{a} \qquad (4b)$$

The final position of the beam is shown in Fig. 3(d). The final end moment at each joint is the algebraic sum of the moments at the respective joint. Therefore,

$$\curvearrowleft m_{F,AO} = \curvearrowleft m'_{AO} + \curvearrowleft m''_{AO} = K_{AO}\,\frac{y_o}{a} + K_{AO}\, C_{AO}\,\frac{y_o}{a}$$

$$= K_{AO}\,\frac{y_o}{a}\,(1 + C_{AO}) \qquad (5a)$$

$$\curvearrowleft m_{F,OA} = \curvearrowleft m'_{OA} + \curvearrowleft m''_{OA} = K_{OA}\,\frac{y_o}{a} + K_{OA}\, C_{OA}\,\frac{y_o}{a}$$

$$= K_{OA}\,\frac{y_o}{a}\,(1 + C_{OA}) \qquad (5b)$$

Corresponding formulas for the right-hand end of beam AB may be similarly derived:

$$\curvearrowright m_{F,OB} = K_{OB}\,\frac{y_o}{b}\,(1 + C_{OB}) \qquad (5c)$$

and

$$\curvearrowright m_{F,BO} = K_{BO}\,\frac{y_o}{b}\,(1 + C_{BO}) \qquad (5d)$$

Values of K and C are taken from standard tables, which are readily available. Final end moments caused by a settlement y_o are:

$$\curvearrowleft m_{AO} = m_{F,AO} + (m_{F,OB} - m_{F,OA})\, d_{OA}\, C_{OA} \qquad (6a)$$

$$\curvearrowleft m_{OA} = m_{F,OA} + (m_{F,OB} - m_{F,OA})\, d_{OA} \qquad (6b)$$

$$\curvearrowright m_{OB} = -\, m_{OA} \qquad (6c)$$

and

$$\curvearrowright m_{BO} = m_{F,BO} + (m_{F,OA} - m_{F,OB})\, d_{OB}\, C_{OB} \qquad (6d)$$

The reaction at point O necessary to restore the settlement y_o is:

$$F_v = \frac{m_{AO} + m_{OA}}{a} + \frac{m_{BO} + m_{OB}}{b} \qquad (7)$$

If a load P is applied at any point along span AO, partial end moments M' will be produced at all the joints. These are computed by distributing the

fixed-end moments at end A and at end O to all the joints. The reaction at point O is obtained from statics (see Fig. 4).

Partial end moments caused by load P acting in span AO are:

$$\curvearrowleft M'_{AO} = M_{F,AO} + M_{F,OA}\, d_{OA}\, C_{OA} \ldots\ldots (8a)$$

$$\curvearrowright M'_{OA} = M_{F,OA}\, d_{OB} \ldots\ldots (8b)$$

$$\curvearrowleft M'_{OB} = -\, M'_{OA} \ldots\ldots (8c)$$

and

$$\curvearrowleft M'_{BO} = M_{F,OA}\, d_{OB}\, C_{OB} \ldots\ldots (8d)$$

Values of M_F are taken from standard tables.

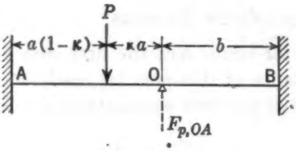

Fig. 4

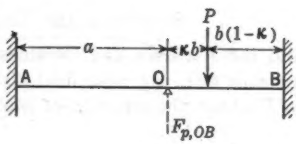

Fig. 5

The reaction at point O to resist load P in span AO is

$$F_{P,OA} = \frac{P\, a\,(1-\kappa) + M'_{OA} - M'_{AO}}{a} + \frac{M'_{OB} + M'_{BO}}{b} \ldots\ldots (9)$$

If the temporary support is removed, point O will deflect and additional end moments will be produced at all the joints similar to those caused by the displacement y_o. Since the force required to restore point O to its original position is evidently equal to $F_{p,OA}$, it is clear that an equal but opposite force is acting downward on the beam at point O after the removal of the support. Therefore, the additional end moments created by this deflection can be obtained by direct proportion from the end moments caused by y_o. The final end moments at each joint are equal to the algebraic sum of the moments at the respective joints; or:

$$\curvearrowleft M_{AB} = \frac{F_{p,OA}}{F_y}\, m_{AO} + M'_{AO} \ldots\ldots (10a)$$

and

$$\curvearrowright M_{BA} = \frac{F_{p,OA}}{F_y}\, m_{BO} - M'_{BO} \ldots\ldots (10b)$$

If a load P is applied along span OB, formulas similar to Eqs. 10 are derived in the same manner (see Fig. 5). Thus, partial end moments because of load P in span OB (compare Eqs. 8) are:

$$\curvearrowright M'_{AO} = M_{F,OB}\, d_{OA}\, C_{OA} \ldots\ldots (11a)$$

$$\curvearrowright M'_{OA} = M_{F,OB}\, d_{OA} \ldots\ldots (11b)$$

$$\curvearrowleft M'_{OB} = -\, M'_{OA} \ldots\ldots (11c)$$

and

$$\curvearrowright M'_{BO} = M_{F,BO} + M_{F,OB}\, d_{OB}\, C_{OB} \ldots\ldots (11d)$$

The reaction at point O to offset load P in span OB (compare Eq. 9) is:

$$F_{p,OB} = \frac{P\,b\,(1-\kappa) + M'_{OB} - M'_{BO}}{b} + \frac{M'_{AO} + M'_{OA}}{a} \quad \ldots\ldots (12)$$

Final end moments corresponding to load P in span OB (compare Eqs. 10) are:

$$\curvearrowleft M_{AB} = \frac{F_{p,OB}}{F_v}\, m_{AO} - M'_{AO} \quad \ldots\ldots\ldots\ldots\ldots (13a)$$

and

$$\curvearrowright M_{BA} = \frac{F_{p,OB}}{F_v}\, m_{BO} + M'_{BO} \quad \ldots\ldots\ldots\ldots\ldots (13b)$$

Stiffness and Carry-Over Factors

To find the K-values and C-values for beam AB, the first step is to find the elastic area (A), the centroidal distance of this area ($\bar{x}$), and the moment of inertia I' about the centroid of each of the two segments of the beam (see

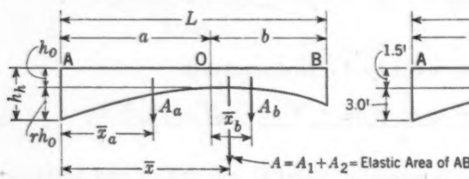

Fig. 6

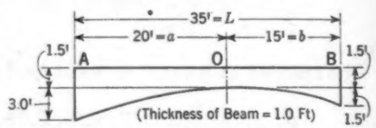

Fig. 7

Fig. 6). This is easily accomplished by the column analogy method[3] from the known values of K and C for the two beam segments; thus:

$$K_{AO} = \frac{1}{A_a} + \frac{\bar{x}^2_a}{I'_a} \quad \ldots\ldots\ldots\ldots\ldots (14a)$$

and

$$K_{OA} = \frac{1}{A_a} + \frac{(a - \bar{x}_a)^2}{I'_a} \quad \ldots\ldots\ldots\ldots\ldots (14b)$$

in which A_a is the elastic area of span AO; $\bar{x}_a$ is the centroidal distance from end A to elastic center of gravity; and I'_a is the moment of inertia of the elastic area about its center of gravity. Furthermore:

$$C_{AO} = \left[-\frac{1}{A_a} + \frac{\bar{x}_a\,(a - \bar{x}_a)}{I'_a}\right] \div \left[\frac{1}{A_a} + \frac{\bar{x}^2_a}{I'_a}\right] \quad \ldots\ldots (15a)$$

and

$$C_{OA} = \left[-\frac{1}{A_a} + \bar{x}_a\,\frac{(a - \bar{x}_a)}{I'_a}\right] \div \left[\frac{1}{A_a} + \frac{(a - \bar{x}_a)^2}{I'_a}\right] \quad \ldots\ldots (15b)$$

The signs were changed in the numerator of Eqs. 15 in order to obtain positive values for the carry-over factors. Solving Eqs. 14 and 15 simul-

[3] "The Column Analogy," by Hardy Cross, *Bulletin No. 215*, Univ. of Ill. Experiment Station, Urbana, 1930.

taneously:

$$\bar{x}_a = \frac{K_{AO}\,(1 + C_{AO})\,a}{K_{AO}\,(1 + C_{AO}) + K_{OA}\,(1 + C_{OA})} \qquad (16a)$$

$$I'_a = \frac{a\,\bar{x}_a}{K_{AO}\,(1 + C_{AO})} \qquad (16b)$$

and

$$A_a = \frac{1}{K_{AO} - \frac{\bar{x}_a}{a} K_{AO}\,(1 + C_{AO})} \qquad (16c)$$

In a similar manner the following expressions for segment OB are derived:

$$\bar{x}_b = \frac{K_{OB}\,(1 + C_{OB})\,b}{K_{OB}\,(1 + C_{OB}) + K_{BO}\,(1 + C_{BO})} \qquad (17a)$$

$$I'_b = \frac{b\,\bar{x}_b}{K_{OB}\,(1 + C_{OB})} \qquad (17b)$$

and

$$A_b = \frac{1}{K_{OB} - \frac{\bar{x}_b}{b} K_{OB}\,(1 + C_{OB})} \qquad (17c)$$

Let:

$$A = A_a + A_b \qquad (18a)$$

$$\bar{x} = \frac{A_a\,\bar{x}_a + A_b\,(a + \bar{x}_b)}{A} \qquad (18b)$$

and

$$I' = I'_a + A_a\,(\bar{x} - \bar{x}_a)^2 + I'_b + A_b\,(a + \bar{x}_b - \bar{x})^2 \qquad (18c)$$

Therefore,

$$K_{AB} = \frac{1}{A} + \frac{\bar{x}^2}{I'} \qquad (19a)$$

$$C_{AB} = \frac{-\frac{1}{A} + \frac{\bar{x}\,(L - \bar{x})}{I'}}{K_{AB}} \qquad (19b)$$

$$K_{BA} = \frac{1}{A} + \frac{(L - \bar{x})^2}{I'} \qquad (19c)$$

and

$$C_{BA} = \frac{-\frac{1}{A} + \frac{\bar{x}\,(L - \bar{x})}{I'}}{K_{BA}} \qquad (19d)$$

Typical Example

It is required to find K_{AB}, K_{BA}, C_{AB} and C_{BA} for the unsymmetrical beam AB shown in Fig. 7; and to plot the influence lines for the fixed-end moments at end A and at end B. Data for segments AO and OA may be taken from the curves in Fig. 8 and Fig. 9. In Fig. 6, let r be a ratio of minimum beam

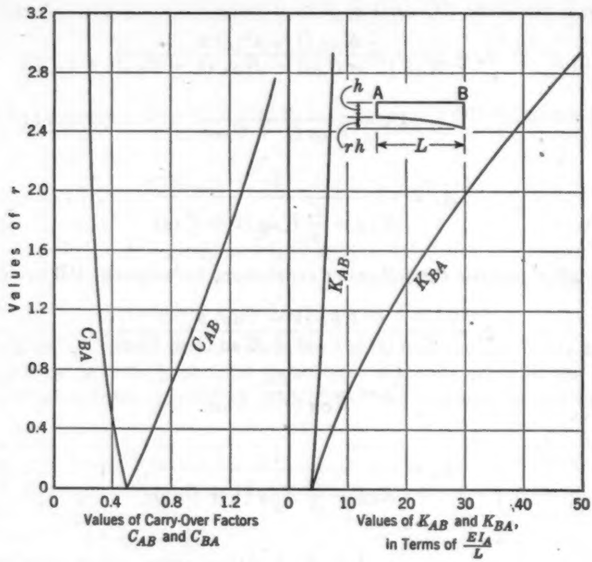

FIG. 8.—CURVES FOR THE SELECTION OF STIFFNESS RATIOS K AND CARRY-OVER FACTORS C

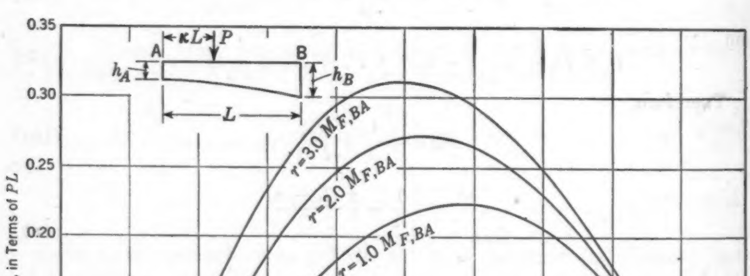

FIG. 9.—CURVES FOR SELECTION OF FIXED-END MOMENTS

depth h_o to haunch depth h_h such that $r = \frac{h_h}{h_o} - 1$. Then (see Fig. 7): $r_A = \frac{3.0}{1.5} = 2.0$; $r_B = \frac{1.5}{1.5} = 1.0$; and $I_o = 1.0 \times 1.5^3 \times \frac{1}{12} = 0.281$ ft⁴. Values for stiffness and carry-over factors at the ends of each beam segment are taken from Fig. 8:

$$K_{AO} = \frac{30.5\,E\,I_o}{20} = 0.43\,E; \qquad C_{AB} = 0.27$$

$$K_{OA} = \frac{6.5\,E\,I_o}{20} = 0.091\,E; \qquad C_{OA} = 1.27$$

$$K_{OB} = \frac{5.35\,E\,I_o}{15} = 0.10\,E; \qquad C_{OB} = 0.91$$

$$K_{BO} = \frac{14.5\,E\,I_o}{15} = 0.272\,E; \qquad C_{BO} = 0.33$$

With the foregoing values substituted in Eqs. 16:

$$x_a = \frac{0.43\,E \times 1.27 \times 20}{0.43\,E \times 1.27 + 0.091\,E \times 2.27} = 14.51$$

$$I'_a = \frac{20 \times 14.51}{0.43\,E \times 1.27} = \frac{532}{E}$$

$$A_a = \frac{1}{0.43\,E - \frac{14.51}{20} \times 0.43\,E \times 1.27} = \frac{29.4}{E}$$

—in Eqs. 17:

$$x_b = \frac{0.10\,E \times 1.91 \times 15}{0.10\,E \times 1.91 + 0.272\,E \times 1.33} = 5.18$$

$$I'_b = \frac{15 \times 5.18}{0.10\,E \times 1.91} = \frac{407}{E}$$

$$A_b = \frac{1}{0.10\,E - \frac{5.18}{15} \times 0.10\,E \times 1.91} = \frac{29.4}{E}$$

—in Eqs. 18:

$$A = A_a + A_b = \frac{29.4}{E} + \frac{29.4}{E} = \frac{58.8}{E}$$

$$x = \left[\frac{29.4}{E} \times 14.51 + \frac{29.4}{E} \times (20 + 5.18)\right] \times \frac{E}{58.8} = 19.85$$

$$I' = \frac{532}{E} + \frac{29.4}{E} \times 5.34^2 + \frac{407}{E} + \frac{29.4}{E} \times 5.33^2 = \frac{2,612}{E}$$

—and in Eqs. 19:

$$K_{AB} = \frac{E}{58.8} + \frac{19.85^2\,E}{2{,}612} \qquad = 0.168\,E$$

$$C_{AB} = \left(\frac{-E}{58.8} + \frac{19.85 \times 15.15\,E}{2{,}612}\right) \times \frac{1}{0.168\,E} = 0.583$$

$$K_{BA} = \frac{E}{58.8} + \frac{15.15^2\,E}{2{,}612} \qquad = 0.105\,E$$

$$C_{BA} = \left(\frac{-E}{58.8} + \frac{19.85 \times 15.15\,E}{2{,}612}\right) \times \frac{1}{0.105\,E} = 0.933$$

Assuming a displacement y_o of 1,000 units at point O, Eqs. 5 yield:

$$\curvearrowleft m_{F,AO} = 0.43\,E \times \frac{1{,}000}{20}(1 + 0.27) = 27.3\,E$$

$$\curvearrowleft m_{F,OA} = 0.091\,E \times \frac{1{,}000}{20}(1 + 1.27) = 10.33\,E$$

$$\curvearrowright m_{F,OB} = 0.10\,E \times \frac{1{,}000}{15}(1 + 0.91) = 12.73\,E$$

$$\curvearrowright m_{F,BO} = 0.272\,E \times \frac{1{,}000}{15}(1 + 0.33) = 24.12\,E$$

By definition:

$$d_{OA} = \frac{0.091}{0.091 + 0.10} = 0.475$$

$$d_{OB} = 1 - d_{OA} \qquad = 0.525$$

—by Eqs. 6:

$$\curvearrowleft m_{AO} = 27.3\,E + (12.72 - 10.33)\,E \times 0.475 \times 1.27 = 28.75\,E$$

$$\curvearrowleft m_{OA} = 10.33\,E + (12.73 - 10.33)\,E \times 0.475 \qquad = 11.47\,E$$

$$\curvearrowright m_{OB} = -\,m_{OA} \qquad = 11.47\,E$$

$$\curvearrowright m_{BO} = 24.12\,E + (10.33 - 12.73)\,E \times 0.525 \times 0.91 = 22.97\,E$$

—and by Eq. 7:

$$F_y = (28.75 + 11.47)\frac{E}{20} + (22.97 + 11.47)\frac{E}{15} = 4.30\,E$$

For load P in span AO equal to 1 lb, Eqs. 8 yield:

$$\curvearrowleft M'_{AO} = M_{F,AO} + M_{F,OA} \times 0.475 \times 1.27 = M_{F,AO} + 0.603\,M_{F,OA} \quad \text{(20a)}$$

$$\curvearrowright M'_{OA} = M_{F,OA} \times 0.525 \qquad = 0.525\,M_{F,OA} \quad \text{(20b)}$$

$$\curvearrowleft M'_{OB} = -\,M'_{OA} \qquad = 0.525\,M_{F,OA} \quad \text{(20c)}$$

$$\curvearrowleft M'_{BO} = M_{F,OA} \times 0.525 \times 0.91 \qquad = 0.478\,M_{F,OA} \quad \text{(20d)}$$

Values of M_F for use in Eqs. 20 are selected from Fig. 9 and entered in Cols. 2 and 3, Table 1. The resulting values of partial end moments are entered in Cols. 4 to 7, and the remaining solution leading to influence line ordinates (see Fig. 10) appear in Cols. 14 and 15, Table 1.

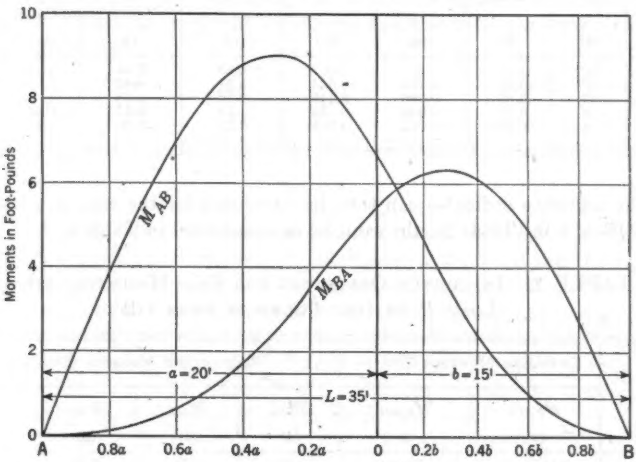

FIG. 10.—INFLUENCE LINES FOR M_{AB} AND M_{BA}

Similarly, for a load P equal to 1 lb in the span OB, Eqs. 11 yield:

$$\curvearrowright M'_{AO} = M_{F,OB} \times 0.475 \times 1.27 = 0.603\, M_{F,OB} \quad \text{(21a)}$$

$$\curvearrowright M'_{OA} = M_{F,OB} \times 0.475 = 0.475\, M_{F,OB} \quad \text{(21b)}$$

$$\curvearrowleft M'_{OB} = -\, M'_{OA} = 0.475\, M_{F,OB} \quad \text{(21c)}$$

and

$$\curvearrowright M'_{BO} = M_{F,BO} + M_{F,OB} \times 0.525 \times 0.91 = M_{F,BO} + 0.478\, M_{F,OB} \quad \text{(21d)}$$

TABLE 1.—INFLUENCE OF ORDINATES FOR END MOMENTS, WITH A LOAD P OF ONE POUND IN SPAN AO

SUMMARY

The advantages claimed for this method are clearly demonstrated in the preceding example.

By readily available curves similar to those in Fig. 9, together with a few simple equations, influence-line data for fixed-end moments for any unsymmetrical beam may be quickly tabulated. The K-values and C-values for the same beam are just as easily determined by curves similar to those in Fig. 8 plus a few more simple equations.

As to the accuracy of the results obtained by this method, it is apparent that it is no less than the accuracy of the curves from which the data for the two segments are taken.

In striking contrast with the tedious computations required by the exact methods, the comparative ease with which accurate results are obtained with this method should be apparent to anyone familiar with the analysis of unsymmetrical beams.

APPENDIX. NOTATION

The following letter symbols, used in the paper, conform essentially to American Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials (ASA—Z10*a*—1932), prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932: Subscripts AB, OA, etc. denote "in span AB," "in span OA"; or (depending on the context) "end A of Span AB," "end O of span OA," etc. Subscript F denotes "fixed-end"; y denotes "caused by settlement"; and subscript p denotes "caused by a concentrated load P."

A = elastic area of a beam $= \sum \frac{\Delta x}{E\,I_x}$;

a = left-hand segment of span L;

b = right-hand segment of span L;

C = carry-over factor;

d = distribution factor, $\frac{K}{\Sigma K}$;

E = modulus of elasticity;

F = force or reaction:

- F_y = reaction at point O of a beam necessary to restore the settlement y_o;
- F_p = reaction at point O of a beam necessary to correct the deflection caused by load P;

h = depth of a beam, with appropriate subscript to denote the section;

I = rectangular moment of inertia of the cross section of a beam $= \frac{t\,h^3}{12}$;

I_o = value of I at a point O;

I' = moment of inertia of elastic area $= \sum \frac{x^2\,\Delta x}{E\,I_x}$;

- I'_x = value of I' for variable segments x of a beam;

K = stiffness of a beam = moment required to rotate the simply supported end of a beam through a unit angle when the other end is fixed;

L = span length $= a + b$;

M = end moment caused by external loads P on a beam:

- M_F = fixed-end moment;
- M' = partial end moment;

m = end moment caused by a displacement y_o:

- m_F = fixed-end moment;
- m' = partial moment, hinged end (see Fig. 3);
- m'' = partial moment, fixed end (see Fig. 3);

P = an externally applied concentrated load;

r = a ratio of the minimum beam depth h_o to the haunch depth h_h (Fig. 6) such that $r = \frac{h_h}{h_o} - 1$;

t = thickness, or width, of the cross section of a beam;

x = variable distance from the left end of a designated span; $\bar{x}$ = distance x to the mass center of an elastic area $= \frac{1}{A}\sum\frac{x\,\Delta x}{E\,I_x}$;

y = deflection; y_o = vertical displacement imposed on a point O;

θ = angle of rotation = $\tan\theta$;

κ = a percentage of span length (see Figs. 4 and 5) depending on the position of load P.

DISCUSSION

William A. Conwell,[4] M. ASCE.—The treatment given by Mr. Lifsitz to this important subject has the virtue of maintaining close contact with fundamentals and thus eliminating elaborate tables. Thus, it appeals to the engineer who prefers to visualize structural action while making his calculations rather than to read results from tables and then interpret them. A favorable comparison between the results of the method of segments and the so-called "exact" methods referred to by the author in the "Synopsis" and "Summary" is not dependent upon any approximation inherent in the method. The only element entering the procedure and likely to affect the accuracy is the degree to which the shape of the beam upon which tables or charts (such as those of Figs. 8 and 9) are based conforms to that of the beam being analyzed.

Despite the fact that the material of the paper is not unduly complicated, it is not easily read. The reason for this difficulty may be traced to two items—organization and sacrifice of clarity and fullness for brevity.

Unlike the "Typical Example" which is superlatively organized, the preceding theory does not proceed logically to a solution. If the theory were to parallel the "Typical Example" there would first be a treatment of "Stiffness and Carry-Over Factors" and then, under "Fixed-End Moments," a sharp division of the steps of the procedure as follows:

1. Bending moments in segmental spans AO and OB resulting from load P;
2. Bending moments in beam AB resulting from a vertical load at point O; and
3. Fixed-end moments in beam AB resulting from load P.

A clear statement of the author's intention at the beginning of each division would aid the reader immeasurably.

An example of brevity at the expense of clarity is evident in the second paragraph under "Fixed-End Moments." The first sentence—"Assume a vertical settlement, y_o, at point O"—immediately raises a question. "Settlement" is usually associated with the relaxation of action or removal of a support of a loaded beam. In the instance under consideration, removal of the temporary support at point O would cause no settlement because the beam is not loaded. If, then, it is desired to produce a deflection at point O, it must be done by positive action—that is, by placing loads on the beam. Only one condition of loading—namely, a vertical load at point O—fits the requirements of the problem, however. It is suggested, therefore, that this step in the process of determining fixed-end moments for span AB be considered merely the computation of the bending moments at points A and B resulting from the application of a vertical load at point O. Thus, y_o is considered a means rather than an end and is relegated to the background where it really belongs.

In omitting the derivation of Eq. 2 brevity is achieved at the expense of fullness and the introduction of rich background material. Although this relation has appeared elsewhere,[5] it would seem more in keeping with the au-

[4] Gen. Engr., Structural Eng. and Design Dept., Duquesne Light Co., Pittsburgh, Pa.

[5] "Design Constants for Beams with Nonsymmetrical Straight Haunches," by August L. Ahlf, *Transactions*, Vol. 110, 1945, p. 1019.

thor's practice of dealing in fundamentals if a more detailed reference or a demonstration were included. The relation goes much deeper than the "principles" of moment distribution which really furnish only the definitions of the terms. The full implication of the equation is apparent only upon return to the principle that the amount of work done by forces acting upon a body is independent of the order of application of the forces. A demonstration similar to the following would seem apropos:

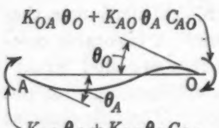

FIG. 11

If a moment $K_{AO}\,\theta_A$ is applied at end A of a beam AO while point O is restrained against rotation, it will produce a rotation θ_A at end A and induce a bending moment, $K_{AO}\,\theta_A\,C_{AO}$, at point O. A similar application of a moment $K_{OA}\,\theta_O$ at point O while end A is restrained will produce a rotation of θ_O at point O and induce a bending moment, $K_{OA}\,\theta_O\,C_{OA}$, at end A. The beam AO under the simultaneous action of these moments is shown in Fig. 11. The work (W) by the application of end moments in the order $K_{AO}\,\theta_A$, $K_{OA}\,\theta_O$ is

$$W = \tfrac{1}{2}\,K_{AO}\,\theta^2_A + \tfrac{1}{2}\,K_{OA}\,\theta^2_O + K_{AO}\,\theta_A\,C_{AO}\,\theta_O \qquad (20a)$$

Similarly, application in the order $K_{OA}\,\theta_O$, $K_{AO}\,\theta_A$ gives for the amount of work,

$$W = \tfrac{1}{2}\,K_{OA}\,\theta^2_O + \tfrac{1}{2}\,K_{AO}\,\theta^2_A + K_{OA}\,\theta_O\,C_{OA}\,\theta_A \qquad (20b)$$

Equating these expressions gives: $\tfrac{1}{2}\,K_{AO}\,\theta^2_A + \tfrac{1}{2}\,K_{OA}\,\theta^2_O + K_{AO}\,\theta_A\,C_{AO}\,\theta_O = \tfrac{1}{2}\,K_{OA}\,\theta^2_O + \tfrac{1}{2}\,K_{AO}\,\theta^2_A + K_{OA}\,\theta_O\,C_{OA}\,\theta_A$; and

$$(K_{AO}\,\theta_A\,C_{AO})\,\theta_O = (K_{OA}\,\theta_O\,C_{OA})\,\theta_A \qquad (21)$$

In general terms, Eq. 21 states that the bending moment at point O, induced by a rotation θ_A, multiplied by the rotation θ_O, equals the bending moment at end A, induced by a rotation θ_O, multiplied by the rotation θ_A. In particular, if $\theta_A = \theta_O = 1$,

$$K_{AO}\,C_{AO} = K_{OA}\,C_{OA} \qquad (22)$$

and a statement of this relation becomes simply: The bending moment at point O induced by a unit rotation at end A equals the bending moment at end A induced by a unit rotation at point O. The principles involved are evidently those of the Maxwell reciprocal theorem.

Clarity again appears to be sacrificed in the twelfth paragraph under "Fixed-End Moments" in the sentence:

> "Since the force required to restore point O to its original position is evidently equal to $F_{p,OA}$, it is clear that an equal but opposite force is acting downward on the beam at point O after removal of the support."

It is suggested that this step, after computation of the reaction $F_{p,OA}$, be considered as follows:

1. Replace the reaction, $F_{p,OA}$, with an equal, upward-acting load $F_{p,OA}$. Of course, this action will leave the state of stress and deflection in the beam

precisely as it was with the reaction in place; but it may now be treated as a single span AB.

2. By the method outlined in the discussion of the second paragraph under "Fixed-End Moments," compute the end moments resulting from a vertical downward load at point O equal to $F_{p,OA}$ and acting alone on beam AB.

3. Superimpose the loading and bending conditions of the second paragraph on those of the first paragraph. The equal and opposite loads at point O cancel each other and the bending moments are those resulting from P only.

Although Figs. 8 and 9 could have been omitted, their inclusion is commendable in that they round out the paper and make it a fairly complete tool. Values more accurate than those that can be read from the diagrams may often be desired but they are readily available in standard tables, as the author states. A description of the shape of beam upon which Figs. 8 and 9 were based would be of value. The application of tables for straight haunches[5] to the beam of the "Typical Example" yields the values $K_{AB} = 0.294\,E$, $C_{AB} = 0.541$, $K_{BA} = 0.159\,E$, and $C_{BA} = 0.997$. When these values are compared with those of the "Typical Example" ($K_{AB} = 0.168\,E$, $C_{AB} = 0.583$, $K_{BA} = 0.105\,E$, and $C_{BA} = 0.933$), some idea is obtained of the extreme variations in these characteristics resulting from differences in shape only.

In view of the foregoing it may be concluded that, despite reading made difficult by easily-removable obstacles, this paper has a more-than-ordinary value and that the presentation of the "Typical Example" is far superior to that of the remainder of the paper.

Ralph W. Hutchinson,[6] Assoc. M. ASCE.—The method of segments is similar to a method developed by engineers of the writer's organization for obtaining the properties of beams with intermediate hinges from those of the solid beam, or the same beam without the hinge. The properties of the solid beam can usually be obtained from published charts whereas available data on beams with hinges are meager.

As in the method of segments the elastic area is first obtained, together with the moment of inertia about its centroid and the location of the centroid. Because of the similarity between a beam with an intermediate hinge and one with a hinge at one end, the formulas used were based on the properties of a beam hinged at one end. By this method a formula for the elastic area A may be expressed in terms of properties of the beam without first solving for the location of the centroid. For comparison with the formula used by the author, this formula may be written in terms of a beam fixed at both ends by including the factor $(1 - C_{AB} \times C_{BA})$:

$$\frac{A}{(1 - C_{AB} \times C_{BA})} = \frac{1 - C_{AB}}{K_{BA}} + \frac{1 - C_{BA}}{K_{AB}} \qquad (23)$$

The properties of the hinged beam are computed by first finding the moment of inertia of the elastic area about the hinge. In the following formulas, the properties of the hinged beam are indicated by adding the letter H to the letter sym-

[6] Associate Bridge Engr., State of California, Sacramento, Calif.

bols used for these same properties in the solid beam: $c = \bar{x} - a$; $I_H = I + A c^2$; $K_{ABH} = \frac{a^2}{I_H}$; $K_{BAH} = \frac{b^2}{I_H}$; $C_{ABH} = \frac{b}{a}$; $C_{BAH} = \frac{a}{b}$; and $d = \frac{I_H}{C\,A}$.

Applying the foregoing equations to the solid beam in the Lifsitz paper: $A = 58.8$; $I = 2{,}612$; $\bar{x} = 19.85$; $a = 7$ ft; $b = 28$ ft; $c = 19.85 - 7.00 = 12.85$ ft; $I_H = 2{,}612 + 58.8 \times 12.85^2 = 12{,}332$; $K_{ABH} = \frac{7 \times 7}{12{,}332} = 0.00397$; $K_{BAH} = \frac{28 \times 28}{12{,}332} = 0.0636$; $C_{ABH} = \frac{28}{7} = 4$; $C_{BAH} = \frac{7}{28} = 0.25$; and $d = \frac{12{,}320}{12.85 \times 58.8} = 16.3$ ft. From the tables in Mr. Lifsitz' paper $(\text{FEM})_A = 8.82$; and $(\text{FEM})_B = 1.69$. For graphical solution the analyst can plot a simple beam moment diagram and draw a closing line through the fixed-end moments for the solid beam. The closing line for the hinged condition is drawn through the simple beam moment curve at the hinge and through the fixed-end moment line at the conjugate point.

After the properties of the beam have been obtained, fixed-end moments may be obtained by either graphical or analytical means. An illustrative example of the graphical method is given in which a hinge is inserted at the fifth-point in the beam used by the author to illustrate the method of segments. The fixed-end moments are computed for a load of $P = 1$ at 12 ft from end A (Fig. 12).

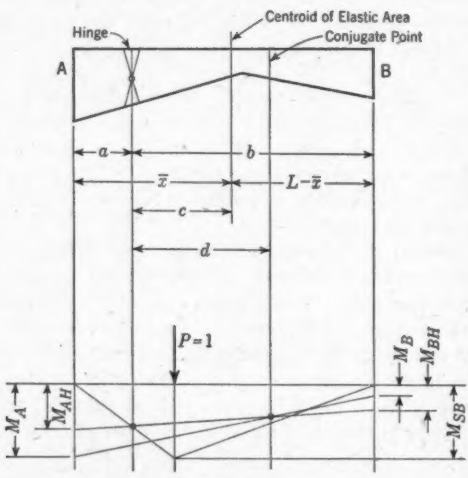

Fig. 12

Time often does not permit an exact determination of the properties of beams of unusual shape, and every engineer has had to rely on approximations extrapolated from working tables. Even though these approximations are usually close enough for the purpose there is a real need for a quick method of obtaining results with a precision equal to data picked from charts for regular beams. The method of segments gives promise of meeting this need, but the

work required for the computation of fixed-end moments is disappointing. Some engineers may find it economical to use the method of segments to determine the elastic properties of the beam and then compute fixed-end moments by a more familiar method.

Before deciding for or against the adaptation of the method of segments as a working tool, one should compare the work involved in a complete solution with the work required by a method of "multiplying factors." Such a method was developed by Carl Wagner, Jr., Jun. ASCE, from contributions by George E. Large[7] and A. W. Earl,[8] Members, ASCE.

THOMAS P. REVELISE,[9] ESQ.—The technique of computing design constants for unsymmetrical beams has been advanced perceptibly by the publication of this paper. However, the writer does not consider the method as general in scope as the author implies (see "Summary"):

> "By readily available curves similar to those in Fig. 9, together with a few simple equations, influence-line data for fixed-end moments for any unsymmetrical beam may be quickly tabulated."

Curves cannot be constructed either for use alone or in conjunction with supplementary methods for computing beam design constants if the shape or cross section of the member is sufficiently discontinuous. Several important types occur in this category. A familiar example is the continuous plate girder, with multiple cover plates of varying lengths, placed unsymmetrically over supports and elsewhere in the spans. In this case, the moments of inertia at short successive sections are both variable and discontinuous, and there is no short cut to a rational solution. The problem is also encountered occasionally in the design of reinforced concrete beams whose cross section at successive points is discontinuous.

The few exceptions do not detract from the merit of Mr. Lifsitz's method and other short-cut methods, which are applicable to most cases encountered in routine structural practice; but it is well to remember that these methods are necessarily based on certain assumptions of geometric continuity, which, if not fulfilled, make recourse to a so-called "exact" analysis the only remaining alternative.

In view of the considerable interest in this subject, evidenced by various published papers, the writer would like to say a word about its most neglected phase—the exact procedure. Most writers seem agreed that an exact procedure is too involved and unwieldy for practical use. The reader is invited to accept this premise without question, since, as a rule, no comparative demonstration is given. Although most textbooks on structural analysis present the theoretical fundamentals, few writers give consideration to a well-coordinated exact procedure arranged to yield, with a minimum of computation, the answers in which the average designer is primarily interested—namely, the stiffness and carry-over constants at both ends of a given beam and the (FEM)-coefficients at both ends for a unit load at the tenth points (or the equivalent, unit influence lines for (FEM) at both ends).

If properly organized, an exact procedure for the determination of beam design constants is much less formidable than is generally appreciated, and its applicability to all cases makes it a valuable tool for anyone engaged in this phase of structural design. Practically any variant of the elastic theory may be used in deriving the necessary expressions. Writers of today show a preference for the method of column analogy. Other variants, such as moment areas, least work, or slope deflection, can be used with fully comparable results.

* K × modulus of elasticity equals absolute stiffness.

Several years ago, the writer arranged a tabular form for the analysis of unusual and borderline cases, which is offered as an example of what can be prepared along this line.

The basic expressions were obtained by developing, algebraically, the fundamental elastic equation—

$$d\phi = \int \frac{M\,ds}{E\,I} \qquad (24)$$

—and using physical summations instead of integrals. If approached in this manner, the most advanced mathematical operation is found to be the solution (for this problem) of two simple simultaneous equations. The resultant expressions were then separated into component parts and rearranged in orderly fashion in a tabular form which is nonmathematical in character and can be executed without reference to the theoretical derivations.

The member to be analyzed is first drawn to a convenient scale and divided into ten sections of equal horizontal length as shown in Table 3. The depth, d, at the center of each section is scaled, and values of $I = \frac{b\,d^3}{12}$ are computed and entered in Col. 2, Table 3. Successive operations are indicated under each column heading; and, upon completion of the form, all necessary design constants, including fixed-end moments at both ends for unit concentrations at the tenth points are obtained. The meaning of the headings for Cols. 7 to 10 may be further clarified by reference to point $x = 3$, as follows:

$$\begin{aligned}
\text{Col. } 7 &= \Sigma\ \text{Col. } 4 - \text{Col. } 4_x &&= 4.47 - (1.03 + 0.79 + 0.61) = 2.04\\
\text{Col. } 8 &= \Sigma\ \text{Col. } 7 - \text{Col. } 7_{x-1} &&= 12.76 - (3.44 + 2.65) = 6.67\\
\text{Col. } 9 &= \Sigma\ \text{Col. } 5 - \text{Col. } 5_x &&= 1.50 - (0.05 + 0.12 + 0.15) = 1.18\\
\text{Col. } 10 &= \Sigma\ \text{Col. } 9 - \text{Col. } 9_{x-1} &&= 7.38 - (1.45 + 1.33) = 4.60
\end{aligned}$$

The example used to illustrate the procedure was chosen to afford a comparison between computed values and those obtained from available curves. The procedure remains the same, regardless of what form the dissymmetry or discontinuity takes.

Forms of the type of Table 3 can be derived independently by other methods, or the form illustrated can be altered or modified to suit the needs or preferences of the user.

Victor R. Bergman,[10] Assoc. M. ASCE.—In the analysis of beams of variable moments of inertia by the moment-distribution method, the work preliminary to the actual distribution frequently requires a major part of the total time involved. The determination of fixed-end moments, stiffness factors, and carry-over factors can be a very tedious and time-consuming task, unless facilitated by the use of tables and diagrams of adequate scope. Therefore, the author's presentation of a fairly simple method for extending the range of applicability of readily available data is to be commended. Incidentally, Eqs. 5 are not peculiar to the problem under discussion; they have been developed elsewhere in connection with other phases of structural analysis.[11]

Several years ago, the writer had occasion to develop a "Method of Sections" in which the procedure for the calculation of fixed-end moments is prac-

[10] Vice-Pres., Godwin Constr. Co., New York, N. Y.

[11] "One-Story Concrete Frames Analyzed by Moment Distribution," *Concrete Information Bulletin No. ST48*, Portland Cement Assn.

tically identical with that presented by Mr. Lifsitz, but in which the method of computing stiffness factors and carry-over factors is somewhat simpler.

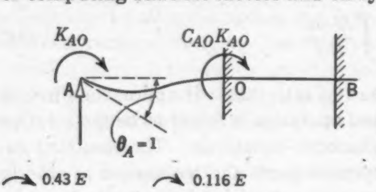

FIG. 13.—STEP 1

Consider the unsymmetrically haunched beam shown in Fig. 7 for which the author, by use of Fig. 8, determined values of K and C for each end of both segments. The writer's procedure for determining values of K_{AB} and C_{AB} involves four simple steps, as follows:

Step 1.—Assume the beam to be both supported and fixed against rotation at point O, and hinged at point A. Apply to end A (Fig. 13) a clockwise moment equal to K_{AO} ($= 0.43\ E$). This will produce on end O of the segment AO a clockwise moment equal to $C_{AO}\ K_{AO}$ ($= 0.116\ E$).

Step 2.—At end A, the applied moment will have produced (by the definition of stiffness factor) a unit rotation. Lock end A in this rotated position and unlock joint O, distributing moments as shown in Fig. 14.

Step 3.—Determine the reaction provided by the temporary support at point O, as follows:

$$F'_O = \frac{0.360\ E + 0.061\ E}{20} + \frac{0.061\ E + 0.056\ E}{15} = 0.0289\ E \ldots\ldots (25)$$

Next remove the temporary support at point O, and replace it with an equal but opposite load. In the computation preceding Eqs. 20, the author found

FIG. 14

FIG. 15

that a load of 4.30 E at point O corresponds to moments at ends A and B equal, respectively, to:

$$m_{AO} = 28.75\ E; \text{ and } m_{BO} = 22.97\ E \ldots\ldots\ldots\ldots (26)$$

By proportion, for a load of 0.0289 E at point O,

$$m_{AO} = \frac{0.0289\ E}{4.30\ E} \times 28.75\ E = 0.193\ E \ldots\ldots\ldots\ldots (27a)$$

and

$$m_{BO} = \frac{0.0289\ E}{4.30\ E} \times 22.97\ E = 0.154\ E \ldots\ldots\ldots\ldots (27b)$$

Step 4.—Combine the end moments calculated in step 3 with those determined in step 2, to arrive at the final end moments at A and B (Fig. 15). After receiving a unit rotation, end A has been maintained in that position;

it is evident, therefore, that the final moment ($=0.167\,E$) is equal to K_{AB}, the required stiffness factor, in accordance with the definition of the term. Furthermore, by the definition of carry-over factor, $C_{AB} = \dfrac{M_{BA}}{M_{AB}} = \dfrac{0.098\,E}{0.167\,E} = 0.586$.

The values thus found are seen to check, very closely, those calculated by the author. The stiffness and carry-over factors at end B, of course, can be determined in a manner similar to that followed at end A. The foregoing method involves only basic moment-distribution concepts, and, therefore, it has some slight advantage in ease and simplicity over that proposed by the author.

A. A. Eremin,[12] Assoc. M. ASCE.—A temporary support, inserted hypothetically, in an unsymmetrical member simplifies the computation of moments, stiffness, and carry-over factors. The algebraic procedures used by Mr. Lifsitz for this purpose can be clarified by the use of graphics. For illustration, the beam in Fig. 1 is analyzed graphically in Fig. 16. The member is sustaining a unit load at the midpoint of distance AO in Fig. 16(*b*).

The characteristic points in the member with a temporary support at point O are shown by the three-line polygon, Fig. 16(*a*). The moments in the member with the temporary support, fixed against linear displacement, are determined by constructing cross lines as shown in Fig. 16(*b*). The effect of a unit displacement at the temporary support is shown in Fig. 16(*c*). The final moments in the member are obtained by the summation of moments in Fig. 16(*b*) and Fig. 16(*c*), multiplied by the factor of elastic displacement of the support at point O. The resulting moments check the values in Fig. 10 very closely. Elsewhere[13] the writer has demonstrated a similar graphical construction for the distribution of moments in a continuous beam with a suspension hinge.

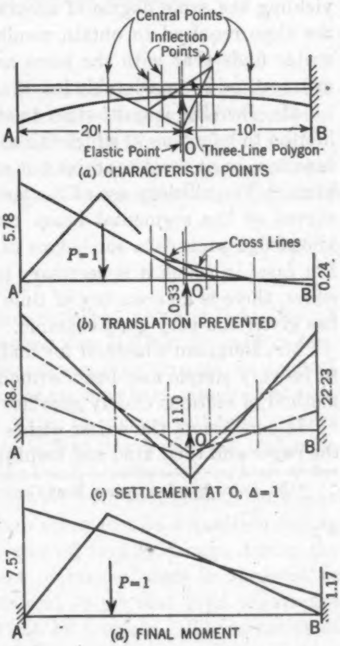

Fig. 16.—Graphic Construction of Moments in an Unsymmetrical Beam

The author's algebraic formulas for moments, stiffness, and carry-over factors serve as the preliminary steps in the distribution of moments in continuous beams. The graphical principles in Fig. 16 may be applied directly to the distribution of moments in any continuous beam or frame containing unsymmetrical members.

---

[12] Associate Bridge Engr., California State Highways Dept., Sacramento, Calif.

[13] "Analysis of Continuous Frames by Graphical Distribution of Moments," by A. A. Eremin, Sacramento, Calif., 1943.

Unsymmetrical members are often used in modern engineering structures; therefore, the paper constitutes a valuable contribution in the analytical interpretation of the temporary support method.

SOL LIFSITZ,[14] ESQ.—By clarifying some of the "hard-to-read" paragraphs of the paper Mr. Conwell has supplemented the paper considerably. As to the omission of the derivation for Eq. 2 which Mr. Conwell mentions, the writer was of the opinion that its inclusion would serve no useful purpose. The demonstration given by Mr. Conwell, based on the principle of work, is only one of several proofs available in the literature on moment distribution. As a matter of fact, the proof of Eq. 2 is inherent in Eqs. 19, where it is seen by inspection that $C_{AB}\, K_{AB} = C_{BA}\, K_{BA}$.

Mr. Hutchinson finds the work involved in the computation of fixed-end moments by the method of segments disappointing, citing the method of "multiplying factors" developed by Carl Wagner, Jr., Jun. ASCE, as an alternative for comparison. The criterion for deciding on either of two methods, both yielding the same degree of accuracy, should be the ease of computation and the time required to obtain results. After comparing the two methods, the writer finds that with the same accuracy of results the time required by his own method is considerably less than that required for the suggested alternative.

Mr. Revelise is quite right in stating that the application of the method is limited to members in which the variation in moment of inertia is a continuous function, or at most contains but a single discontinuity in each segment of the beam. The efficient use of the method is confined to cases for which tables or curves of the segmental beam constants are available, and to the writer's knowledge such data for beams of highly discontinuous outline do not exist. For cases in which it is necessary to derive the beam constants from first principles, there is no economy of time over other methods, of which Mr. Revelise has given one very good example.

Mr. Bergman's method for finding stiffness and carry-over factors appears to be very simple and bears evidence that his approach to the problem in his method of sections closely parallels that of the writer's method of segments.

In conclusion, the writer wishes to thank the discussers for their interest in the paper and their kind and helpful criticism, which he found very stimulating.

NEW PROJECT FOR STABILIZING AND DEEPENING LOWER MISSISSIPPI RIVER

By Charles Senour,[1] M. ASCE

With Discussion by Messrs. Charles W. Okey, F. Newhouse, Gerard H. Matthes, and Charles Senour.

Synopsis

The project authorized by the 1944 Act for stabilizing and deepening the Lower Mississippi River between Cairo, Ill., and Baton Rouge, La., included in flood control bill H. R. 4485 (approved December 22, 1944) and Public Law No. 534 (78th Congress, Chapter 665—second session), is the necessary sequel to the flood control and navigation improvement hitherto accomplished, which it is designed to supplement and protect.

Introduction

There is presently maintained for navigation between Cairo and Baton Rouge (head of deep-water navigation) a channel not less than 300 ft wide and 9 ft deep at lowest water. This condition or better obtains naturally throughout much of the year; but, at low stages, some of the so-called crossing bars, which constitute broad-crested sand weirs between the deep water in successive bends, require dredging. The river consists, in general, of alternating pools and crossings. The pools, lying along the concave banks of the bend, tend to scour in high water and fill somewhat on declining stages but always are from 40 ft deep to more than 100 ft deep. The crossings, however, build up many feet by deposition during high-river stages and some of them do not scour off rapidly enough during the decline to maintain the 9-ft depth. A fleet of nine dredges is operated to correct deficiencies as rapidly as they occur and to prevent their occurrence by premaintenance dredging where trouble can be foreseen. The capacity of the river to carry commerce is practically unlimited as long as the crossings can be maintained at proper depth, since there are no locks or other bottlenecks of any sort. The tonnage now being moved is limited only by the availability of carriers; between 1935 and 1944 it increased from 5$\frac{1}{2}$ million tons per yr to

Note.—Published in February, 1946, *Proceedings*. Positions and titles given are those in effect when the paper was received for publication.

[1] Chf. Engr., Mississippi River Comm., Vicksburg, Miss.

13½ million tons per yr. Data on commerce from the mouth of the Ohio River to, but not including, Baton Rouge for the years 1935–1944 are as follows:

Year	Total tons
1935	5,595,991
1936	5,786,129
1937	6,574,573
1938	6,915,034
1939	7,009,130
1940	7,055,675
1941	9,605,602
1942	9,474,591
1943	10,891,691
1944	13,115,914

History

Flood control of the Lower Mississippi began with the earliest settlements along its banks. It was, and is, absolutely essential to dependable agriculture on the flood plain. From time to time the proposition is advanced that flood protection has been a mistake and that the soil should have been rejuvenated by natural overflows. This plan has no advocates among the 3,000,000 people who live behind levees in the lower alluvial valley, for floods were early found to be too long sustained, and too uncertain as to season, to permit satisfactory correlation between overflows and farming operations.

Fortunately, the topography of the region is ideally suited to flood protection by levees. In general terms, the 20,000,000 odd acres subject to overflow comprise a flood plain of low relief about 600 miles long and from 30 miles to 110 miles wide, divided by major tributaries into seven main basins ranging in size from 956 sq miles to 6,648 sq miles.

The terrain slopes downward away from the river instead of toward it; and the natural watercourses that drain the slopes roughly parallel the river and discharge into the tributary which forms the lower boundary of the basin. Thus, some very long levee lines can be used without drainage complications of any consequence. The Yazoo Basin, for example, extending from Memphis, Tenn., to Vicksburg, Miss., embraces an area about the size of Connecticut and Rhode Island combined. It is protected by a levee 272 miles long. The Tensas Basin, about the size of North Ireland, is protected by a continuous levee 380 miles long, extending from Pine Bluff almost to Old River, in Louisiana. The levee lines do not cross the tributaries which separate the basins, so the lower ends of the basins are subject to backwater.

Proposed Plan of Flood Control

Fig. 1 shows the general features of the present plan of flood control. Briefly, this plan embraces (1) the confinement of the project flood by levees to the main channel of the river from the Commerce Hills to Cairo, and between New Madrid, Mo., and the mouth of Red River; (2) an overbank floodway about 5 miles wide supplementing the leveed river channel between Cairo and New Madrid when stage exceeds 55 ft on the Cairo gage; (3) an equal division

of project flood flow in the vicinity of the mouth of Red River, half continuing down the main river between levees, and half down the Atchafalaya Basin. Of the flow to be carried by the Atchafalaya Basin, part will pass down the Atchafalaya River (which is leveed for some 40 miles below its head) and part will flow through leveed overbank floodways paralleling the Atchafalaya River on the east and west. The plan also includes a controlled outlet into Lake Pontchartrain at Bonnet Carré some 20 miles above New Orleans, La., which is to abstract up to 250,000 cu ft per sec and thereby keep New Orleans stages from exceeding 20 ft on the Carrollton gage. Supplemental features are the protection of the St. Francis Basin against headwater floods on the St. Francis River by reservoir construction, channel improvement, and levees; the protection of the Yazoo Basin by similar methods against headwater floods of the Yazoo and of the backwaters of the Mississippi; the protection by levees of parts of the Red River backwater area, and of the White River backwater area; and the improvement of Bayou Rapides, Bayou Boeuf, and Bayou Cocodrie in Louisiana.

The project flood is the maximum flood which the

FIG. 1.—FLOOD CONTROL PLAN FOR THE ALLUVIAL VALLEY OF THE MISSISSIPPI RIVER

War Department's hydrologists and the meteorologists of the Weather Bureau consider reasonable to expect. Estimated discharge at Cairo is 2,450,000 cu ft per sec (reduced from a probable value of 2,600,000 cu ft per sec by headwater reservoirs). At the latitude of Arkansas City, Ark., discharge is estimated at 3,065,000 cu ft per sec; and at Red River, at 3,000,000 cu ft per sec.

As adopted in 1928, the plan for flood control did not include the aforementioned supplemental features; nor did it contemplate confinement of project flood flow to the leveed river channel between the Arkansas and Red rivers. Calculations had indicated that such confinement would require unreasonable increases in the height of existing levees. In the vicinity of Arkansas City, for example, the grade would have had to be raised about 15 ft.

Since the levees were already about 22 ft high on the average, and occasionally attained heights of from 30 ft to 40 ft, the resultant structures would have been so large that their cost would have appeared prohibitive had it been considered practical to make them dependably safe with the materials and foundations available.

Therefore, part of the flow of extreme floods between the Arkansas River and the Red River was to be carried by an overbank floodway leveed from the Arkansas River to the head of the Red River backwater area. The floodway was to follow the valley of the Boeuf River, west of Macon Ridge. Local interests opposed its construction; so it was shifted to the east of Macon Ridge and became known as the Eudora Floodway Project—where it was no less obdurately opposed by the people in that part of the basin.

In the meantime, however, great progress had been made in lowering the flood flow line by channel rectification through cutoffs and corrective dredging. The cutoffs were made by dredging through the narrow necks or peninsulas created by the river's meander. The distances across the necks varied from 1.4 miles to 4.8 miles, and the distances around the bends were from 7.3 miles to 17.2 miles. The fall between opposite sides of the necks ranged from 2.2 ft to 5.4 ft. Fifteen artificial cutoffs have been made and one occurred naturally in 1929. In conjunction with the cutoffs, certain chutes which fitted into the new river alinement better than did the main channel were developed by dredging. These operations have shortened the former low-water river distance of 545 miles between Memphis and Old River (mouth of Red River) by about 170 miles or 28%. By 1941, it had become apparent to everyone that the flood plane had been reduced more than 12 ft at Arkansas City and more than 6 ft at Vicksburg. Thus, the levee raising necessary to confine the project flood in the river channel was reduced to moderate and practical dimensions; and in August, 1929, Congress authorized abandonment of the Boeuf and Eudora floodway projects and the substitution of moderately enlarged levees capable of carrying the project flood from the mouth of the Arkansas River to Old River.

The recurrent necessity through the years of enlarging and re-enlarging the levees has resulted in raising them to imposing heights. When brought to the 1941 grade the levees of the Yazoo Basin, for example, will average about 30 ft high and will be from 270 ft to 290 ft wide at the base plus whatever berms may be required for foundational stability. As the size of levees has

increased, the cost per mile has increased disproportionately because of the considerably greater length of haul, and because of the present necessity for expensive foundation treatment over part of the line that was stable at the former height.

This condition, together with several other factors, has been emphasizing more and more one of the most troublesome of the river's characteristics—namely, its tendency to meander by caving its banks. No matter how wide and high the levee, no matter how impregnable against the assault of floods, it is an easy and frequent victim of bank caving. In earlier years, retreat from caving banks by the simple process of setting the levee farther landward wherever it was threatened was an easy and fairly inexpensive expedient—but that is no longer true. Levees are so massive that construction on a more retired position is very costly; and, since the ground normally drops away to the landward, the new location is almost invariably on lower ground. This physical phenomenon, in addition to requiring a higher levee, also frequently means that the new foundation is less stable than the old; and two or more years may be required for construction to avoid overloading the base and causing resultant failure.

This much time is not always available. The bank sometimes caves very rapidly. For example, at Homochitto, near Mayersville, Miss., while the engineers struggled (none too calmly) to make an extremely high setback levee stand up on a weak foundation, the bank receded 1,200 ft in three months. In 1943, caving banks required the construction of 18½ miles of levee setbacks costing approximately $4,800,000. During the ten years since 1935, caving banks have necessitated the construction of 135 miles of setbacks at approximate cost of $13,000,000. Most of this expenditure represents a total loss, since setting the levee back in no way advances the program. Moving the levee is pure appeasement of the river's insatiable appetite for land—an appetite which largely precludes the industrial or even agricultural development of riparian property, causes shoaling of channel and harbors, and, over a period of years, engulfs a surprising acreage. Accretion on one bank keeps pace with erosion on the other, but accretion is in the form of a sand bar which will not become useful for generations, while erosion claims the best and highest lands.

Considered as a geologic process, the lateral movement of the river is a matter of give and take; and, except perhaps for occasional horseshoe lakes and various scars and swales, the flood plain abandoned by the stream, in time, becomes as good as the one which it invades. However, this theory does not hold true where only periods commensurate with the short span of human life are considered and when the practical aspects of present-day economy govern. Within the memory of those who live in the valley, river meander has meant loss. The levees are almost always moved back. Even when an occasional accretion achieves a usable elevation and fertility it is not practical as a rule from the economic standpoint to include it within the levee system, since the cost per acre of protecting such isolated areas greatly exceeds the return. The levee of the lower Yazoo Levee District extending from about 25 miles above Rosedale, Miss., to Vicksburg, is 178 miles long, but not one

mile stands today upon its original location. Indeed, since 1880, the length of levee yielded to the river by setbacks in this particular district has aggregated 305 miles. The average distance between the controlling levee lines on opposite banks of the river between Memphis and Vicksburg is almost a mile greater than it was 40 years ago.

A continuation of this process of attrition must inevitably make serious inroads on the resources of the region. For example, if the channel and banks of a river are sufficiently stable, industries can load their products directly into barges; and they can import raw materials and fuel most economically by water. One effect of bank and channel instability is to discourage the establishment of such river ports and terminals.

In describing the flood control plan which was later adopted by the Act of May 15, 1928, paragraph 131 of Document No. 90, Seventieth Congress, calls attention to the menace of bank caving to the levee system and its deleterious effect upon the navigation channel in the following language:

> "131. *Channel Stabilization.* Since the levees within the limits of this project are to be greatly enlarged, they will be much more expensive than heretofore, so something must be done to avoid the frequent moving of them from the proximity of caving banks. In addition, the river cannot be regulated for low water navigation until the banks are made stable, this both to keep the channel in one place and to stop the enormous dumping of earth into the river by bank caving. A general bank protection scheme must be carried out * * *."

This statement was made in 1928. The events of succeeding years have not lessened the need. On the contrary, they have rendered it more or less imperative, for, it will be remembered, the finally adopted plan for flood control between the Arkansas River and the Red River by confinement of flow to the leveed channel is based upon the reduction in flood heights caused by shortening the river; and a return toward former length by continued bank caving would mean a corresponding return toward former flood heights and the necessity for overbank floodways—with consequent loss of the large investment made in channel rectification.

Methods of preventing bank caving are few and costly. Temporary relief may sometimes be had by dredging. The situation at Homochitto previously referred to has been corrected for the time being by this means. The circumstances are seldom such that this method is suitable, however, and at best the remedy is usually not permanent. Deflecting dikes of various types have been tried but they also are usable at very few places. The main reliance has always been upon bank revetment, consisting of mats of various types such as woven willow, lumber, asphalt, and articulated concrete, laid upon the river bed from water surface to the toe of slope which may be anywhere from 40 ft to 140 ft below low water and from 120 ft to 350 ft or more offshore. The bank above the water line may be paved with asphalt, or with riprap or articulated concrete laid on a gravel base.

Partly because of scarcity of lumber, willows, and man power, the most widely employed type of subaqueous revetment currently is the articulated concrete mattress, composed of concrete slabs 14 in. wide, 4 ft long in the

upstream-and-downstream direction and 3 in. thick, spaced 1 in. The slabs are cast in groups of twenty and are reinforced and connected by wire mesh, fabricated of noncorrosive No. 8 gage wire in sheets 4 ft by 25 ft, to form a twenty-slab unit of those dimensions. Units are laid side by side on the inclined ways of a launching barge, and $\frac{5}{16}$-in. or $\frac{7}{16}$-in. launching cables occupy the $1\frac{3}{4}$-in. spaces left between each pair of adjacent units and pass over drums on the launching barge. Loops of the reinforcing mesh projecting from the ends of the slabs of adjacent units are fastened to the launching cables by clips or twist wires to form a mattress 25 ft wide measured normal to the shore and 140 ft measured parallel to the shore. The mattress is anchored ashore by noncorrosive wires leading from the loops of reinforcing mesh projecting from the shoreward slabs to screw anchors spaced from 4 ft to 8 ft apart. It is lauched partly by withdrawing the barge riverward, concurrently paying off the launching cables. As soon as the ways are sufficiently cleared, a second series of units is placed upon them, made fast to the launching cables, and attached to the riverward ends of the preceding series by means of projecting loops of the reinforcing mesh. The procedure of launching and of adding units is repeated until the mattress has been carried as a continuous sheet a short distance riverward of the toe of the underwater slope. Then, the launching cables are cut at the barge, the outer end of the mattress released, and the barge moved in to the bank ready to assemble the next mattress immediately upstream, with an overlap of from 5 ft to 10 ft on the one previously placed.

Because of the large investment in plant required, and the short working season, revetment has heretofore been placed by hired labor. It costs from about $650,000 to $700,000 a mile under 1946 conditions as to labor and materials. An intensive research program is underway to develop a less expensive product and one that can be made more attractive to contractors from the plant angle; there is reason to believe that progress is being made.

Halfway measures cannot be adopted in an effective bank revetment program. The river's unrevetted bends are not static, but tend to move down the valley, resulting in a constant migration of the caving banks and resultant bars. A revetment put in at great expense to meet an emergency one year may be masked by a sand bar a few years later; or the current may be progressively directed against the bank farther and farther beyond it and thus require repeated extensions. The procedure of protecting the banks only where immediate disaster impends is wasteful and ineffective. However, it has been the only course possible with the funds made available and the other urgent demands upon them. The ideal method would be to stabilize all the bends at once. That is obviously impossible. The next best course would be to work downstream in orderly sequence from certain points where the stream is fixed in location by the presence of bluffs.

The force of events appeared to have made a general stabilization of the river's banks the next and essential step in the improvement. However, this would involve large sums of money and the modification of a fundamental aspect of regimen. It seemed advisable, therefore, to approach such stabilization with caution and, before recommending that it be undertaken, to make

certain, if possible, (*a*) that the need was in fact as real as it seemed; (*b*) that there was not some geologic or other cause that would arrest meander or restrict its ultimate scope to limits that could be permitted; (*c*) whether the river's past history indicated that if let alone it would in fact regain the length eliminated by cutoffs as the rapid caving since their completion seemed to indicate; (*d*) whether restriction of meander by artificial means would set up conditions adverse to other aspects of regimen; and (*e*) to what extent revetment of banks would be required to effect satisfactory stabilization.

The Commission had been concerned, of course, with problems of meander for many years; but the river is so large, its phenomena so complex and interrelated, its geology so complicated, and its cycles of change so deliberate, that several fundamental questions had either no answer or too many conflicting answers.

Certain facilities have become available for investigation that were not formerly extant. The making of literally thousands of deep borings in the alluvial valley by the petroleum industry, and coverage of the valley by aerial photographs in connection with the crop control program of the Department of Agriculture provide opportunities, far beyond anything ever approached before, for studying the geologic background of the river. The significance of the oil-well logs is too apparent to require comment. The value of aerial photographs is that ancient river courses and other phenomena not discernible to an observer on the ground are easily detectable in an aerial photograph, and once located in this manner may be examined on the ground to the extent desired.

Another recently developed method of investigation is model experimentation. In the model the numerous variables which combine in nature to obscure one another's effects can be isolated and controlled; cycles of floods and low

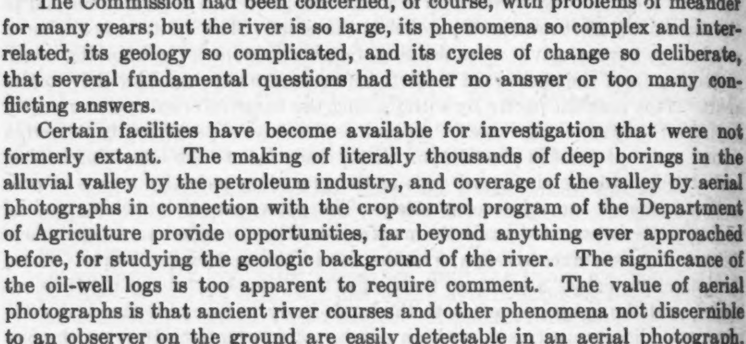

FIG. 2.—EAST-WEST CROSS SECTION AT THE SOUTHERN LIMIT OF THE MISSISSIPPI EMBAYMENT, ALONG LATITUDE 34° 00′ (see Fig. 1)

waters that would consume years in nature can be reproduced in the model in a matter of hours. It seemed possible that exploration of the river's geology, and model experimentation might resolve some of the questions that the usual methods of observation had not entirely clarified.

The geologic investigation was undertaken by H. N. Fisk of Louisiana State University at Baton Rouge as consulting geologist to the Commission, from whose data Figs. 2 to 5 have been reproduced. The borings made in connection with exploration for oil were supplemented as necessary to develop

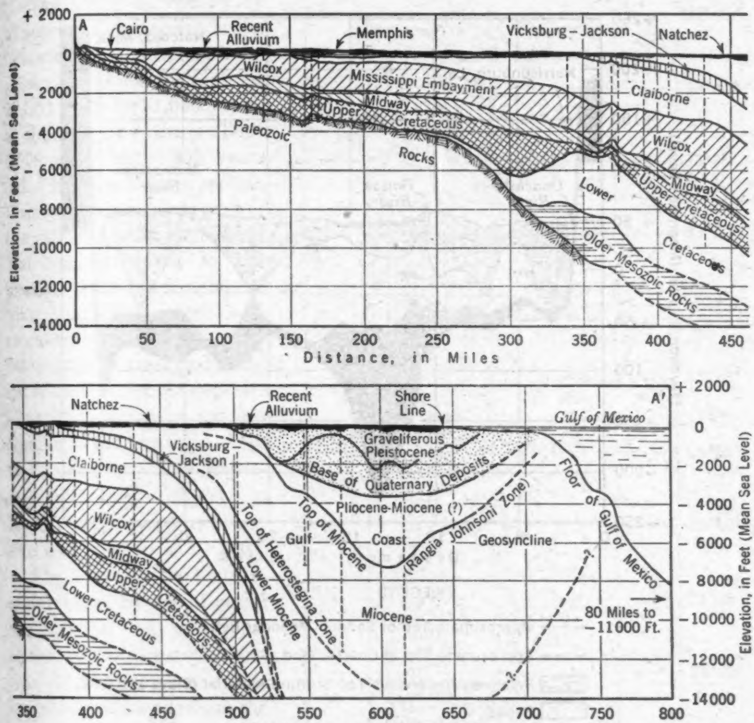

FIG. 3.—NORTH-SOUTH CROSS SECTION, CENTRAL GULF COASTAL PLAIN (see Fig. 1)

geologic cross sections of the valley; and the study of aerial photographs was followed by field exploration. The results were interesting and useful.

The Paleozoic floor of the lower alluvial valley apparently dips down to form a great north-south structural trough roughly following the course of the modern river and an east-west geosyncline along the Gulf Coast. Fig. 2 is a west-east cross section through the structural trough at about the latitude of Rosedale, Miss. Fig. 3 is a profile along the trough and through the geosyncline. The floor of the north-south trough is about 15,000 ft below sea level at the latitude of Natchez, Miss., 10,000 ft below sea level at Lake Providence, La., 5,000 ft at Rosedale, and 3,500 ft at Memphis. The bottom of the Gulf Coast geosyncline is about 20,000 ft below sea level. These depressions are thought to have resulted from the weight of the sediments which fill them

and which were brought down by tributary streams from the Appalachians and the Ouachita-Ozark Mountains for the 180,000,000 years to 200,000,000 years comprised in the Mesozoic era and the Tertiary period of Cenozoic time. No stream of great size seems to have entered the valley from the north until

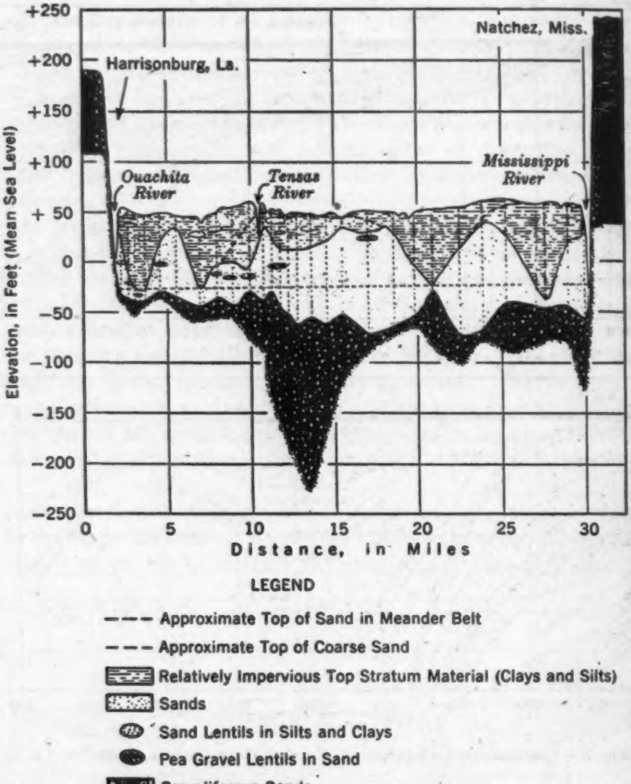

FIG. 4.—WEST-EAST CROSS SECTION FROM HARRISBURG, LA. TO NATCHEZ, MISS., SHOWING THE GENERALIZED NATURE OF THE ALLUVIAL FILLING OF THE VALLEY CUT DURING THE LAST GLACIAL STAGE (see Fig. 1)

the ice cap of the first glacial stage of the Pleistocene epoch interrupted northward flowing drainage and ponded it, and the drainage overflowed the divide into the lower alluvial valley, about 1,000,000 years ago. Several periods of glaciation and retreat of the ice cap followed—the former always resulting in a lowering of sea level and the deep entrenchment of streams in the alluvial plain; the latter, in rising ocean levels and the refilling of the valley and the

basins. The retreat of the last glacier (late Wisconsin stage) began about 30,000 years ago. At that time sea level was about 350 ft below present elevation, and the slope of the entrenched valley, gradually steepening as it approached the sea, was about twice that of the present valley.

The filling of the valley to approximate present levels following final retreat of the glacier consumed from about 20,000 years to 24,000 years, so the present plain is about 6,000 years to 10,000 years old. Fig. 4 is a cross section through the narrowest part of the valley—at the latitude of Natchez—extending to the Tertiary level, and it shows that the Pleistocene, and recent sediments to depths far below present river bed, consist of easily erodible deposits comprised of coarse gravels grading finer upward into sands and silts. The Mississippi River carried gravel into the Gulf of Mexico until sea level had risen to El. −200.

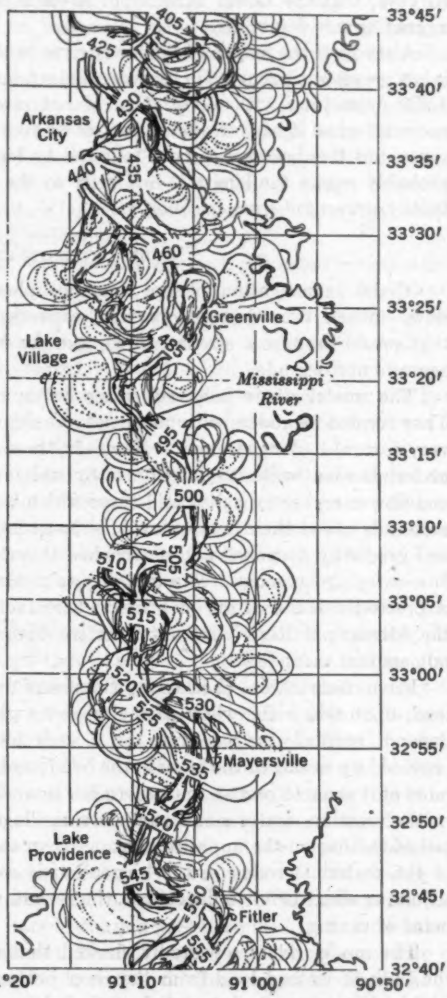

FIG. 5.—MISSISSIPPI RIVER MEANDER BELT

Fig. 5 records the history, as developed by use of aerial photographs, of a typical section of the present 2,000-year-old meander belt. The reach shown extends from the Arkansas River to Fitler, Miss. The meander belt has covered a width of from 15 miles to 20 miles. The study did not disclose any basis for believing that future behavior will differ materially from past behavior. It seems well established that, unless its meanders are artificially checked, in course of time the river will destroy everything within many miles of its present course.

The study of ancient meanders has developed another interesting fact—namely, that the elevations of the banks along the river's various courses and

the depths of its previous channels are practically the same as the elevations of its present banks and its present thalweg depths at correlative locations. This is convincing evidence that the river is not an aggrading stream in the ordinary sense of that term, and confirms the indication of data procured by surveys, that the Lower Mississippi River is now a "poised" stream—neither aggrading nor degrading.

A study of the length of the lower river in the sixteen reconstructed courses it has previously occupied in its present meander belt shows that it has remained 1,200 miles long with a variation of not more than 10%. Shortening has occurred when it has forsaken a part of its course to take a more advantageous route, but this has always been followed by lengthening. Thus, the river will probably regain the length it had prior to the cutoff program if it is not artificially prevented from so doing.

Model Investigation

Model investigation of the meander phenomenon proved unexpectedly slow. Much time and energy were expended in trying to find a material that would produce a stream which, like the Mississippi River, would neither aggrade nor degrade.

The model rivers behaved either better or worse than the Mississippi. They formed meanders with pools and crossing bars and point bars and became very natural-looking streams. However, those molded in granular, cohesionless materials soon began to deteriorate by widening and shoaling and lost depth and flow-carrying capacity; and those which were molded in difficultly erodible materials caved their bends slowly, showed much less tendency to build bars, and gradually deepened and entrenched themselves with increases in bankfull flow-carrying capacity. This inability to produce a poised condition, although it precluded the creation of a model stream that would behave exactly like the Mississippi River, did not interfere with the study of the general phenomenon of meander.

From observation, checked by the use of dyed sand, the movement of bed load, upon which the whole of the meander phenomenon seems principally to depend, normally appeared to be a very local movement. The load was provided by caving of the bank in the bend; and, where the bends were uniform, most of it came to rest on the convex bar immediately below—a part depositing in the crossing, and a small part moving diagonally across to deposit on the tail of the bar on the opposite bank. When the bends were not uniform some of the material eroded in the longer bends would be carried on through an adjoining short bend to deposit on the second or third convex bar beyond the point of caving.

The model rivers repeatedly showed that a meandering stream picks up the bulk of its bed load from the river bottom. If the banks are high and friable, the removal of material at their base causes them to slough off into the stream, thereby increasing the width and decreasing the depth with resultant steepening of the water-surface slope. If the stream still receives more bed load than it can handle, even with its increase in slope, the process

continues until at length, if the surplus of load persists, it becomes a shallow and sometimes a "braided" stream whose low-water flow is carried in a series of small interconnected channels wandering across the surface of its sediment-filled trough.

When the banks are tough, they do not slough off so readily when load is picked up from the bed; and so, instead of being surfeited with bed load, the stream is starved and continues to remove material from the bed with consequent deepening and flattening of slope and with small tendency toward building up crossing bars between successive pools. This type of stream is illustrated in nature by the deep river below Baton Rouge where the banks and bed cutting across the clay deposits of a Pleistocene delta are fairly resistant to erosion. There as elsewhere on the Lower Mississippi River, however, a balance seems to have been struck between the forces at work, so that there is not any evidence of continuing entrenchment.

When the caving banks of the model rivers were protected by revetment, they could no longer cave into the stream; and, in consequence, the quantity of bed load was reduced. In general, the bends deepened, and the flow-carrying capacity either ceased deteriorating or positively improved—usually the latter—and sometimes to a remarkable extent, when the revetment extended throughout each bend. No good reason is apparent why revetting the banks of the Mississippi River should not reduce the bed load in that stream, nor why such reduction should not similarly affect flow capacity.

Revetment is placed in caving bends. Hence, its direct effects are upon the bends rather than upon the crossings. However, since the crossing bars are formed by the deposition of bed load, reducing the quantity of bed load by restricting its procurement to the bed of the river should tend to discourage the growth of the crossing bars, which interfere with navigation.

Most of the crossings do not offer any difficulties to 9-ft navigation under present conditions. For example, a recent typical channel report at very low water for the river between Cairo and the mouth of the Arkansas River, where most of the dredging of crossings is required, lists a total of seventy-four crossings. Of this number, five were 9 ft deep, thirty nine were 12 ft deep or more, and thirty were from 10 ft to 11½ ft deep. Where trouble does occur, it is usually due to a dissipation of the flow as a thin sheet over a wide expanse of sand bar or as several shallow divided channels across the bar. Its concentration into a single channel of moderate width would correct the deficiency. Revetment alone probably cannot accomplish this. However, if the migrating bends are revetted, so that their positions and curvature do not change from year to year, it should be practical in many cases to confine the extreme low-stage flows over the crossing bars to courses predetermined by low dikes which would not in any way interfere with flood flows but would only come into play to prevent the formation of multiple or too wide low-stage bar channels.

Because of the reduction in quantity of bed load and stabilization of channel that revetting the banks would entail, the amount of dredging now performed should insure the maintenance of a channel at least 12 ft deep after the banks have been stabilized.

Summary

Concurrently with the model studies, analysis was conducted to develop the probable length of revetment required to stabilize the river upon an acceptable alinement. The study developed that, in the 737 miles between Cairo and Baton Rouge, 97½ miles of effective bank revetment were already in place, and indicated that, to stabilize the banks between the two points, about 230 additional miles would be required—representing an aggregate of 44½% of the total river length and a cost of about $165,000,000. Allowing $35,000,000 for possible improvement dredging and the construction of low dikes, the cost of the total requirement was estimated at about $200,000,000.

The whole question is succinctly summarized in the following statement from the report of the Mississippi River Commission (Document No. 509, Seventy-eighth Congress, second session):

> "The Commission is of the opinion that stabilization of the river is necessary in order to retain reduction in flood heights obtained by channel rectification, and is advisable for the purpose of safeguarding the main Mississippi River levees and protecting the investment which they represent. The Commission is of the further opinion that such stabilization may materially increase the flood carrying capacity of the river channel and together with the maintenance dredging already authorized, will provide a minimum depth of 12 feet at low water for navigation.
>
> "The great investments made by the Government and the local people in the levee system, the constantly increasing population and property values protected by the levees, and the benefits accruing to the country as a whole from the navigation of the river in both war and peace justify the further expenditures required."

DISCUSSION

Charles W. Okey,[2] M. ASCE—In describing the new project for stabilizing and deepening the Mississippi River, and recording a condensed history of the development of the present flood control plans, Mr. Senour has performed a service of great value. This paper is a most valuable summary of the results of geologic investigations by the Corps of Engineers, U. S. Army, for the past several years on the Mississippi River below Cairo, Ill.

This new project is gigantic, as compared to anything tried elsewhere, both in the cost of the proposed work, and the size of the river and volume of flows involved. The field observations and the model investigations give good reason to believe that the principal objects of the project will be attained in the years to come. The principal uncertainty seems to be: What will be the progressive development of the crossing bars between the bends? If the supply of bed load from the upstream caving banks were reduced by revetment, then dredging might be reduced. As Mr. Senour states, if the migrating bends have their position and curvature fixed by revetment, low dikes would be a possible solution for a channel across those bars where the required depth is not maintained by the river itself. Without such low dikes to confine the low-water flow to a predetermined course, the elevation of the crossing bar might be reduced by less bed-load supply, but with a corresponding reduction in the elevation of the water across the bar, resulting in no substantial increase in navigable depth.

The prevention of the loss of levees on caving banks and the prevention of a gradual increase in the length of the channel, so beneficially reduced by cutoffs in the past few years, are objectives of great importance. They are much to be desired even though a great increase in the navigable depth over the crossing bars might not be automatically attained and continuously preserved at low-water stages.

The writer has been interested in this matter since March, 1911, when he read a manuscript copy of a paper by the late Maj. T. G. Dabney, for many years the chief engineer of the Yazoo-Mississippi Levee District. That paper (which was not published) had been originally written as a plea to the Mississippi River Commission to do what is now proposed by the project authorized in the 1944 Act. In reading Mr. Senour's paper, the writer's mind traveled along a familiar path which seemed to agree with Major Dabney's plea to the Mississippi River Commission. This plea of Major Dabney's if found in the records of the Mississippi River Commission or in the levee board office at Clarksdale, Miss., would constitute a most interesting commentary on Mr. Senour's paper.

F. Newhouse,[3] Esq.—The practice of building bigger and better levees to control a meandering river has proved ineffective on the Lower Mississippi, as is revealed in this valuable and interesting paper. The experiments and

[2] Head Hydr. Engr., TVA, Knoxville, Tenn.

[3] Twickenham, Middlesex, England.

research described in the paper appear to have led the authorities to decide to deal with this engineering problem by adopting a method whose necessity can be deduced from basic theory.

Any river carves its course through its own alluvial plane by the erosive power of its current. This erosive power depends on the velocity of the water, and the degree of erosion depends on the resistance of the soil. A river, therefore, achieves stability when its velocity is such that it cannot erode its channel. Velocity, of course, depends on slope. This fact leads to the basic theory that the shape of the channel of a river depends on two things only—(1) the slope and (2) the soil through which the river flows. The slope in turn depends on two quantities—(*a*) the fall from the source to the sink and (*b*) the length of the course.

For practical purposes, the fall must be accepted as fixed over any river as a whole, since it can only be changed to a significant extent by earth movements. On individual reaches the slope could be altered by building weirs and falls, but such construction would be attended by economic and engineering difficulties, probably prohibitive because of their extent on large rivers.

The other element in slope, length of course, is altered by the forces of nature in two ways: The river eats into one bank or the other forming a curve and carries the eroded material onward, in a series of repeated depositions and erosions, until it reaches the sea. Shoals are built up and the land is gradually advanced, by the deposition of the eroded material and of the silt brought down from the catchment area by normal (or abnormal) denudation. At some river mouths this formation is very conspicuous, as, for instance, at the Rosetta and Damietta mouths of the Nile River. Any map, even a small-scale map, shows the capes formed in the smooth coast line of Egypt.

The combined effects of the curves formed by erosion and of the deposition at the mouth lengthen the course of a river and therefore reduce the slope and hence the velocity. Finally, a state of equilibrium is established in the flood bed of the river, when the velocity is so reduced that it can no longer produce scour. Such a condition is easily upset by slight local variations in velocity whose effect is to set the deep channel of the river swinging from side to side. The channel then becomes a series of curves, full of shifting shoals, and tends constantly to erode one bank or the other. Everything possible has been done by nature in the way of reducing slope and velocity to fit the soil, without producing a satisfactory river channel for man's purposes. Therefore, action must be taken on the second factor that affects the course of a river—namely, the soil through which the river flows.

Nature changes soil by denudation but not in a manner designed to offer greater resistance to erosion. Excessive denudation of the catchment area causes floods to carry a heavier charge of silt, and produces sandbanks, inequalities in current, erosion, and general instability; but it does not improve a river—just the reverse! In fact, soil cannot be improved by nature, from the point of view of resistance to erosion, and the indisputable conclusion is that it must be protected by the art of the engineer—by the use of stone. Thus theory has led to the conclusion that revetment alone can stabilize the course of a river.

Cutting off a bend on a river must increase velocities locally, and start again the aforementioned erosion and other ill effects. If every cutoff is not revetted as it is built, the "Works" should be given the code name of "Operation Sisyphus."

It has been decided to revet cutoffs on the Mississippi, but the extent of the revetment of the cross section has not been stated in the paper. If the banks alone are revetted, there will be erosion of the bed and the revetment on the slopes will be underscoured, and will collapse, with consequences easy to foresee. It would be of interest to know the steps being taken to meet this danger and, eventually, how they succeed.

Gerard H. Matthes,[4] Hon. M. ASCE—The author is to be commended for the conciseness with which he has presented the historical and physical sequences of flood control and channel regulation in the Lower Mississippi Valley; also, for setting forth so clearly the stable characteristics of the river as regards its being neither an aggrading nor a degrading stream. This truly remarkable stability, despite its ceaseless meandering, has been fundamental to the success of much of the engineering work executed. Broadly viewed, it is the basic justification for the large expenditures for flood control and river-channel improvement that have been made in the past, and for the expenditures yet to be made.

Had the physical conditions in the Lower Mississippi Valley paralleled those in Mesopotamia (Iraq), its history would have been differently written. Mesopotamia, an alluvial valley of comparable size, has been, and still is, outstanding for the difficulties that beset its large irrigation and flood control works. The sediment deposited by two large rivers, the Tigris and the Euphrates, raises river beds and flood plain at a rapid rate. Great floods, repeatedly, have buried, under silt, the extensive irrigation systems, levees, and even entire cities whose ruins have been found at successive levels underground. The alluvium, furthermore, has built out into the Persian Gulf 170 miles in 5,500 years or at the average rate of 160 ft a year. In marked contrast are the extremely slow advance of the mouths of the Mississippi into the Gulf of Mexico, and the absence of bed aggrading in the 1,000 miles of Lower Mississippi River.

The river has suffered aggradation only to the extent of a few feet at its junction with the Ohio due to local conditions downstream created by the hand of man. In other places, the bed has become lowered as much as 5 ft where cutoffs or dredging operations have shortened the channel. Aside from these local changes (which resulted from channel improvement), the low-water profile has shown but little change. An interesting checkup became available in 1936 when the low-water profile of that year was compared with that of 1901, both representing extreme low-water conditions with fairly comparable discharges. It was found that the elevation above sea level, of the water surfaces at New Madrid, Mo., Memphis, Tenn., Vicksburg, Miss., and Angola, La., on these two occasions were in close agreement, differences ranging from 1 ft to almost zero. The important point brought out by this comparison was that,

[4] New York N. Y.

wherever the river had not become affected by engineering operations, its low-water profile had not been altered by natural causes over a period of 35 years.

These stable characteristics of the Lower Mississippi are referred to by the author when he terms it a "poised river." As this is an unfamiliar term as applied to rivers, a word of explanation is in order. The word "poised" was first used in 1941[5] to denote a status in which a stream shows no apparent natural tendency toward over-all raising or lowering of its bed. It is merely a convenient label for such a status in connection with the construction and maintenance of engineering works, the useful life of which commonly does not exceed half a century. The word implies no permanency, however; rather, it implies the possibility that the status may change at any time, or may be in the process of changing, as measured over the long course of geologic time. A river may be "poised" regardless of whether, concurrently, the land surface of its flood plain is being raised or eroded. Such, in substance, was the prevailing status of the Lower Mississippi up to 1932 when major channel improvements were undertaken.

The subject of the river's stability is of interest to engineers for another reason; namely, the widespread misunderstandings that are entertained concerning it. Statements have emanated from supposedly well-informed sources[6,7,8,9] to the effect that the Lower Mississippi is "forever" building up its bed and banks to higher levels, and that, consequently, the levees built for protection against overflow will have to be raised "indefinitely" as flood crests reach higher elevations. In a geological sense, the river is actually an aggrading river, because were it not for the levees it would continue to raise its flood plain by depositing silt. Deposits of this kind still take place on overflowed areas which have no levee protection, as evidenced by the gradual filling of lakes and sloughs in backwater areas. On the whole, however, the silt layers deposited by the Lower Mississippi, as described by the author, have been much thinner than commonly imagined; otherwise they would have obliterated the early channel courses of the river of 2,000 years ago.[10]

Charles Senour,[11] M. ASCE.—The writer is grateful for the several discussions of his paper and for the consideration and thoughtfulness which they exemplify.

With regard to Mr. Okey's arresting reference to a paper by the late Maj. T. G. Dabney (to whose memory a handsome granite marker has been erected at the head of the Yazoo Basin levee), it may be stated that, although this particular paper has not come to light either at Vicksburg (Miss.) or Clarksdale (Miss.), the desirability and eventual necessity for more or less complete stabilization of the banks of the lower Mississippi have been voiced by various writings of Major Dabney both prior and subsequent to 1911, and also, from

time to time, by others. The very considerable sum of money and the large plant investment involved in such an undertaking, the necessity of accomplishing the work at a fairly rapid tempo, and the apparently more urgent need for other types of work have, in the past, inhibited anything beyond academic consideration of such a project. Authorization of the present undertaking was made possible largely through the efforts of Maj.-Gen. Max C. Tyler, M. ASCE, who was president of the Mississippi River Commission between 1939 and 1945.

With reference to the question of the direct effect of bank stabilization upon actual depths over the crossing bars without low dikes to direct low-water flow, it may be remarked that Mr. Okey's observations are borne out by the model studies made at the Waterways Experiment Station at Vicksburg. In all cases the model river bed lowered when completely stabilized. In some cases, the resultant actual low-water depths over the crossing bars increased; in others the bed and water surface were lowered in practically equal measure. It seems certain that at many points dredging must continue even after stabilization, but, it is hoped, with greatly improved results in navigable depths for equal effort.

As Mr. Newhouse states in the preamble to his interesting analysis, the necessity for bank stabilization can be deduced from basic theory. It is not believed that—for many years past, at least—engineers have cherished the hope that the construction of levees could solve the meander problem. Mr. Newhouse mentions that the shape of a river channel depends upon two factors only—the slope, and the character of the soil through which the river flows—and that slope depends only upon the fall from source to mouth and the length of the stream's course between those points. So inextricably interrelated are the factors that govern river regimen, that, although the shape of the channel does indeed depend upon slope and soil characteristics of bed and banks, in a large degree, the slope, itself (at least with respect to quite long reaches of the stream), is determined by the soil characteristics of bed and banks, tough materials apparently conducing to flat, and sandy materials to steeper, slopes.

Mr. Newhouse also stresses a very important point in his comment as to the extent of the cross section revetted upon the Mississippi River, and the possibilities of trouble inherent in revetment of the banks alone. It is true that, with only the banks protected, the river bed will generally scour at the outer edge of the revetment. On the Mississippi River the revetment is normally built to the toe of the bank's slope and beyond the toe a distance sufficient to permit it to follow down as deepening occurs. The assumption is made, for purposes of design, that the ultimate depth attained will approximate the maximum depth observed elsewhere in the general vicinity where bank recession is not in progress. The revetment is articulated and so is flexible; it has considerable strength in tension. By virtue of these characteristics it is able, in some cases, to adjust itself to a moderate amount of gradual deepening without apparent distress. In other cases, repairs are required. The process of adjustment takes place a great distance beneath the surface of the muddy stream and its mechanics are not observable. It seems probable that, when the adjustment takes place by a gradual flowing out of sand from beneath the mat-

tress, the latter accommodates itself to the change without much damage. However, when the character of the bank is such that a considerable deepening occurs in advance of bank movement, and for this or some other reason the movement partakes of the character of a slough of sizable proportions, the outer parts of the mattress, despite its considerable strength, are ruptured and replacement of the riverward sections is indicated. Plans have been under consideration for some time for a large-scale experiment with clear water to continue to investigate the mechanics of failure, but the problem poses certain practical difficulties. The matter is also being studied from another angle—the possibility of using low abatis dikes or similar permeable current-retarding structures sunk and anchored at the toe of the revetment to prevent erosion at that immediate point and to force the locus of deepening farther channelward. Some experimental work along this line has been performed on model rivers, and it is possible that an installation will be made in the prototype during 1947.

Mr. Matthes' scholarly observations anent the contrasting characteristics of the Mississippi and Mesopotamian alluvial valleys are most interesting, as is his discussion of the implications and limitations of the term "poised" as used to connote the river's lack of apparent tendency to aggrade or degrade. As to aggradation of the flood plain, the deposition of silt from overbank flows took place for centuries along the present meander belt of the river before its floods were confined by levees which, in a geological sense, are parvenu indeed. The heavy deposits, however, consisting of the coarser sediments, took place on the immediate banks, which, accordingly, in course of time, became natural levees sloping off landward into the lowlands upon which the silt deposits were less generous. Since the river's meander was constantly caving its immediate banks, it was constantly tending to work its way into lower and lower ground. Thus, while through the medium of its flood deposits it was always tending to increase the general elevation of its banks, it was at the same time tending to decrease bank elevation by caving the highest ground into the river, thereby forcing the bank line back into lower terrain—which in turn built up and in turn caved in, and so ad infinitum. The net result of all this "give and take" appears to be a present natural levee at about the same height as those of previous meander belts. It can scarcely be doubted that the general elevation of the lowlands too remote from the stream to be attacked by it must have increased through the years, but, as stated by Mr. Matthes, the deposits, except at the immediate banks, appear to have been comparatively light and—over most of the territory—have been stopped entirely by the construction of levees. Some building of the batture (the land lying between the levee and the river) is in progress, particularly below Baton Rouge, La., where in many places the levee looks appreciably higher when viewed from the land side than it does when viewed from the river side. Hydrographic surveys, repeated at intervals over most of the period of levee building, have revealed no general tendency toward any aggradation of river bed. The necessity for upward revision of levee grades from time to time has been brought about entirely by

the increasingly more complete confinement of flood flows warranted by the continuing economic development of the alluvial plain.

W. E. Elam, M. ASCE, chief engineer, Board of Mississippi Levee Commissioners, has advised by letter that the assertion that none of the levees of the lower Yazoo Levee District remains upon its original alinement is in error—that according to a map of the district made in 1867 by its then chief engineer, Minor Meriwether, he has located (in small stretches scattered here and there through the almost 180 miles of line) a little more than 27 miles that the river has overlooked. The assertion referred to has been current for some years in this vicinity. It apparently represents an erroneous conclusion drawn from a statement in the 1943 report of the levee board to the effect that the river had claimed 305 miles of its levees since 1880. The writer is at a loss to explain such crass inefficiency in a stream as generally thorough in such matters as is the Lower Mississippi, but is glad to make the correction.

SHIPWAYS WITH CELLULAR WALLS ON A MARL FOUNDATION

By M. M. Fitz Hugh,[1] Esq., J. S. Miller,[2] Esq., and Karl Terzaghi,[3] M. ASCE

Synopsis

Two full-length submerged shipways, whose walls consist of cellular cofferdams, are described in this paper. The cells of the cofferdams are filled with marl and founded on marl. The term "marl" is applied to a rather dense, greenish, calcareous sediment which has the grain-size characteristics of a fine, silty sand but, in an undistrubed state, the consistency of a stiff clay. The shipways are separated from each other by a partition wall which also consists of a cellular cofferdam. All the cells are of the diaphragm type. The hydrostatic uplift on the floors of the shipways is relieved not only by weep holes in the concrete mat but also, wherever necessary, by sand wells that drain the subsoil at a considerable depth below the floors.

The theoretical principles for the design of cellular cofferdams have been described elsewhere.[4] In connection with the design of the new shipways the local hydraulic and geologic conditions precluded an accurate forecast of the deflection of the walls and of the force that tends to lift the shipway floors. In this paper it will be shown that the risk due to such inevitable initial uncertainties can be eliminated completely by appropriate observations during construction, combined with modifications in the details of the design as soon as the required data become available.

General Layout and Soil Conditions

The general layout and two typical cross sections through the shipways are shown in Fig. 1. In a paper published in 1943, C. B. Jansen, M. ASCE,

Note.—Published in November, 1945, *Proceedings*. Positions and titles given are those in effect when the paper was received for publication.

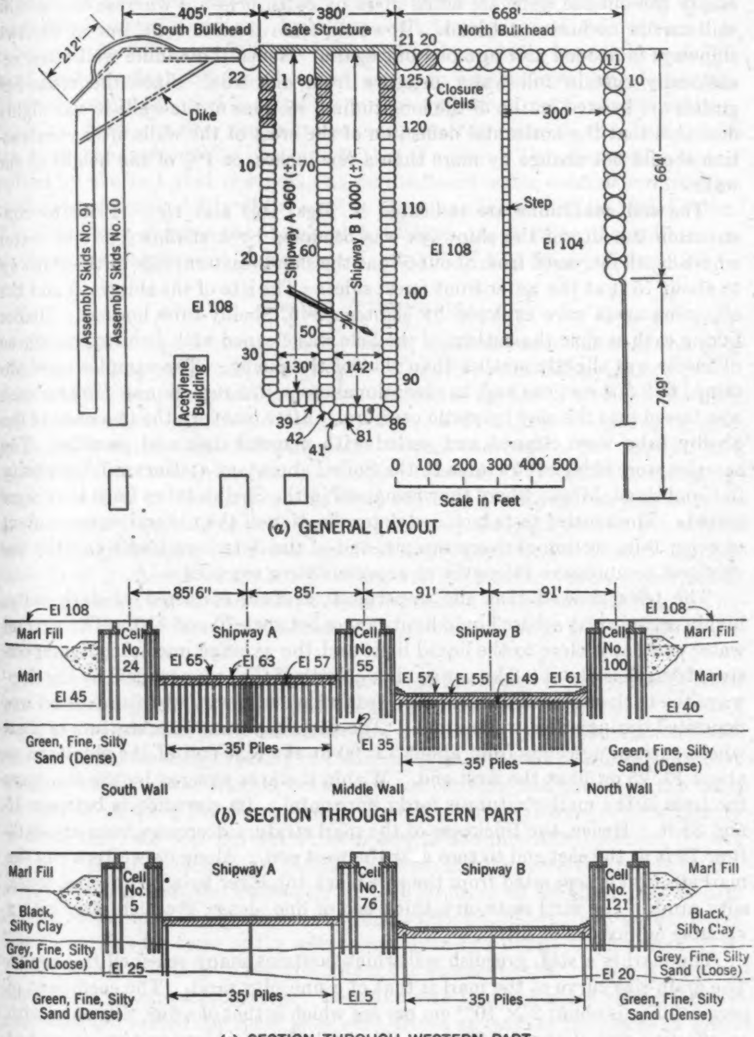

Fig. 1.—Plan and Typical Sections of Shipways

included a view of shipway B after completion.[5] While both shipways are empty the outside walls are acted upon by earth pressure whereas the middle wall carries no horizontal load. However, from time to time, one of the two shipways is flooded and pumped out again. Hence the middle wall must occasionally sustain full water pressure from one side. Since the crane-rail girders are located on top of the longitudinal sections of the walls it was highly desirable that the horizontal deflection of the crest of the walls after construction should not change by more than a few inches, or 1% of the height of the wall.

The soil conditions are indicated in Figs. 1(*b*) and 1(*c*). Prior to construction the site of the shipways was occupied by a shallow body of water whose depth increased from about 5 ft at the shore (eastern) side of the shipway to about 15 ft at the water front (west side). The site of the shipways and the adjoining areas were explored by eighteen 2-in. Shelby-tube borings. Before taking each sample the bottom of the hole was cleaned with a soil spoon whose diameter was slightly smaller than that of the casing. The samples were obtained in 2.5-ft sections and, in exceptional cases, in 5-ft sections. The sampler was forced into the clay by static pressure. After recovery the two ends of the Shelby tube were cleaned and sealed with a metal disk and paraffin. The samples were shipped in crates to the Soils Laboratory at Harvard University in Cambridge, Mass., where they remained in the Shelby tubes until they were tested. The routine tests included determination of the natural water content of every 6-in. section of every sample, and of the Atterberg limits and the unconfined compressive strengths of representative samples.

The tests showed that the uppermost stratum consisted of dark, silty, highly organic clay whose liquid limit ranges between 70 and 110. The natural water content is close to the liquid limit and the average unconfined compressive strength is about 0.2 kg per sq cm. North of the area occupied by the shipways the dark clay contains lenses of peat which suggest that this material was deposited during a low-water stage. The dark clay rests on a stratum of marl whose surface descends from about El. 90 at the east end of the shipways to about El. 25 or 30 at the west end. Within the area covered by the shipways the base of the marl stratum is fairly horizontal. Its elevation is between 15 and 30 ft. Hence, the thickness of the marl stratum decreases from about 60 ft or 70 ft at the east end to zero near the west end. Along its western rim the marl stratum is separated from the soft black top layer by a bed of fine, loose, silty sand. The marl rests on a thick bed of fine, dense, greenish sand with a variable admixture of silt.

The marl is a stiff, greenish soil which contains many sea-shell fragments. The grain-size curve of the marl is that of a fine silty sand. The coefficient of permeability is about 2×10^{-6} cm per sec which is that of a fine, silty sand with an effective size of about 0.02 mm. Slow triaxial compression tests furnished a value of 32° as the angle of internal friction of the marl, which is also the angle of friction for a silty sand. However, the Atterberg limits are those of a silty clay. The plastic limit is about 20 and the liquid limit varies between 30

[5] "Constructing the Shipways," by C. B. Jansen, *Civil Engineering*, July, 1943, p. 313.

and 40—in exceptional cases reaching 45. The natural water content ranges between 22 and 34. The apparent contradiction between the results of the mechanical analysis and the Atterberg limit tests suggests that the marl is completely flocculated. The clay and the fine silt particles are firmly united in hard clusters which behave like sand grains during the mechanical analysis. However, when the marl is remolded for the purpose of performing the Atterberg limit tests, the flocs are destroyed and, as a consequence, the character of the marl changes from that of a sand to that of a clay. This assumption is supported by the fact that remolding at an unaltered water content reduces the coefficient of permeability of the marl to about one thirtieth of its initial value. Remolding also reduces the shrinkage limit from about 20 to about 15 and it increases the compression index from about 0.05×10^{-5} to about 5×10^{-5}.

Design of Shipways

The walls of the shipways were designed on the assumption that the cells were to be filled with sand and gravel. However, immediately before beginning construction, the owners and the contractor agreed to fill the cells with marl because local experience had proved that artificial fills consisting of marl gradually become very stiff and stable. Since the base of the eastern and middle part of the shipway floors is located between 35 ft and 45 ft below the original surface of the marl, all the marl required for filling the cells became available while making the excavation for the shipways. Hence, the substitution of marl for sand and gravel involved a very considerable saving. On the other hand, it introduced an element of uncertainty into the design, which had to be compensated by careful observations in the field during construction and by occasional modifications of the design in accordance with the results of the observations.

The most vital decision in connection with the design of the shipway walls was in choosing the depth of penetration of the sheet piles. In a previous paper the writer has shown[4] that a cellular cofferdam on a soil foundation is not safe unless the bearing capacity of the sheet piles, per unit of width, is at least equal to 1.5 times the friction between the sheet piles and the fill of the cells, per unit of width of the sheet piles. When the shipways were designed, early in 1940, this rule was not yet known, and in the published theories for the design of cellular cofferdams, the depth of penetration received no consideration. Nevertheless, the contractor decided to drive all the sheet piles to firm bearing, regardless of the depth at which sufficient resistance is encountered. The sheet piles for some of the cells were driven to a depth of more than 50 ft. This precaution is largely responsible for the success of the job and it discloses remarkable practical judgment. To make sure that the sheet piles were well anchored and seated the sheet piles were driven at least to the depth at which the driving of test sheet piles required about twenty blows of a single-acting steam hammer (5,000-lb ram and 15,000 ft-lb per blow) per foot of penetration. In this connection it should be mentioned that a steel sheet pile which is interlocked with an adjacent pile offers a greater resistance against driving than a single one.

The design of the shipway floor was based on the observation that the floors of old dry docks in the vicinity of the new shipway did not heave. The floor of the deepest of these docks is at El. + 65, or 35 ft below mean tide level. These floors consist of lagging spiked to the caps of pile bents driven to support the ships. The floors of these dry docks have never shown any signs of heaving, which indicates that the upward hydrostatic pressure on the base of the marl stratum at about El. 30 (Fig. 1) at the site of these floors is smaller than the weight of the marl. If the floors of the old dry docks were covered, not with lagging, but with concrete, they could not be lifted except by water accumulating between the marl and the floors. Such an accident can be prevented easily by weep holes in the concrete floor. Hence, the designer duplicated the old floors, except that he replaced the lagging by a plain concrete mat punctured by weep holes consisting of 4-in. relief pipes. Prior to pouring the underwater concrete, the pipes were driven into the marl. These pipes are spaced 12 ft on centers on lines 4 ft out from each wall, and 22 ft on centers on lines about 48 ft apart across the shipways.[6] The water that comes out of the weep holes flows into covered drains and discharges into small pump sumps near the gate structure at the western end of the shipways.

Consideration of the geological situation at the site of the shipyards indicates that the conditions determining the danger of heave at the site of the new shipways are by no means necessarily identical with those at the site of the old dry docks. First, the distance between the center line of the middle wall of the new shipways and that of the deepest of the old dry docks is about 2,350 ft. Over such a distance the elevation of the base of the marl may vary considerably. Second, for a given thickness of the marl the hydrostatic uplift on the base of the marl stratum depends on the ratio between the permeability of the fine green sand and the marl. This ratio also varies from place to place within unknown limits. Third, part of the hydrostatic uplift on the base of the marl at the site of the old floors may be carried by shearing stresses along vertical planes through the outer boundry of the floors. Since the floor of shipway A is very much wider than that of either one of the floors of the older shipways, the perimeter shearing resistance per unit of area of the floor is smaller. This difference has an important influence on the hydrostatic pressure required to produce heave. Since the factor of safety of the old floors is unknown, all these circumstances had to be considered as potential sources of danger.

In connection with shipway B, the design of the floor on the basis of local precedent involved an additional risk because, during the period from the unwatering of the shipway to the placing of concrete to the finished floor level, the surface of the concrete floor was located at El. 55, or 10 ft below the level of the old floors. This situation was without any precedent at the site of the shipway floors. To make sure that the floor would not heave while the shipway was unwatered for the first time, the piezometric pressure in the pore water was measured at different points of the base of the marl stratum beneath the floor of shipway B at different stages of unwatering. The results of the observations are used to estimate in advance the hydrostatic pressure condition for complete

[6] "Constructing the Shipways," by C. B. Jansen, *Civil Engineering*, July, 1943, p. 310.

drawdown. If the pressure ever threatens to become excessive, it can be relieved by means of sand wells before the shipway is completely emptied.

In both shipways the concrete floor is supported by 35-ft green pine piles (or longer). The tops of all the piles were notched and encased in the concrete over a length of at least 2 ft. The layout of the piles was determined by the loads to be carried by the piles while ships are being built or repaired in the shipways. Each pile is assigned a maximum load of 20 tons.

The shipways are served by cranes that travel on tracks parallel to the center line of the shipways.[7] Each crane rail rests on the crest of a concrete wall which in turn is supported by piles.

The specifications required that the space behind the north and south walls of the shipways be filled to a distance of about 300 ft from each wall up to El. 108, and beyond 300 ft to El. 104. The western face of the backfill north of shipway B is supported by a cofferdam consisting of cylindrical cells with a diameter of 51 ft. This is known as the north bulkhead (Fig. 1). This bulkhead is remarkable inasmuch as it was constructed under exceptionally unfavorable soil conditions and no attempt was made to consolidate the marl in any of the cells except the closure cell. The results of the observations on the bulkhead have been published elsewhere.[4]

Incidents During Construction

The process of constructing the cofferdam and the construction equipment have been described by Mr. Jansen.[6] Within the area to be occupied by the shipway floors the marl was excavated by a heavy-duty dredging clamshell bucket operated from a derrick boat. It was either deposited directly in the cells or rehandled by barge and again by clamshell. In some instances the marl dropped out of the bucket in one big chunk, but usually it broke up into small lumps. During the first weeks after a cell was filled, the fill consisted of stiff chunks embedded in a matrix which was so soft that it offered very little resistance to the penetration of a man's finger. The sides, even of shallow test pits, had to be braced. The soil for filling the space behind the south wall was excavated by a suction dredge in a shallow borrow pit north of the shipway area and then was transported to the site through a pipe line about 2,000 ft long. In its natural state the material resembled the dark, silty clay which covered the marl at the site of the shipways. The filling operations started at the east end of the south wall. The fill consisted of clay balls with a diameter of about 4 in. embedded in a dark colored, almost liquid matrix. This material was so soft that it was not possible to walk on its surface.

During the construction of the cofferdams the deflection of the crest of the length walls (east-west walls) was ascertained about once every two weeks. While the highest part of the surface of the hydraulic fill was still 4 ft below final grade, the crest of the eastern part of the south wall adjoining the fill moved about 3 in. inward. During the following weeks, with the elevation of the top of the fill remaining unchanged, the greatest deflection of this wall in-

[7] "Constructing the Shipways," by C. B. Jansen, *Civil Engineering*, July, 1943, Fig. 2, p. 311.

creased to more than 5 in., as shown by the deflection curve a, Fig. 2. Subsequent driving of some of the piles for supporting the track for the gantry cranes south of the south wall further increased the greatest deflection to more than 7 in., as shown in curve b, Fig. 2, and the deflection continued to increase

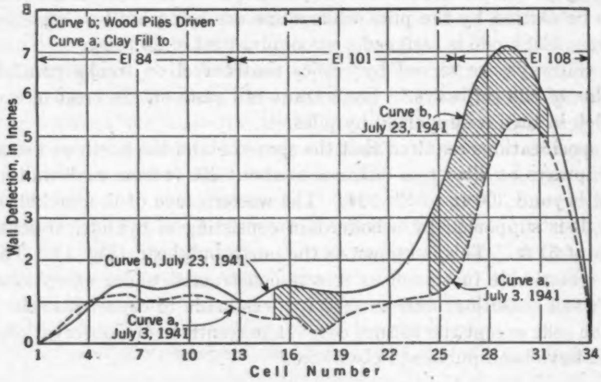

FIG. 2

at constant horizontal pressure on the wall at a considerable rate; yet the inside of the south wall was still acted upon by full water pressure. Since the removal of this pressure would triple the overturning moment it became increasingly doubtful whether the wall would survive unwatering the adjoining shipway.

The excessive deflection of the wall was obviously due to two independent causes—inadequate stiffness of the fill in the cells and the absence of internal friction in the hydraulic fill. To remedy the situation it was decided to increase the stiffness of the marl fill in the cells by compaction and drainage and to replace the hydraulic fill with gravel.

Replacement of the hydraulic fill by gravel offered an opportunity for a further reduction of the unbalanced pressure on the cofferdams by unwatering the gravel. Fig. 3, which is a vertical section through the gravel fill, shows that the gravel rests on marl and is covered with marl whose permeability is very low. After the east end of the gravel pocket also had been covered with marl, it was possible to maintain the water level in the gravel pocket adjoining the south wall, with a total length of almost 1,000 ft, at 20 ft below mean tide level by pumping not more than 0.5 gal per sec. This quantity is so small that it was later decided to divert the water from the gravel pockets, by pipes through the cellular walls, into the shipways and to pump it out of the sumps that collected the leakage from the weep holes and gate seats.

The effects of the partial replacement of the clay backfill by a gravel fill, and of draining the gravel pockets on the unbalanced horizontal pressure and on the overturning moment, are illustrated by Table 1. Line 1, Table 1, con-

tains the values corresponding to the original conditions, and lines 2 and 3 contain those corresponding to the modified design.

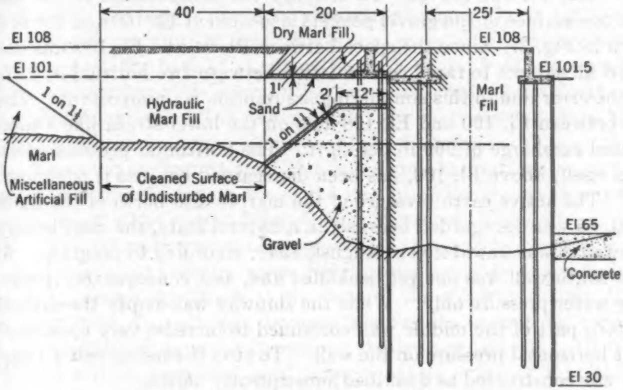

FIG. 3.—SECTION AT STATION 4 + 50 (±)

TABLE 1.—EFFECT OF DRAINAGE AND REPLACEMENT OF CLAY BACKFILL BY GRAVEL

Line	Description	Horizontal Pressure (Kips per Foot)		Overturning Moment (Kip-Feet per Foot)	
		South wall	North wall	South wall	North wall
1	Wall entirely backfilled with black clay........	112	...	1,605	...
	Modified Design:				
2	Water in the gravel pocket at El. 80.......	28.6	36.1	325	441
3	Gravel pocket flooded........................	53.7	65.8	669	905

The estimate of the values contained in Table 1 was based on the following data which were determined in the laboratory:

Material	Pounds per cubic foot
Brackish water..........................	63.4
Saturated dark clay backfill.............	110
Submerged dark clay backfill............	48
Saturated marl fill......................	120
Submerged marl fill.....................	57
Moist gravel...........................	112
Submerged gravel......................	67

The active earth pressure p_A on the wall was computed by means of Rankine's equation for cohesionless soils,

$$p_A = p \tan^2\left(45 - \frac{\phi}{2}\right) = Np \quad \ldots\ldots\ldots (1)$$

in which: ϕ is the angle of internal friction; p is the vertical unit pressure in the soil at any depth; and $N = 1.00$ for the black clay backfill (original condition), and $N = 0.20$ for the gravel. To simplify the computation it was assumed that the top surface of the gravel pockets is located at El. 100 and not at El. 94, as shown in Fig. 3. Since the space between El. 94 and El. 100 was occupied by a marl fill subject to rapid consolidation between two horizontal, permeable layers, the error due to this simplifying assumption is unimportant. The marl backfill between El. 100 and El. 108 acts on the lower strata like a uniformly distributed surcharge of 960 lb per sq ft. The horizontal pressure exerted by the marl itself, above El. 100, has been disregarded because it is almost equal to zero. The active earth pressure of the marl in situ north of the north wall below El. 65 was disregarded because, in a natural state, the marl is very stiff.

Shipway A was unwatered in August, 1941, according to program. At that time the south wall was not yet backfilled and, as a consequence, it was acted upon by water pressure only. While the shipway was empty the deflection of the western part of the middle wall continued to increase very considerably at constant horizontal pressure on the wall. To stop the movement a temporary support was constructed as described subsequently herein.

While the water was being pumped out of shipway B, in January, 1942, the pressure-gage observations indicated exceptionally high piezometric levels at the base of the marl beneath the eastern part of the shipway. This pressure was relieved temporarily by installing shallow sand wells (lower end at about El. 20). At a later date, after the shipway had been in operation for more than a year, the provisional sand wells were replaced by permanent ones whose lower end is located at about El. 0.

Since January, 1942, observations have shown that the average movement of the crest of the middle wall due to the application of full water pressure alternately from the north and the south remains within a range of less than 3 in. which, from a practical point of view, is negligible. This result indicates that the attempt to consolidate the fill in the cells was successful.

Observations During and After Construction

The deflections of the crest of the walls were determined about once every two weeks by measuring the offset of each cell from a base line. One base line was established for every wall. Observations on the short north-south walls were begun but were soon discontinued because it became evident that the deflection of these walls is very small compared with that of the long east-west walls, for reasons discussed elsewhere.[4]

The deflection observations were supplemented by the measurement of the length of the upper edge of all the cross-walls of all the cells immediately after filling the cells with marl, after driving the wooden piles, and after driving the sand piles that were used for consolidating the fill in the cells. After shipway A was unwatered, the deformation of the inner walls of several cells of the adjoining cofferdams was surveyed carefully. The survey was repeated on a few cells of the middle wall after shipway B had also been pumped out.

Several months before shipway B was unwatered, seventeen pressure gages of the Bourdon type were installed in shipway A to obtain some information re-

garding the distribution of the pore-water pressure through the subsoil of the shipway; thirteen of these gages were connected with observation points located at a shallow depth below the shipway floor and four were connected with points located beneath the base of the marl stratum, at about El. 25. A short time before shipway B was unwatered, six gages were installed to measure the hydrostatic pressure at the base of the marl beneath shipway B and, in addition, four 6-in. observation wells were drilled from the crest of the north and the middle wall through the fill in the cells and the marl stratum into the fine, green sand. All the pressure gages were of the Bourdon type.

After construction was finished the deflection observations on the middle wall were repeated—(*a*) before one of the two adjoining shipways was flooded, (*b*) several times while it was flooded, and (*c*) several times after it was unwatered. The temporary pressure-gage installation was replaced by a permanent one, of thirty-one pressure gages, which furnishes fairly complete information on the pressure conditions at the base of the shipway floors. The well observations were discontinued, because the results cannot be relied upon unless the hydrostatic pressure conditions change very slowly. All the other observations will be continued until there is ample evidence that the elastic properties of the walls and the permeability of their base have become practically constant.

Sand-Pile Compaction of Fill in Cells

Since compaction of a saturated soil requires the expulsion of pore water, the efficacy of any attempt to compact a mass of saturated soil by mechanical means in a short time depends on the permeability of the soil. One of the most expedient means of compacting saturated relatively permeable soil consists in ramming sand or gravel into it. This method has been practiced for centuries in marsh lands. If the sand is rammed into holes made by driving piles or tubes into the ground, the columns of sand thus obtained are known as sand piles. The process of ramming increases, temporarily, the pressure in the soil surrounding the seat of the successive impacts and the excess water can escape in a horizontal direction into the voids of the sand piles. By bailing or pumping from the sand piles for several weeks after their installation, simple gravity drainage is added to the effect of the drainage produced by driving the sand piles.

If the permeability of a soil is as low as that of a fine silt or clay, driving sand piles into it merely causes the soil to rise between the sand piles with almost no change in water content and the process of subsequent gravity drainage is too slow to be of practical value. A failure to consolidate a clay fill in cells by gravity drainage was experienced on the cofferdam used for raising the *Maine*. The fill consisted of sandy to heavy clay excavated by means of a hydraulic dredge. In some cells the water was pumped from 3-ft by 3-ft shafts and in others from 8-in. wells with perforated walls;[8,9] yet the effect of pumping was disappointing. In the process of drainage toward wells

[8] *Engineering Record*, Vol. 63, 1911, pp. 548–549.

[9] Discussion by D. A. Watt of "Unusual Coffer-Dam for 1,000-Foot Pier, New York City," by Charles W. Staniford, *Transactions*, ASCE, Vol. LXXXI, December, 1917, p. 544.

the hydraulic gradient is maintained very much longer than during the process of driving sand piles into the soil. Hence, if bailing from filter wells fails to produce noticeable consolidation, it is practically certain that the driving of sand piles would also be ineffective.

The fill in the cells of the shipways consisted of stiff chunks of marl embedded in a soft matrix. The sole purpose of compaction was to weld the stiff chunks together by driving the excess water out of the matrix. Owing to the peculiar properties of the marl, the matrix seemed permeable enough to permit fairly rapid drainage. Therefore, it was decided to try the sand-pile procedure, and experience showed that the decision was justified.

Every sand pile is inevitably surrounded by a mantle of remolded marl whose permeability is very much smaller than that for the remainder of the fill. In order to establish, within the fill, a large unobstructed area of contact between fill and drain in addition to the partly obstructed area of contact with the sand piles the design illustrated in Fig. 4 was finally adopted. Fig. 4 (*a*) is

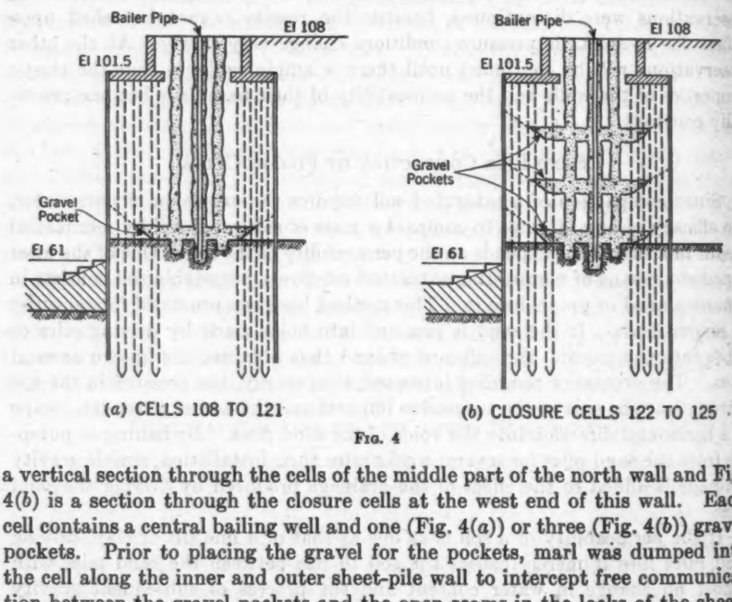

Fig. 4

a vertical section through the cells of the middle part of the north wall and Fig. 4(*b*) is a section through the closure cells at the west end of this wall. Each cell contains a central bailing well and one (Fig. 4(*a*)) or three (Fig. 4(*b*)) gravel pockets. Prior to placing the gravel for the pockets, marl was dumped into the cell along the inner and outer sheet-pile wall to intercept free communication between the gravel pockets and the open seams in the locks of the sheet-pile walls. During the filling operations the site for the bailing well was occupied by a 12-in. casing whose lower end rested on the surface of the lowest layer of gravel. After the cell had been filled with marl, a 4-in. bailer pipe was lowered into the 12-in. casing; the space between the two casings was filled with gravel; and the outer casing was pulled. The next step consisted in driving the sand piles, as described elsewhere by Mr. Jansen.[6] The driving of additional sand piles was discontinued when the total number of blows required to drive the shells for the piles (12-in. tubes with capped lower end) be-

came equal to 5,000. For the north wall, whose cells contained a softer fill than the other walls, 6,000 blows were specified.

Immediately after a sand pile was installed the voids in the sand were empty. However, as soon as the next pile was driven, the sand pile became saturated, and the water flowed out of the sand and flooded the surface of the fill. This phenomenon demonstrated the relatively high permeability of the matrix in the fill. After the first sand pile was installed, bailing from the well

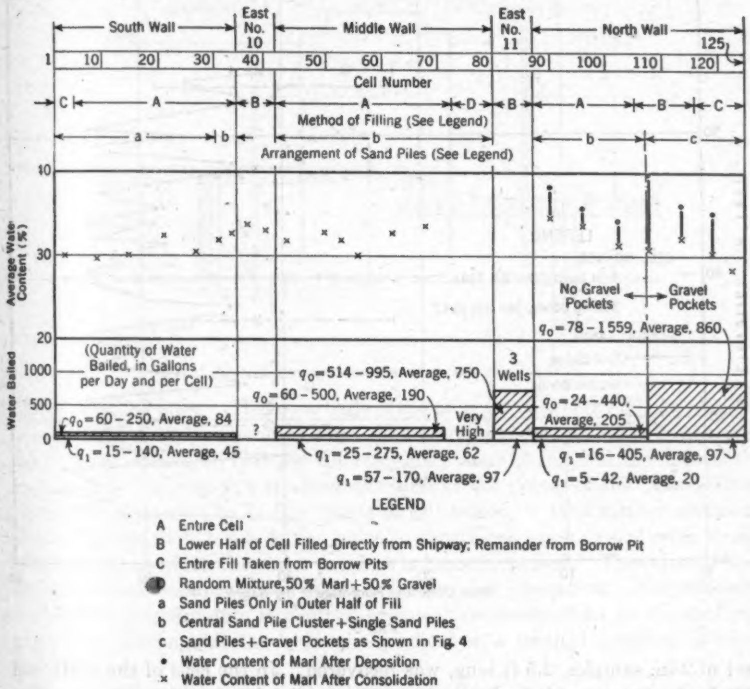

FIG. 5

was begun. Records were kept of the quantity of water removed from each cell per day. They showed that the inflow into each well decreased at a decreasing rate. After about three weeks the inflow became constant, which indicated that the water content of the fill ceased to decrease. Hence, about ten days later bailing from this cell was discontinued. Information regarding the initial and the final rate of flow toward the wells is given at the bottom of Fig. 5.

A constant flow toward the wells can be maintained only by seepage from permanent sources of water into the cells, partly through the marl stratum which constitutes the base of the fill in the cells and partly through the locks of the sheet piles. Approximate computations based on the flow-net method

indicated that the observed rate of flow and the measured hydraulic gradients can be accounted for only by assuming that the loss of head associated with the percolation of the water across the rows of sheet piles was negligible.[4]

In order to collect information on the effect of the sand piles on the water content of the marl fill in the cells, 22 Shelby-tube borings were made from the top of the dam to the base of the fill in the cells. From each hole a continuous

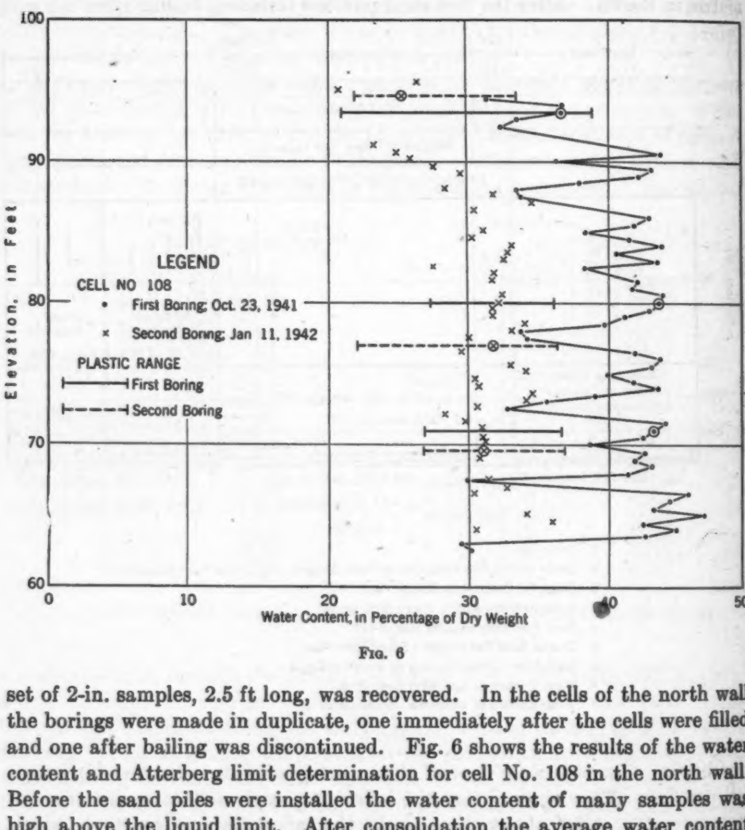

FIG. 6

set of 2-in. samples, 2.5 ft long, was recovered. In the cells of the north wall the borings were made in duplicate, one immediately after the cells were filled and one after bailing was discontinued. Fig. 6 shows the results of the water content and Atterberg limit determination for cell No. 108 in the north wall. Before the sand piles were installed the water content of many samples was high above the liquid limit. After consolidation the average water content was roughly equal to that of the parent material in its original state. Fig. 5 represents a digest of the results of the tests and observations.

After all the cells were filled and drained, test shafts were excavated in six cells of the south, middle, and north walls from El. 72 to El. 75. In all these shafts the marl appeared to be very firm and the matrix (which, at the outset, was a source of justified concern) had become as firm as the undisturbed marl.

HYDROSTATIC PRESSURE CONDITIONS BENEATH THE SHIPWAY FLOORS

Fig. 7 is a simplified vertical section through the middle wall and the adjoining shipways A and B. The shipway floors are tied to the foundation piles and the sum of the resistance of the individual piles against pulling is considerably greater than the weight of the soil between the piles. Therefore, the floors cannot be lifted without lifting, simultaneously, the major part of the body of

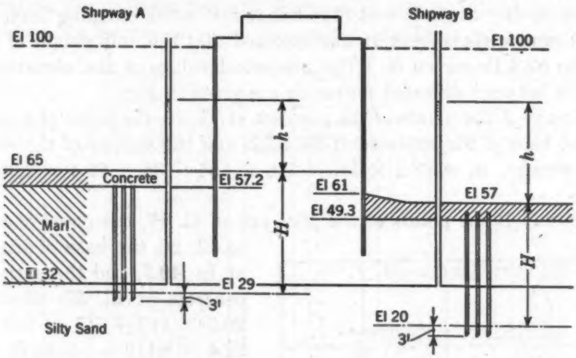

FIG. 7.—SIMPLIFIED SECTION THROUGH THE MIDDLE WALL

soil between the piles. The lower ends of the piles are very thin and can readily be pulled out of the surrounding soil. Therefore, it is assumed that the potential plane of separation between the stationary mass of soil and the mass that goes up with the piles is 3 ft above the level of the points of the piles. This plane will be referred to as the "plane of separation." It is further assumed that the piezometric levels at the plane of separation are identical with those at the points at which the water pressure is being measured. These points are located at some distance above or below the plane of separation. Nevertheless the preceding assumption is justified because the observations on the shallow gages have shown that the hydraulic gradient in a vertical direction is very small.

In the following p_t equals total submerged weight of soil, concrete, and water located between the plane of separation and the surface of the shipway floor (total weight reduced by full hydrostatic uplift), in pounds per square foot of the shipway floor; h equals hydrostatic head with reference to shipway floor (difference between the elevation of the piezometric level and the elevation of the shipway floor); H equals vertical distance between the plane of separation and the shipway floor; and γ_w equals unit weight of water. The force that tends to lift the submerged mass of soil and concrete above the plane of separation is $h\,\gamma_w$ and the force that resists this tendency is p_t per unit of area. Therefore, the factor of safety with respect to a rise of the floor is equal to the ratio

$$G_s = \frac{p_t}{h\,\gamma_w} \qquad \text{(2a)}$$

provided the shipway is empty. If the water rises in the shipway to an elevation h_1 above the floor, the resisting force remains unchanged while the uplift decreases from $h\,\gamma_w$ to $(h - h_1)\,\gamma_w$. Hence,

$$G_s = \frac{p_t}{(h - h_1)\,\gamma_w} \qquad (2b)$$

When computing the resisting unit force p_t it was assumed that the unit weight of the concrete is equal to 156 lb per cu ft and that of the saturated marl 110 lb per cu ft. Since it was found that the water escaping from the weep holes and sand wells is fresh, it was assumed that the unit weight of the water is equal to 62.4 lb per cu ft. The numerical values of the elevations of the boundaries between different materials are given in Fig. 7.

In shipway A the points of the piles are at El. 26, the plane of separation at El. 29, the base of the concrete at El. 57.2, and the surface of the concrete at El. 65; whence, $p_t = 28.2 \times 110 + 7.8 \times 156 - 36 \times 62.4 = 2{,}080$ lb per sq ft.

In shipway B the points of the piles are at El. 17, the plane of separation at El. 20, the base of the concrete at El. 49.3, and the surface of the concrete at El. 57; whence, $p_t = 29.3 \times 110 + 7.7 \times 156 - 37 \times 62.4 = 2{,}110$ lb per sq ft.

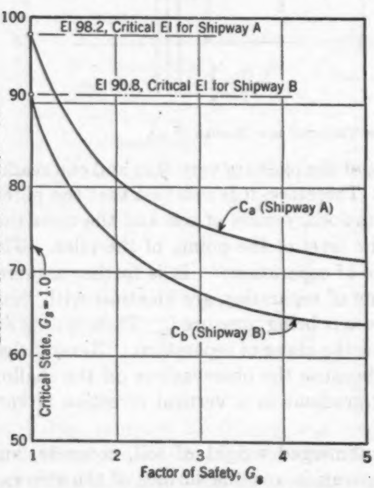

FIG. 8.—RELATION BETWEEN THE ELEVATION OF THE PIEZOMETER LEVEL AND THE FACTOR OF SAFETY

In Fig. 8, curve C_a represents the relation between the elevation of the piezometric level and the corresponding factor of safety G_s for the floor of the empty shipway A, and C_b represents the corresponding relation for the empty shipway B. By means of these curves one can determine, for any given piezometric elevation, and without any computation, the corresponding factor of safety G_s of the shipway floor, provided the shipway is empty. If the water stands in a shipway at an elevation h_1 above the floor, the corresponding G_s can be computed by means of Eq. 2b.

Fig. 8 shows that the danger of a heave of the floor of shipway A does not arise under any conditions of operation. However, for shipway B both the theoretical data given in Fig. 8 and the observations during the process of unwatering shipway B in January, 1942, indicated that the ultimate factor of safety with respect to the heave of the floor at the east end of shipway B would be considerably smaller than 1.5. To increase the factor of safety for this section of the floor, twenty-eight sand wells were installed during the process of unwatering in the following manner: 3-in. pipes were driven through 4-in.

openings in the eastern part of the concrete floor of shipway B and through the marl into the greenish sand to about El. 20. Then the interior of the pipe was emptied by means of an air jet and the pipe was pulled. While pulling the pipe its lower end was always kept full of coarse sand. Thus a vertical drain was formed with its lower end at about El. 20.

After shipway B was completely pumped out, the temporary system of pressure gages was replaced by a permanent one comprising thirty-one gages. The observation points were beneath the base of the marl, at about El. 25. Fig. 9(*a*) shows the curves of equal piezometric elevation, about six months

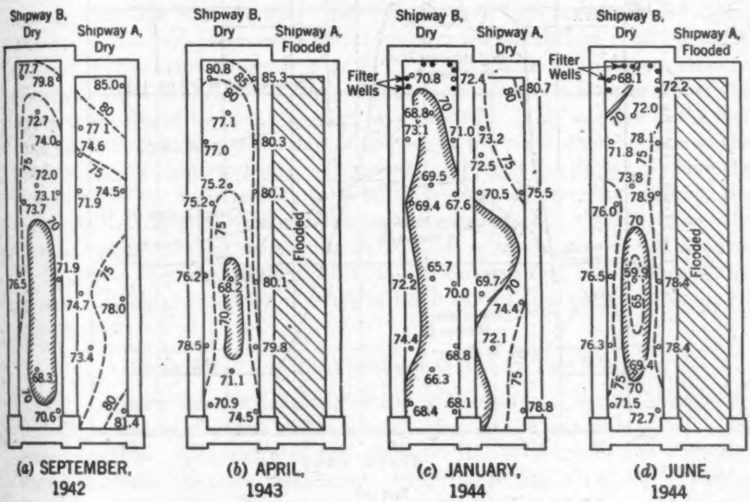

FIG. 9.—CURVES OF EQUAL PIEZOMETRIC ELEVATION

after shipway B was pumped out for the first time. The location of each gage is marked by a small circle. The diagram indicates a fairly steep hydraulic gradient from the land end (east) toward the outboard end. Furthermore, the water that escaped from the weep holes was fresh. These observations show that the seepage into the shipways is ground water from the land side and not sea water from the estuary.

The total leakage through the weep holes (630 gal per hr) was several times greater than the quantity computed on the assumption that the water flows toward the concrete floor only through the marl. This finding indicates that a considerable part of the leakage follows the rows of sheet piles in a vertical upward direction.

As often as a shipway is filled with water, the hydrostatic pressure at the base of the marl stratum goes up, but subsequent unwatering reduces it again to the initial value. The time lag between the change of the water level in the shipway and the corresponding change of the pore-water pressure at the base of the marl beneath the adjoining shipway is very small. It can be accounted

for by a slight swelling of the marl due to the increase of the seepage pressure at unaltered total pressure during the filling of the shipway and subsequent slight reconsolidation while the shipway is again being pumped out. Fig. 10 shows the effect of flooding and unwatering shipway B on the readings of two of the gages in shipway A and on the water level in an observation well in the north wall. The abscissas represent the time; the ordinates of curve (1) indicate the

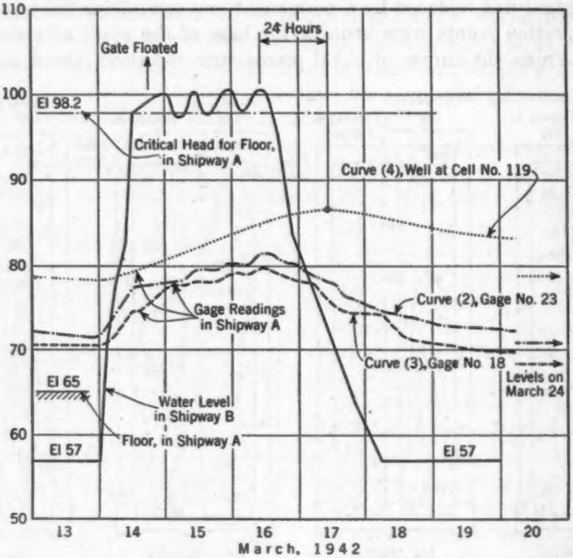

FIG. 10

water level in shipway B and those of curves (2) and (3) the piezometric levels computed from the gage readings. Curve (4) indicates the variations of the water level in the observation well. It plainly discloses the lag due to the resistance against the flow of the water into and out of the well. On account of this lag the well readings cannot be relied upon unless the hydrostatic pressure conditions change very slowly.

Fig. 9(*b*) shows the curves of equal piezometric level at the base of the marl beneath shipway B while shipway A was flooded in April, 1943. In the vicinity of the east end of the shipway the piezometric elevation ranged between 80 and 85. According to Fig. 8 the corresponding factor of safety with respect to heave ranges between 1.4 and 1.1, which is rather close to unity. In order to increase the margin of safety, seven filter wells were installed in January, 1944, in the western end of shipway B (see Fig. 9(*c*)). Their lower ends are at about El. 0. To construct these wells, 3-in. extra-heavy casings were jacked into the ground through weep holes. The lower end of each casing was capped with a steel disk. The jack pressure required to force the capped casing to a depth of about 50 ft into the stiff soil was about 12,000 lb.

After a casing was jacked to the required depth, its interior was filled with pea gravel at a compressed air pressure of about 20 lb per sq in.; then the casing was pulled. The compressed air prevented the walls of the hole from collapsing while the pea gravel was dropping out of the casing into the hole. The steel plate that plugged the lower end of the casing during jacking remained in the ground. After each well had been installed, the discharge was measured with a water meter that was attached temporarily to the upper end of the well. Immediately after installing the well the discharge was greater than 20 gal per hr. It decreased at a decreasing rate and after about one week the discharge of every well became fairly constant and equal to about 15 gal per hr. The average discharge from the weep holes was less than 1 gal per hr per weep hole. The curves of equal piezometric elevation after the installation of all the wells, in January, 1944, are shown in Fig. 9(*c*). Although all the wells are close to the eastern end of shipway B, they reduce the piezometric elevation over the entire area covered by both shipways by about 5 ft. This was due to the fact that the wells intercepted the flow of seepage at the place where it entered the soil beneath the shipway floors. In the eastern part of the shipway, where the margin of safety with respect to a heave of the floor was too narrow, the specified safety requirements are now more than satisfied. Fig. 9(*d*) shows the curves of equal piezometric head in June, 1944, while shipway A was flooded.

By comparing Fig. 10(*d*) to 10(*b*) it can be seen that the sand wells increased the minimum factor of safety of the floor of shipway B from about 1.1 to more than 2.

Deflection And Elastic Properties of The Walls

Fig. 11 represents the deflection of the crest of each of the three east-west walls immediately after the wall was acted upon for the first time by one-sided water pressure. The cause of the characteristic W-shape of the deflection curves has been discussed elsewhere.[4] Referring to Fig. 11(*a*), on November 20, 1941, the top of the fill was at about El. 100 and the gravel pocket was still filled with water. The excessive deflection of the eastern part of the south wall is due to the permanent deflection produced by the lateral pressure exerted by the clay backfill, prior to the removal of this fill and to the consolidation of the marl fill in the cells. The deflections that occurred after these events are represented by the ordinates of curve (*B*), Fig. 11(*a*). They are greatest near the western end where the closure cells are located. The excessive deflection of the cells near the west end of the middle wall is due to the fact that the fill in these cells rests on soft mud, whereas that in the other cells rests on stiff marl. The effect of the compressibility of the base of the fill on the deflection of cofferdams has been analyzed elsewhere.[4]

The most instructive data were obtained from observations on the middle wall which is periodically acted upon by water pressure either from the north or from the south. In Fig. 12(*a*) the plain curves indicate the relation between the unbalanced horizontal pressure and the deflection for cell No. 75, at which the deflection of the middle wall was greatest. Shipway A was pumped out in August, 1941, while shipway B was still flooded (curve ab). During the first twelve days after shipway A had been completely emptied, the deflection of

cell No. 75 increased by more than 3 in., whereupon it was decided to reduce the free height of the wall in the proximity of cell No. 75 by means of a concrete sill, C in Fig. 12(*d*), with a height of 2 ft, bearing against the foot of the wall. Since the deflections continued to increase, although at a lesser rate, as shown

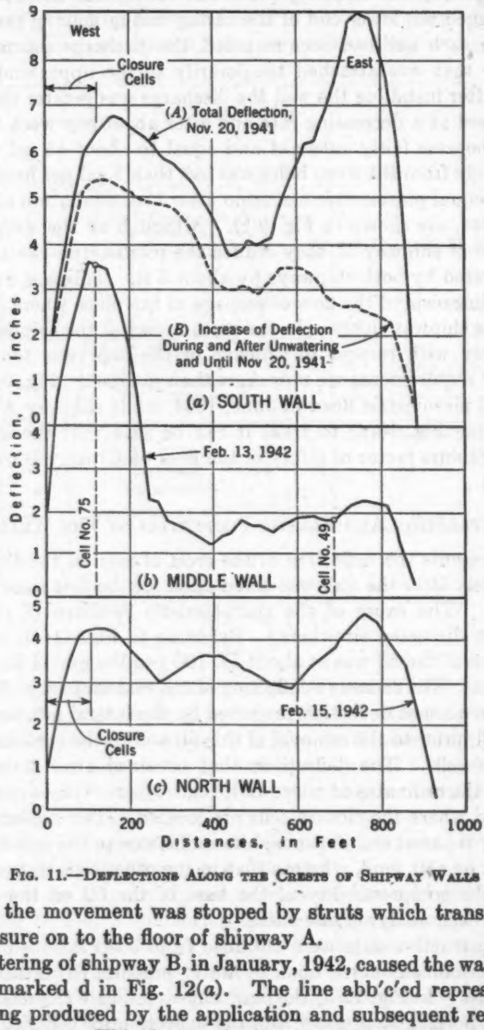

FIG. 11.—DEFLECTIONS ALONG THE CRESTS OF SHIPWAY WALLS

in Fig. 12(*b*), the movement was stopped by struts which transferred the unbalanced pressure on to the floor of shipway A.

The unwatering of shipway B, in January, 1942, caused the wall to move into the position marked d in Fig. 12(*a*). The line abb′c′cd represents the first cycle of loading produced by the application and subsequent removal of one-sided water pressure. This first cycle (August, 1941, to January, 1942) was followed by two others in March, one in August, and one in November, 1942. The crest movements produced by the first cycle in March and by that in

November are represented by the hysteresis loops C_2 (blank) and C_4 (shaded area), respectively. Finally, in April, 1943, shipway A was filled while B was empty (shaded area C_5).

Cell No. 75 is one of those cells of the middle wall in which the fill rests on mud. For comparison, the effect of cyclic loading on a cell with a stiff marl base (cell No. 49) is shown in Fig. 12(*a*) by dashed lines. The deflection produced by the first application of the one-sided water pressure on either cell No. 75 or cell No. 49 was much greater than that produced by any of the following applications. Similarly, the recovery of both cells due to the first removal of the horizontal pressure was much greater than that due to the following ones. These differences indicate a considerable increase of the stiffness of the middle wall between January and March, 1942. It is most likely due to a combination of several causes, including additional consolidation of the fill in the cells caused by pumping out both adjoining shipways, increase of lock friction due to rusting, and increase of stiffness of the marl fill by aging.

The data represented in Fig. 12 permit a rough evaluation of the average modulus of elasticity of the middle wall. If τ_s represents the average shearing stress at the base of the wall and θ denotes the angular deflection of a cell, the average modulus of elasticity in shear for the cell is

$$G = \frac{\tau_s}{\theta} \qquad (3)$$

According to the laws of mechanics the modulus of elasticity E for materials with a Poisson ratio of 0.25 to 0.5 ranges between 2.5 G and 3.0 G. The angular deflection of cell No. 49 due to the overturning moment $M = 630$ kip-ft per ft was 0.00195. On the basis of this value, the modulus of elasticity of the middle wall at cell No. 49 is approximately 190 tons per sq ft. The E-value for a clay with the stiffness of the marl ranges between 50 and 100 tons per sq ft. The E-value for a double-wall sheet-pile cofferdam is strictly equal to that of the fill. Hence, the average deflection of such a cofferdam would be from two to four times greater than that of a cellular cofferdam with equal dimensions. The difference is due almost exclusively to the lock friction in the cross-walls.

To supplement the results of the field observations the factor of safety G_s was computed for the middle wall, with respect to failure due to one-sided water pressure with one of the adjoining shipways flooded and the other empty. In a previous paper[4] it has been shown that a cellular cofferdam fails as soon as the shearing force on the neutral vertical plane of the dam becomes equal to the sum of the shearing resistance of the fill and of the friction in the locks which are located in this plane. The resisting moment M_s due to the lock friction can be computed on the assumption that the shearing resistance of the fill is zero. To compute the resisting moment M_f due to the shearing resistance of the clay it must be assumed that the lock friction is zero. The total resisting moment M_r per unit of length of the dam is then equal to

$$M_r = M_s + M_f \qquad (4)$$

It has been shown further that the overturning moment tends to pull the sheet piles on the water side out of the ground and to push those on the land

side into the ground. At the instant of failure of the cofferdam by shear the force that acts on the sheet piles becomes equal to V_r per unit of width of the sheet piles.

The coefficient of lock friction f has not yet been reliably determined. Hence, when computing the numerical value of the factor of safety G_s, two extreme values, 0.2 and 0.3, were assigned to f. Finally, it was assumed that the fill in the cells rests on a solid base. For the eastern and the middle part of the wall this assumption is justified. However, in the western part of the wall the fill in the cells rests on a highly compressible stratum of soft clay. According to theory[4] this condition reduces the factor of safety considerably and it accounts for the excessive deflection of this part of the wall, shown in Figs. 11 and 12.

If M indicates the overturning moment produced by the one-sided water pressure and M_r the resisting moment given by Eq. 4, the factor of safety of the wall is determined by the equation

$$G_s = \frac{M_r}{M} = \frac{M_s + M_f}{M} \qquad (5)$$

Computations furnished the following results:

(*a*) For the case of water pressure from the north: $M_s = 418$ ($f = 0.2$) to 625 ($f = 0.3$) kip-ft per ft; $M_f = 486$ kip-ft per ft; $M = 454$ kip-ft per ft; and safety factor $G_s = 2.00$ ($f = 0.2$) to 2.45 ($f = 0.3$). On the water side of the neutral plane the sheet piles were pulled at the instant of failure with a force of $V_r = 18.4$ ($f = 0.2$) to 22.6 ($f = 0.3$) kips per ft. On the shipway side they were pressed down with the same force. The resistance of the piles against pulling or pushing was considerably greater than these values.

(*b*) For the case of water pressure from the south: $M_s = 516$ ($f = 0.2$) to 775 ($f = 0.3$) kip-ft per ft; $M_f = 532$ kip-ft per ft; $M = 562$ kip-ft per ft; $G_s = 1.86$ ($f = 0.2$) to 2.32 ($f = 0.3$); and $V_r = 21.2$ ($f = 0.2$) to 26.5 ($f = 0.3$) kips per ft.

At the instant of failure the shearing stresses at the boundaries of the fill would still be considerably smaller than the shearing strength of the clay. Hence, the failure would occur while the distribution of the pressure on the base of the fill is still fairly uniform. In both the loading cases (*a*) and (*b*) the overturning moment M produced by the one-sided water pressure is either slightly greater (if $f = 0.2$) or considerably smaller (if $f = 0.3$) than that part, M_s, of the total resisting moment of the wall which could be carried, if necessary, without the assistance of the shearing strength of the fill in the cells.

Observations Concerning the Sheet-Pile Walls of the Cells

The steel shell of the cells consists of straight-web, steel sheet piles with a web 1/2 in. thick. Fig. 13 is a section through a lock and Fig. 14 represents the relation between lock tension and unit elongation in the direction of the tensile force. The height of the specimen measured in the direction of the locks was 2 in. One of the ten specimens tested failed in the web, and the others failed

in the finger or thumb at stresses ranging between 17,750 and 20,950 lb per in. According to Fig. 14 the failure strain is about 3.5%. Because of the small height of the specimen, the initial play in the lock was negligible. The initial play in the locks of a row of sheet piles is about 1/4 in. which increases the strain at failure in the direction of the hoop tension from 3.5% to about 5%. It should be noticed that the stress-strain curve in Fig. 14 is almost horizontal between a stress of about 5,000 and 10,000 lb per in.

FIG. 13

The process of driving the sheet piles was described by Mr. Jansen.[6] A short time before shipway A was pumped out, it was discovered that a pair of sheet piles was driven out of groove, below El. 60, in each of four cells of the middle wall. Considering the fact that the cofferdams comprised 125 cells and that the marl was stiff, this record is very good. The damage was repaired easily by concreting the shipway floor to a distance of 20 ft from each end of each defective section in an east-west direction and to a distance of 20 ft to the north of it in advance of the remainder of the shipway floors. This operation was preceded by driving all the piles to be located within these areas.

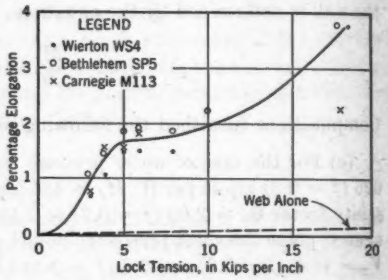

FIG. 14

To form some conception of the deformation of the steel walls of the cells, the following observations were made by the Dravo Corporation: Measurement of the length of the upper edge of the cross-walls of every cell after each operation which might change the tension in these walls; survey of the shape of two Y-piles and of the sheet piles at the middle third points of the arcs on the inside of cells No. 15 and No. 31 in the south wall, immediately after shipway A was pumped out and a few weeks later, after the piles for supporting the crane track south of the wall were driven; survey of the shape of two Y-piles, of the center sheet of the arc and of horizontal sections through the arc at El. 68 and El. 111 on cells No. 5 (south wall), Nos. 72 and 73 (middle wall), about three weeks after shipway A was pumped out and on cell No. 120 (north wall) about two weeks after unwatering shipway B; survey of the entire shape of cell No. 53 (middle wall), two weeks after shipway B was pumped out; and survey of the south face of cells Nos. 113, 116, and 124 of the north wall and of both faces of the cell No. 75 (middle wall), four months after shipway B was pumped out.

Table 2 contains the average elongation of the upper edge of the cross-walls, as well as the range of the extreme values. The table shows that the driving of wood and sand piles nearly doubled the elongation and increased the elongation of most of the cross-walls to more than 2%. It should be noticed that the driving of sand piles increased the elongation much less than the driving of

[a] Estimated

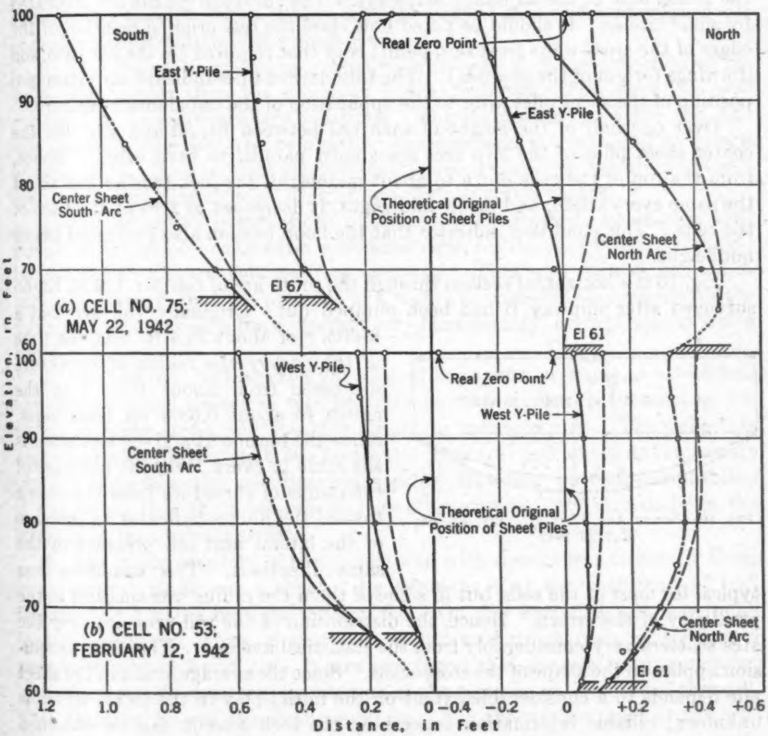

FIG. 15.—CHANGE IN THE SHAPE OF THE CELLS OF THE MIDDLE WALL CAUSED BY AN UNBALANCED HORIZONTAL PRESSURE

wood piles; yet the volume displaced by the sand piles is greater than that displaced by the wood piles. These facts suggest that the driving of wood piles increased the lock tension to a value greater than 5,000 lb per in. at which the stress-elongation curve in Fig. 14 flattens out. They also suggest that the lock

tension prior to driving the wood piles was appreciably smaller than 5,000 lb per in.

The change of the shape of the cells caused by an unbalanced horizontal pressure is illustrated by Fig. 15. In each case the solid line indicates the shape and position of the outer edges of one of the cross-walls and the dash-dot line indicates the shape and position of the center sheet of the arcs, about four months after the unbalanced water pressure on the middle wall was removed by unwatering shipway B. Since the elastic recovery (curves cd and c_1d_1 in Fig. 12 (*a*)) was slight compared with the preceding deflection, the shape of the cells is almost identical to that of the cells prior to the removal of the unbalanced pressure. The position of the sheet piles was measured by offsets from the center line of the adjoining shipways. The surveyed points are indicated by small circles. It should be noted how close the real original position of the edges of the cross-walls (real zero point) is to that required by the construction drawings (origin of the abscissa). The thin dashed lines indicate the estimated position of the sheet piles prior to the application of the unbalanced pressure.

Over one half of the height of each cell between El. 80 and El. 100, the center sheet piles of the two arcs are almost parallel to each other. Hence, from the top of the cells down to about midheight, the lock tension was about the same everywhere; and below midheight, it decreased to zero at the base of the cells. This condition indicates that the hoop tension also decreased below midheight.

Fig. 16 is a horizontal section through the south arc of cell No. 124 at El. 65 surveyed after shipway B had been pumped out. Originally the arc had a radius r of about 24.4 ft. At the time of the survey the radius of curvature decreased from about 0.92 r at the crown to about 0.68 r on both sides. Since the tension at a given elevation is the same in every lock, the decrease of the radius of curvature from the crown toward the hinges indicates an increase of the lateral unit soil pressure in the same directions. This condition was typical for most of the cells, but in some of them the radius was smallest in the proximity of the crown. Hence, the distribution of the soil pressure over the arcs scatters very considerably from the statistical average. The same conclusion applies to the shape of the cross-walls. Since the average strain in the sheet pile depends to a considerable extent on the initial play in the locks, which is unknown, reliable information concerning the lock tension can be obtained only by means of strain-gage measurements on the web. The provisions for such measurements must be made before the sheet piles are driven. On account of imperfect fit in the locks, only the averages of readings on a great number of pairs of reference points can be relied upon. A practicable method for measuring the lateral pressure in the fill of the cells has been suggested elsewhere.[10]

SUMMARY

1. Comparison between the cost of the shipways and the cost of other recently constructed dry docks showed that the design described in this paper was remarkably economical. Savings were achieved by providing the shipways with walls of the cellular type and by taking advantage of local soil conditions.

2. On account of the radical departure from conventional methods the design was inevitably based on various more or less uncertain assumptions. However, by systematic field observations during construction it was possible to correct the initial errors and to modify the design during construction in accordance with the findings. This procedure avoided the risk of a failure in spite of the novelty of the design, and the cost of the modifications did not exceed a small fraction of the total savings.

3. The observations during construction showed that the deflection of the walls was greater than the designers had anticipated. This condition was remedied by two independent measures. The stiffness of the fill in the cells was increased effectively by compaction and drainage, accomplished by means of sand piles. The unbalanced horizontal pressure on the outside walls was reduced by replacing the clay backfill by a drained gravel backfill.

4. The deflection observations confirmed the theoretical conclusion that the deflection of long cofferdams with fixed ends, resting on a firm base, should be greatest at a short distance from each end. They also showed, in accordance with theory, that the presence of a highly compressible layer beneath the fill in the cells increases the deflection very considerably, everything else being equal.

5. The relation between the unbalanced horizontal pressure on a wall and the corresponding deflection was found to be very similar to the relation between shearing stress and shearing strain for cohesive soils. The deflection increases more rapidly than the horizontal pressure, and at constant pressure the deflection increases at a decreasing rate. However, by trial computation it was found that the sheet-pile enclosure contributes very materially to the stiffness of the entire structure.

6. The factor of safety of the middle wall with respect to a failure by shear on a vertical plane was estimated by assuming that the coefficient of lock friction had a value between 0.2 and 0.3. On this assumption it was found that the factor of safety of that part of the wall which rests on solid marl ranged between 1.8 and 2.4. It was also found that the overturning moment had almost no effect on the distribution of the pressure on the base of the wall. This distribution was practically uniform. For the western part of the wall the factor of safety was considerably smaller than the foregoing values because this part of the wall rests on a very compressible base.

7. The results of a survey of the shape of the cells, after filling them with marl, showed that the hoop tension in the sheet-pile enclosures has almost the same value at any elevation within the upper two thirds of the height of the cells. Within the lower third it decreases in a downward direction to almost zero at the level of the base. Therefore, the unit elongation of the upper edge

of the cross-walls is practically equal to the maximum horizontal unit elongation of the sheet-pile enclosure of the cells.

8. While bearing piles and sand piles are being driven into the fill in the cells the lock tension is increased by an amount that cannot be predicted reliably. To make sure that the lock tension remains within safe limits the stretch in the upper edge of the cross-walls was measured repeatedly while driving the piles. The results of the measurements combined with those of previous tension tests with short sheet-pile sections indicated that the lock tension never exceeded 10 kips per in.

9. The design of the shipway floors was based on the assumption that the flow of the ground water toward the weep holes reduced the hydrostatic uplift on the base of the marl stratum which contained the piles; but the amount of reduction was not known. To observe whether the floors were safe with respect to heave, gages were installed which registered the water pressure at about the level of the points of the piles.

10. While the shipways were pumped out for the first time, gage readings were made at regular intervals. The readings showed that the safety of the floors with respect to heave will be adequate at any operating stage of the shipway, except at the eastern end of the floor of shipway B. By installing seven 3-in. filter wells beneath that part of the floor the piezometric head was reduced over the entire area covered by the shipways by about 5 ft. This local remedy served its purpose and it was much more economical than the customary method of preventing a heave by increasing the thickness of the floors.

Acknowledgments

The submerged shipways described in this paper were a project of the Bureau of Ships, U. S. Navy, under the general supervision of O. L. Cox, Admiral, U. S. Navy, and appreciation is expressed to the Navy Department for permission to publish the data contained in the paper.

BALANCED DESIGN IN URBAN TRIANGULATION

By Charles D. Hopkins,[1] Esq.

With Discussion by Messrs. Walter S. Dix, Henry W. Hemple, L. G. Simmons, C. A. Whitten, Ronald F. Scott, and Charles D. Hopkins.

Synopsis

It seems hardly necessary to stress the desirability for selective design since this first step in erecting engineering structures is decisive. Of course, the design, the mathematical processes, and the actual construction must be given equal weight if the operation is to be successful, consistent with the greatest degree of accuracy within the limits of justifiable expenditure. Granted the establishment of adequate mathematics and the development of competent physical implements (made available in the field of geodetics by the efforts of many practitioners through the years), it seems timely to make an effort to discuss the too-little-mentioned subject of design.

This paper, placing primary emphasis on the subject of triangulation design, nevertheless contains several statements regarding the mathematical processes. These statements are included solely to suggest some of the provocative ideas that were encountered during the course of the study, in the hope that further and more searching discussion may be stimulated.

Actual field results of applying the theories presented herein were so favorable as to be almost beyond understanding. In its beginnings, the idea of "balanced design in urban triangulation" originated from curiosity concerning the striking similarity in characteristics (of which there are many) of bridge and roof trusses and triangulation networks. For example, in the English truss a particular panel is used repeatedly, whose counterpart in triangulation is the component figure; but, because of physical limitations in the field, it would rarely be possible to erect a network of urban triangulation using only a single type of figure, such as the completed quadrilateral. Therefore, for very practical reasons, other types of figures are used which should be as closely related as possible.

Note.—Published in November, 1945, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Geodetic Engr., Office, Chf. of Engrs., U. S. Army, Washington, D. C.

Chronologically, developments occurred in reverse order. The list of figure types discussed in Part 2 and designs for the field work mentioned in Part 3 were under way in 1937. In the interim, the field and final results (presented subsequently in Table 2) were being made available. As the results accumulated, the comparisons became apparent, and were deemed sufficiently unusual to warrant an attempt to find reasonable explanation for cause.

Introduction

An accurate triangulation scheme is the prime necessity as a foundation for the erection of a traverse structure to control property dimensions. This is particularly true in establishing geodetic control systems in urban areas since high property values prevalent therein are a most significant factor in determining the level of accuracy to be attained.

The desirable accuracy of horizontal urban control has been stated as not less than 1 part in 15,000 at the remote extensions of the traverse from triangulation.[2] This ratio of accuracy is based on the measurable precision within which a building can be constructed with relation to a given property line.

The control system, comparable to a local public utility to serve the needs of an area, should be capable of producing the required accuracy at any point within the jurisdictional limits where it may be demanded. Serious and unavoidable losses in accuracy must be anticipated in extending the control, from the triangulation through various phases of traverse, to define every property block in the area. It is desirable, therefore, that the basic triangulation be as strong as practical considerations will permit. Inherent weakness in the triangulation can cause almost insuperable difficulties, if the unpredictable distribution of discrepancies, in triangulation and traverse observations, is unfavorable and causes unacceptable localization of error. Localized error that cannot be corrected properly can rightly be called structural failure.

The necessity for well-designed figures at measured precision bases was recognized early, probably due to the fact that base lines were relatively short and the length element was undergoing rapid expansion to a longer average line of sight. The component figures of arcs of triangulation between measured bases, however, were not always so well designed, and in some cases simple triangles, singly or in groups, are found interspersed with much stronger geometrical figures. Similarly, local-area nets are sometimes characterized by mixed design. Absence of balanced design can produce only unpredictable results. For example, the triangulation nets in two adjacent cities, upon completion in the field, appeared equally acceptable; yet the final indexes of accuracy from the least-squares adjustments of each had little in common. One result was judged to be extremely good and the other very poor. Actually, both results were erratic accidents because selective predesign of the structures was not a controlling factor and consistency in design was lacking in both networks.

[2] "Technical Procedure for City Surveys," *Manual of Engineering Practice No. 10*, ASCE, 1934, pp. 74 and 106.

By nature, the triangulation structure is difficult to analyze, because it is an indeterminate structure, and, therefore, has no rigid explanation. It is an engineering structure, subject in general to the same physical laws, but differing in that, visibly, its physical make-up can be appreciated only on a detailed layout map. The scattered monuments that perpetuate the station locations on the ground do not afford any understanding of the scheme. It is possible, however, to identify certain characteristics of the structure by a study of the pattern of the distribution of discrepancies resulting from observations, and to arrive at rational conclusions that should be helpful.

Part 1. Effects of Changes in Design

Obviously, any study of triangulation design based on actual arcs or nets would require enormous labor, and since many factors would modify final conclusions this idea was abandoned in planning the present study. By selecting types of actual component figures for individual examination, the outlook was made more promising, but even then certain difficulties remained, principally the lack of a reference base for common comparison. Although the absolute values of angles in actual triangulation can never be humanly known, discrepancies in observations can be distributed in the most consistent manner by a least-squares adjustment. Furthermore, changes in design would dictate the pattern of distribution. With these ideas in mind, the decision was reached to study the characteristics of design through comparison of the results from least-squares adjustments of ideal figures, whose absolutes are known.

For this purpose, four types of figures were selected—a central-point quadrilateral, a pentagon with and without central point, and a central-point hexagon. Using the perfect form for each figure wherein the absolute values of the angles are known, assumed discrepancies were applied to each angle. The assumed discrepancies were restricted in magnitude and range, and were uniformly applied—in tenths of seconds, 0.1 to 0.3, plus and minus successively, clockwise at each station and counterclockwise around the figure. By removing successive diagonal lines from the figure, the design could be changed by stages from saturation (that is, all diagonals being included) to the point where the figure becomes merely a combination of triangles. Thus, by making a series of adjustments for each stage of design, the various distributions of discrepancies could be tabulated and examined. In all, more than one hundred separate least-squares adjustments of the ideal figures were completed, and the results tabulated and graphed.

In the four types, the distribution of assumed discrepancies was made as similar as possible so that the final adjusted values would be closely comparable. Certain advantages are found in using the hexagon, however, since it covers wider range in design development and the results permit broader study and understanding. Therefore, the central-point hexagon is selected for discussion (see Fig. 1).

In making the series of least-squares adjustments for the hexagon (seven in all), the first involved the central-point figure without diagonals, and then the figure with the diagonals, included one by one in their numbered order.

Without diagonals the figure consists of six triangles in which the exterior lines lack double determination. With the inclusion of diagonal 1 (numbers

denoting diagonal lines are circled), the figure consists of a quadrilateral (in which all lines have double determination; that is, all lines are sides of at least two triangles) and four simple triangles. Diagonal 2 produces two quadrilaterals and two simple triangles; but, with the inclusion of diagonal 3, every line in the entire figure has reached double determination. In other words—the design-development stage being indicated by the number of included diagonals—at 0 the design is that of simple triangles, at 1 and 2 the design is mixed, and at 3 the design has reached the initial state of complete double determination. At 4 and 5 the design is classified as double determination increasingly compounded, and at 6 the ultimate of design is reached where double determination is completely compounded. It is pointed out that the inclusion of diagonal groups either 1, 2, and 3, or 4, 5, and 6 would produce double determination.

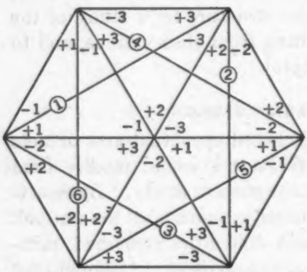

FIG. 1.—HEXAGONAL FIGURE, WITH THE PATTERN OF DISCREPANCIES GIVEN IN TENTHS OF A SECOND

The assumed discrepancies applied to the angles of the hexagon (Fig. 1), and the pattern and regularity of their distribution, produce a series of triangle closures that are of consequence to the study.

In any figure or combination of figures, there is a total in closures that is a constant. Referring to Fig. 1, it will be noted that the discrepancies at the perimetric angles within each of the radial triangles counteract each other; therefore, the triangle closure in each radial triangle will be identical to the discrepancy at its central-point angle. The algebraic sum of the central-point-angle discrepancies is zero, and thus the algebraic total-triangle closure in the entire figure is also zero. This total-triangle closure for the entire figure will remain constant regardless of the number of diagonals that may be inserted. The insertion of diagonals serves to divide and subdivide the discrepancies in the angles, and forms and reforms the resultant triangle closures. Likewise, the complementary side equations state and restate the proportional sine-to-side discrepancies. The total closure to be reconciled in each of the seven least-squares adjustments, therefore, remains a constant throughout the seven stages of design, upon which can be based a study of the mechanical changes produced in the series of adjustments, as evidenced by variations in the distribution of discrepancies.

After completing the series of adjustments, the corrected directions were tabulated. It then was possible, since the ideal hexagon is a perfect geometrical figure, to ascertain how efficiently the assumed discrepancies were distributed and what degree of approach to the absolute was attained. Therefore, another series of terms was tabulated—the absolute directions minus the corrected directions—which are designated Δ. The Δ-tabulations, without regard to sign, were then plotted, as shown in Fig. 2. On these graphs, the vertical section shows the increase in magnitude; and the horizontal section, the occurrence of Δ-terms in equal magnitude, to the total number of terms

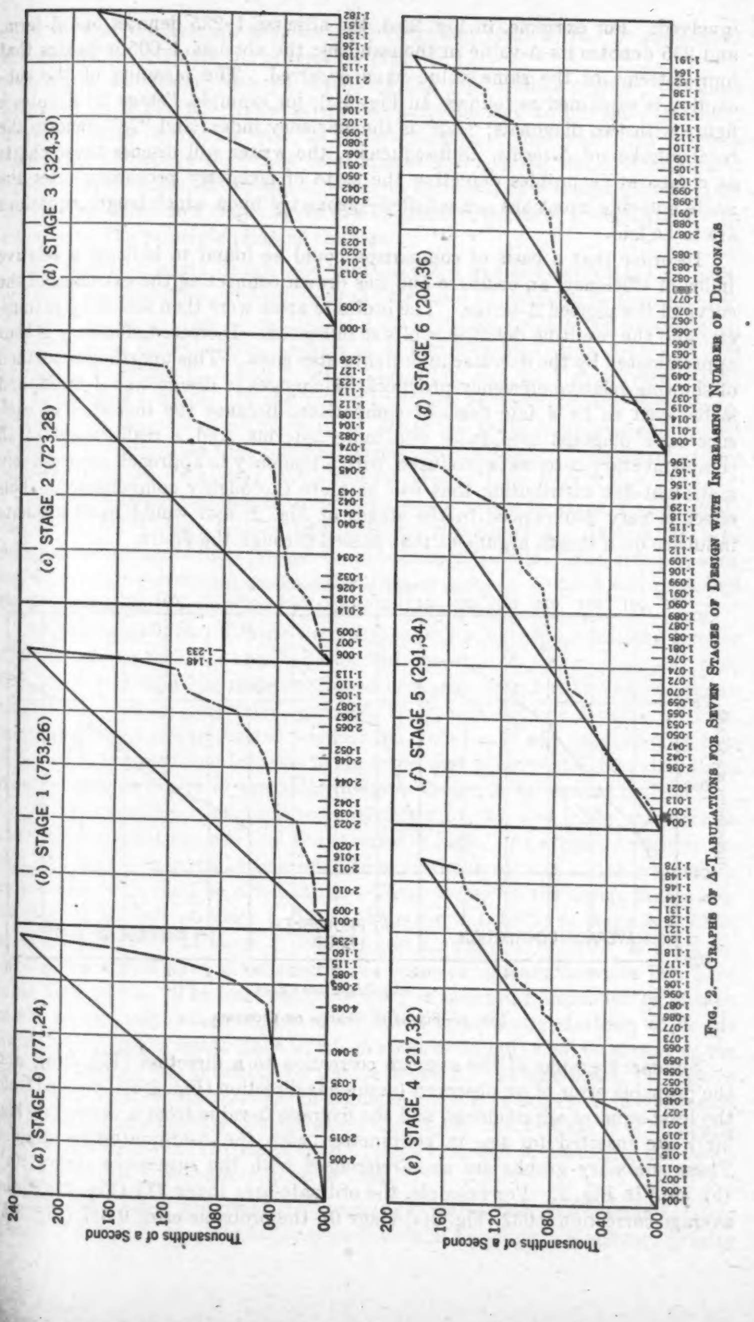

FIG. 2.—GRAPHS OF Δ-TABULATIONS FOR SEVEN STAGES OF DESIGN WITH INCREASING NUMBER OF DIAGONALS

involved. For example, in Fig. 2(*a*), the abscissa 1–235 denotes one Δ-term, and 235 denotes its Δ-value in thousandths; the abscissa 4–005 indicates that four Δ-terms of the same value have occurred. The meaning of the subcaption is explained as follows: In Fig. 2(*c*), for example, "stage 2" denotes a figure with two diagonals; "723" is the efficiency index; and "28" denotes the total number of Δ-terms. Subsequently, the writer will discuss these charts as comparative profiles depicting the state of geometry prevailing after the angle and side equations are satisfied—geometry upon which length equations are to be laid.

In order that a basis of comparison could be found to indicate a relative index of efficiency, an ordinate line was drawn connecting the extremes of the curve of the plotted Δ-terms. The ordinate areas were then scaled by planimeter and the resulting definitions of size indicated. Increased efficiency is thus approximated by the decrease in ordinate-area sizes. This unorthodox method of showing relative efficiency produced by changes in design was devised, and is believed to be a fair basis of comparison, because the inclusion of each successive diagonal introduces two more Δ-terms, and a realinement of all complementary Δ-terms is produced, with a tendency to approach progressively a straight-line distribution that will be more thoroughly compensated. This effect is very pronounced in the stages of Fig. 2, and would have ultimate influence on a length argument that passed through the figure.

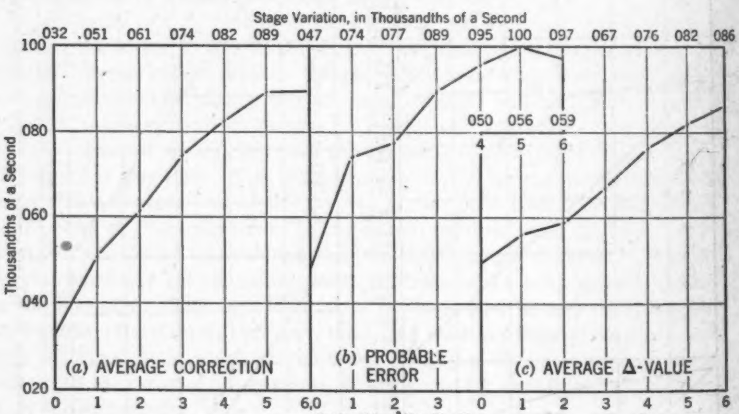

FIG. 3.—SUMMARY GRAPHS OF CRITERIA

Summary graphs of the average correction to a direction (Fig. 3(*a*)) and the probable error of an observed (assumed) direction (Fig. 3(*b*)), derived from the least-squares adjustments, and the average Δ-value from a direction (Fig. 3(*c*)) are inserted for use in conjunction with the Δ-ordinate-area graphs. These summary graphs are cross-referenced with the successive stages ((*a*), (*b*), etc.) in Fig. 2. For example, the ordinate-area index 771 (Fig. 2(*a*)), the average correction 0.032 (Fig. 3(*a*) stage 0), the probable error 0.047 (Fig. 3(*b*)

stage 0), and the average Δ-value 0.050 (Fig. 3(*c*) stage 0) can be considered collectively to complete the criteria for stage 0.

Certain conclusions can be stated on the information outlined on these graphs (Figs. 2 and 3). Because the triangulation structure is indeterminate, the conclusions cannot be facts, in the strict sense of that word, but it seems reasonable to believe that they can indicate strongly the trend of cause and effect. Incidentally, the specimen hexagon in its stages of design development can be considered as a single figure or as a small network of triangulation. In either case, the principle remains the same.

(*a*) Simple-triangle design and mixed design are not acceptable in high-precision triangulation, misleading final data from adjustment to the contrary. Stages 0, 1, and 2 (Figs. 2(*a*), 2(*b*), and 2(*c*)) plainly point to an unconcluded distribution of discrepancies. Stages 0, 1, and 2 in Figs. 3(*a*), 3(*b*), and 3(*c*) as related to stages 0, 1, and 2 (Figs. 2(*a*), 2(*b*), and 2(*c*)) show values that are misleadingly small. It is obvious that lack of geometrical conditioning, produced by diagonals, might result in either favorable or unfavorable distribution of discrepancies that could adversely affect a base-to-base chain, or any part of a network—a matter which will be referred to in Part 3.

(*b*) The severe decrease in the ordinate-area index in stage 3 (Fig. 2(*d*)) can be expected since double determination is completed. At this stage of design, a minimum of lines produces a maximum of results. The ordinate-area index, average correction, probable error, and average Δ-value have reached the lowest common minimum in double determination.

(*c*) Stages 4, 5, and 6 (Figs. 2(*e*), 2(*f*), and 2(*g*)) show a relatively smaller decrease in the ordinate-area indexes, but the related stages 4, 5, and 6 in Figs. 3(*a*), 3(*b*), and 3(*c*) show continued increase—with but two exceptions in stage 6—in average correction, probable error, and average Δ-value. Unless very exceptional circumstances warrant the inclusion of any or all of diagonals 4, 5, and 6, the resulting increase in time and cost is not justifiable; also, these diagonals are in excess of the uniform-figure design to be treated in Part 2.

(*d*) It is possible to summarize conclusions (*a*), (*b*), and (*c*) by reference to the theory of least squares and the exercise of logic. As applied to triangulation, the theory is given as follows: The sum of the squares of the corrections to the directions shall be a minimum. These terms for the design stages are: At stage 0, 0.0340; at stage 1, 0.1083; at stage 2, 0.1442; at stage 3, 0.2273; at stage 4, 0.2996; at stage 5, 0.3708; and at stage 6, 0.3919. If graphed, these terms would have the characteristic curve of increase shown in Fig. 3 for other final terms. The least-squares theory is satisfied independently in each of the seven design-stage adjustments, but it is necessary, further, to decide which least-squares result (that is, which stage of design) shall be chosen as the specific one that will probably be the most useful. At this point, the logic of economy should be the only deciding influence; and, as expressed in conclusion (*b*), the logic of economy points rather directly to the first state of complete double determination, produced by diagonals 1, 2, and 3, providing the maximum of results with the minimum of lines.

In planning and executing the foregoing investigation, the components are greatly reduced in magnitude for convenience in handling. Similarly, greatly

reduced models of trusses are used to study load stresses and subsequent reactions. Nevertheless, the process, however reduced, can guide thinking in connection with the much larger problem of planning and executing an actual urban network. The criteria for acceptance of field observations[3] constitute a restriction of the magnitude and range of discrepancies in observed angle values in somewhat the same manner that artificial restriction has been applied to the assumed discrepancies in the ideal hexagon. Of course, there is an infinite variety of patterns in the distribution of discrepancies since the structure is indeterminate, but the trends in results will be constant. Quite naturally, it should be remembered that the magnitude and range of actual discrepancies in a network are expected to be much larger and are correspondingly more decisive.

Part 2. Uniform Unit Figures

To make the best use of advantageous trends, it is necessary to build up a reasonably complete series of closely related geometric figures, hereinafter to be called unit figures. They are designed to incorporate the useful characteristics suggested as regards the hexagon in Part 1. Such a series is presented in Table 1.

The ideal hexagon is the perfect form of the unit figure shown as type 4, Table 1. With shifts in the location of central points and changes in shape, the figures apparently become more difficult to identify; but this need not be misleading, since each type includes a definite number of physical members that is characteristic of one type only. In the series it will be seen that types 1 and 6 are used in varying combinations to make up the remaining composite types. All are equally useful in designing the urban net from reconnaissance operations.

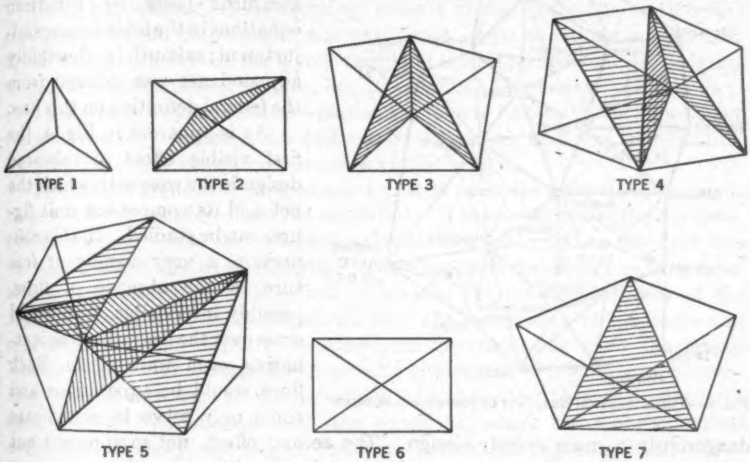
The types of unit figures shown in Table 1 are in two groups—one with central point and the other with diagonals only. The completed central-point triangle and the completed quadrilateral are the basic unit figures. In the first of these one triangle overlaps three and in the second two triangles overlap two (overlap in each case for double determination). In the composite types, attention is directed to the central-point figures and the regular increase in the number of diagonals employed; and, in type 7, attention is directed to the pentagon with four diagonals. In that manner, types 2, 3, 4, and 5 combine a central-point triangle, in each, and one, two, three, and four quadrilaterals, respectively, in compound overlap (see crosshatched areas) needed for unit-figure geometry. Similarly, type 7 combines two quadrilaterals. The close relationship in visible characteristics is quite apparent in all these types. An indication of the close similarity in mathematical characteristics is shown by the reduced spread of the $\frac{D - C}{D}$ terms (see Table 1), in which:[4] D is the number of directions observed in the figure (always assuming that the starting line is held fixed); and C is the number of conditions to be satisfied in the least-squares adjustment.

[3] "Technical Procedure for City Surveys," *Manual of Engineering Practice No. 10*, ASCE, 1934, p. 11.

[4] *Ibid.*, Eq. 1, p. 14.

It will be noted that certain diagonals are not used; therefore, various choices in selecting the required number of diagonals are possible. This is a very useful circumstance in resolving reconnaissance and designing difficulties, and in the elimination of poorly shaped triangles. It is thus possible to design

TABLE 1.—SERIES OF COMPONENT UNIT FIGURES AND THEIR CHARACTERISTICS



Type	Unit figure (C-p = "central point")	Diagonals	$\frac{D-C}{D}$	Adjustment Conditions	
				Angle	Side
1	C-p triangle........	....	0.60	3	1
2	C-p quadrilateral........	1	0.56	5	2
3	C-p pentagon........	2	0.55	7	3
4	C-p hexagon........	3	0.54	9	4
5	C-p heptagon........	4	0.53	11	5
6	Quadrilateral........	2	0.60	3	1
7	Pentagon........	4	0.56	5	2

the urban net by abutting component unit figures of relatively similar physical properties.

PART 3. ACTUAL RESULTS IN THE FIELD

During the years 1937 to 1941, the writer collaborated with local personnel engaged in the construction of several urban triangulation nets. At that time, even though the idea of balanced design for triangulation existed only as a line of logic, based upon past experience and research, it was possible in most instances to demonstrate successfully the usefulness of the design, which was used subsequently in designing several urban networks. As an example for discussion the basic triangulation net for the City of Minneapolis, Minn., is reproduced in Fig. 4.

This network has sixteen component unit figures, including nine quadrilaterals, two central-point triangles, four central-point quadrilaterals, and one central-point pentagon. Two precision base lines were measured—Main-Columbia and Holy Angel-Cedar. The line Aggie-Snelling, established in length and azimuth by the U. S. Coast and Geodetic Survey, was held fixed, being related to the measured bases by condition equations in the least-squares adjustment; azimuth for the rigidly adjusted net was derived from the federal definition on this line.

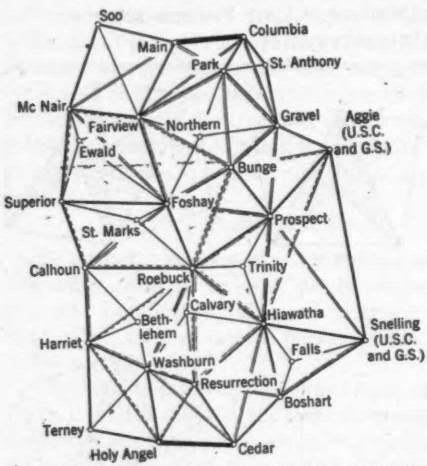


Fig. 4.—Triangulation Net, City of Minneapolis, Minn

As is apparent in Fig. 4, the first visible effect of balanced design is the ease with which the net and its component unit figures can be studied. In this connection, a very significant feature is the absence of lines, possibly intervisible, that would cross over the heavy lines accentuating each unit figure. Such lines would be superfluous and could only serve to complicate dangerously a more orderly design. The second effect, not so apparent but present nevertheless, is the pattern of geometrical condition equations necessary in the least-squares adjustment to distribute discrepancies from observations.

Disregarding the length argument for the moment, there are sixty angle equations and thirty-one side equations. The angle equations, all of which occur as unit-figure conditions, require no special comment. There are two distinct varieties of side equations, however: (*a*) Figure-side equations, twenty two in number, that occur complementally to the angle equations in the individual unit figures; and (*b*) vertex-side equations, nine in number, occurring at the interior stations that are the vertices of abutting lines between unit figures.

In this net the vertex stations are: Fairview, Park, Foshay, Bunge, Roebuck, Prospect, Washburn, Resurrection, and Hiawatha. The limit lines of the vertex equations are shown in Fig. 4 by lines of three styles placed on the side of the limit lines nearest the vertex station. These vertex-side equations serve to knit the scheme geometrically, by relating each unit figure to every other, as the figure-side and angle equations relate the members of each unit figure.

Specifically, the function of the vertex-side equation is to establish coincidence of the abutting lines between unit figures at the pole—that is, at the vertex station. Likewise, the figure-side equations produce coincidence of certain unit-figure lines at selected figure poles, and, in conjunction with the angle equations, complete the integration of the individual unit figures. The

process of integration proceeds from the individual unit figures, geometrically, through the vertex-side equations—relating figure to figure and vertex to vertex—to every part of the entire net. Each unit figure and its condition equations abut other unit figures and their conditions, and the vertex-side equations overlay each other and the unit-figure conditions in fish-scale fashion. There can be no doubt regarding complete integration and, furthermore, the highest possible degree of uniformity throughout the network.

Using transparent plastic sheeting, cutouts of the figure-side and vertex-side equations can be prepared; the selection of angle equations in each unit figure can be indicated on the layout map; and the cooperative effects, designed to produce mathematical rigidity, can be examined by overlay. In this way, also, the presence of an identical equation that would be fatal in the adjustment can be detected. Actually, this seems to be the graphic statics of triangulation whereby geometric integration becomes visible in form.

The length argument, superimposed as it is upon the geometrically conditioned network, can be considered separately. The necessary length equations, two in number, relate the measured bases to each other and to the fixed line through selected chains of triangles. There are discrepancies in passing from base to base and base to line, but, in view of the extreme accuracy of the measured lengths, these discrepancies after the satisfaction of the angle and side conditions can scarcely be considered as originating from the length measurements. Therefore, they represent the degree of failure in compensation in the angles used in the base-chain triangles, after these triangles have been effected by the angle and side equations, which are the geometrical conditions. Finally, the length equations (which are trigonometrical conditions) are superimposed and the total base-to-base discrepancy after adjustment is disclosed; and, if this final length discrepancy is highly acceptable, cannot it be considered as evidence that the geometrical adjustment, produced by the angle and side conditions, was but little disturbed by the length conditions? Furthermore, does it not afford evidence that all discrepancies were most consistently and favorably distributed, limited only by the mathematical process, throughout a network that is uniformly designed? In this connection, reference is made to the ultimate influence attributed to a compensated distribution of the geometrical discrepancies as suggested in Part 1.

Lastly, there are the final results from the least-squares adjustment that are accepted as the indicative proof. Criteria for the acceptance of urban triangulation schemes were presented in 1934 by the Committee of the Surveying and Mapping Division on City Surveys.[5] These specifications and the results of four actual operations, the networks of which were designed by abutting component unit figures of the types listed in Table 1, are summarized in Table 2.

In reviewing these somewhat surprising results, it should be remembered that, according to the theory of probability, any single result in this field can be called accidental, as can also any pair of results; but, when the third and the fourth are considered, the chance that the results are accidental becomes

[5] "Technical Procedure for City Surveys," *Manual of Engineering Practice No. 10*, ASCE, 1934, p. 12.

so remote that the circumstances call for another explanation—the inevitable conclusion in this case being cause and effect, with emphasis on balanced design as a basic cause.

To be sure, for all practical purposes, scheme C, Table 2, is just as useful as scheme B, despite the large difference in the adjusted base-to-base discrepancies. (The designations A, B, and C are used herein to identify three other city networks similar in design to the Minneapolis scheme.)

TABLE 2.—SUMMARY OF RESULTS, APPLIED TO URBAN TRIANGULATION

No.	Description	Manual 10[a]	Minneapolis[b]	Scheme A	Scheme B	Scheme C
	(a) Results Attained from Field Observations					
	Triangle Closures, in Seconds:					
1	Average	1.50	0.91	1.22	1.31	1.09
2	Maximum	5.00	3.26	3.21	2.94	2.50
	Sine-to-Side Discrepancies, in Seconds:					
3	Average	0.70	0.56	0.48	0.64	0.49
4	Maximum	2.00	1.83	1.65	2.13	1.60
5	Probable error of measured bases[c]	600,000	1,657,000	1,638,000	1,678,000	1,850,000

[a] *Manual of Engineering Practice No. 10*, ASCE, 1934, p. 12. [b] Basic triangulation net for the City of Minneapolis, Minn. (see Fig. 4). [c] Ratios, 1 : 600,000, etc.

The significant fact is that, as a prerequisite to the other necessary phases of construction, it is possible by selective design to exceed the specifications for the length argument and to satisfy the other final criteria in four networks of similar design, without a single failure to date, at the same time producing the effect uniformly throughout each network. From networks of such consistent strength, extensions of traverse to provide adequately spaced control stations can be planned and executed very confidently, as has been amply demonstrated in practice.

It is disheartening to discover, during the development of a traverse layout from triangulation, the inexplicable presence of an area of weakness in an urban control system. It would seem to be only good judgment to build as strongly as is possible, rather than to be forced by circumstances to attempt the rationalization of disappointment that could have been avoided.

ACKNOWLEDGMENT

Fig. 4, the basic triangulation net for the City of Minneapolis, is reproduced with the kind permission of Frederick T. Paul, M. ASCE, City Engineer.

DISCUSSION

WALTER S. DIX,[6] Assoc. M. ASCE.—The paper is a comprehensive analysis of a basic problem in urban area precision survey engineering, important to many surveyors and engineers, yet understood or considered by an alarming few. The author's research and effort on this paper are valuable contributions to the knowledge and advancement of professional surveying and engineering.

It is imperative that, for the degree of accuracy warranted by modern municipal precision surveys, not one single step in the direction of equilibrium for final values of an urban network should be neglected—that, whereas attention has been given in the past to full consideration of the laws of gravity, refraction, and trigonometry in city triangulation, not enough thought has been applied to equally important laws of balanced design, involving engineering philosophy with mathematical, geometrical, and algebraic analysis, to produce truly homogeneous accuracy.

In substance, the theory of homogeneity in this instance is that the reality of engineering has been added to the science of mathematics to produce the surprising data in the author's tabulation of final results.

The author is completely justified in comparing localization of error in an urban triangulation network, to the inherent weakness of a similarly localized error in structural design; and, as the author has indicated, experience shows that arbitrary acceptance of over-all closure adjustment in triangulation schemes heterogeneously composed of unsymmetric figure patterns of varying strength, as true index of homogeneous accuracy of the scheme, can quite conceivably conceal some local accrual of weakness.

The possibility of such concealment of local error in over-all closure values has previously been mentioned by G. D. Whitmore, M. ASCE, C. C. Miner, Assoc. M. ASCE, and W. O. Byrd who state:[7]

> "The writers have long felt that too much emphasis has been placed on the 'just happened' closure of the entire loop, and not enough on designing measuring instruments and measuring procedures that will insure uniform precision for each and every tangent of the entire traverse. Experience shows that traverses having circuit closures of high order, such as 1:10,000 or 1:20,000, may conceal errors, in individual courses, of the order of 1:1,000."

This statement follows closely the author's argument in favor of closer unit consideration in design, and solution of urban triangulation systems, to insure greater integral accuracies within the accepted over-all accuracy index.

Any precautionary measure taken toward eliminating the possible concealment of error is a step in the direction of optimum engineering design. The deliberate design of urban triangulation by compounding component unit figures, and the analytical selection of balanced equations for homogeneous solution with multiple determination alternatives, as propounded by the author

[6] Cartographic Engr., Maps and Surveys Div., TVA, Washington, D. C.

[7] *Transactions*, ASCE, Vol. 108, 1943, p. 598.

(as compared with the over-all solution of an accidental heterogeneous triangulation pattern resulting only by intervisibility from conveniently available tall buildings, hill tops, tanks, etc.), is certainly a step in that direction. Furthermore, station towers should even be erected where required when found advantageous for optimum design strength in following out the overlapping unit-figure network in urban triangulation.

Portable towers are used by the United States Coast and Geodetic Survey to aid visibility and to help control figure strength in basic triangulation arcs of the United States; but, to the writer's knowledge, erected towers have seldom if ever been specially placed for urban triangulation, except scaffolding or platforms built up to augment convenient roof structures.

With reference to the author's closing statement, any latently discovered weakness in an urban triangulation system requiring rationalizing by arbitrarily adjusting the values of subsequent determinations is more than disheartening disappointment; it is an engineering tragedy. Urban networks, by characteristic unity, are capable of complete predesign. Other than false economy or meager budget (itself a false economy), there seems little argument contrary to urban triangulation network predesign.

Henry W. Hemple,[8] M. ASCE.—The subject of urban triangulation design has been presented by Mr. Hopkins in a vivid manner. Engineers engaged on this type of work will benefit by his general concept of design. The principles which the author recognizes have been in use for many years and are established as standard for precise surveys.

The comparison of triangulation design to that of structures is an apt illustration, but the comparison is analogous only to a certain point; beyond that the similarity does not exist. It should be understood, however, that specifications for design, observational procedure, computation, and adjustment are so rigid for urban and precise triangulation surveys that, if the basic measurements and observations were adequate and if the specifications were otherwise adhered to, there would be no weak determination of positions or lengths in the scheme.

In the design of structures there are various known factors, or those that may be correctly estimated for, producing stresses for which structural members whose strength characteristics are known can be provided. In triangulation work, unknown physical conditions may be of a nature to produce lateral refraction of light rays and introduce errors in the directional measurements. These effects cannot be called errors due to structural failures, and there is no element of design that can be introduced to guard against them. They are errors resulting from unknown causes which cannot be compensated for, and only by reobservation under good atmospheric conditions can they be eliminated.

If the computation and adjustment of a triangulation scheme have met the specifications, these discrepancies must be due to imperfect measurements or observations. The degree of failure that might be acceptable can be antici-

[8] Chf., Div. of Geodesy, U. S. Coast and Geodetic Survey, Washington, D. C.

pated from the strength of any design. If the failure exceeds this limit, certainly the design is not at fault. In this concept, Mr. Hopkins' statement (see heading, "Introduction") that "Localized error that cannot be corrected properly can rightly be called structural failure" will have no basis.

Many factors enter into the formation of a scheme of triangulation. Topographic and other conditions will not always permit the location of the stations at points that will give the ideal design. Lines over which undue refraction may be expected must be avoided. Stations on opposite ends of the lines of the scheme must be tested for intervisibility. Base lines must be provided at the proper intervals so that adequate length control is available. Connections to adjacent federal control must be made so that there will be a continuous coordinated scheme throughout the area. Adequate strength of figures must be inherent in the triangulation figures formed. The scheme selected should be such that it can be carried through with economy and yet maintain the accuracy desired.

One is not justified in spending an undue amount of effort and time with the resulting increased cost, striving for ideal figures, when there are other possible solutions easier of execution which will satisfy the criteria for urban surveys. The competent engineer evaluates all these considerations and arrives at a scheme that can be executed economically and still satisfy the requirements of the specifications.

The U. S. Coast and Geodetic Survey has adopted the practice of providing at least one base line near the larger cities for length control of the federal net in that locality. Lines of the federal net and their azimuths may be accepted into the urban scheme with assurance that they are determined with adequate accuracy for city survey purposes. In cities where urban surveys exist at the time the federal net is carried to them, connections are made to the local surveys and their lengths are held if the work has been done with standard specifications for that type of control.

Mr. Hopkins has considered only the internal forces affecting a scheme of triangulation. When area triangulation is adjusted to an established scheme surrounding it, the maximum external forces are encountered. The engineer can be certain that, if the observational data will withstand the test of this adjustment, the fundamental control and the new survey have each been determined with high accuracy.

Mr. Hopkins has shown a keen appreciation for strong figures in triangulation and this fundamental principle must be recognized by all those engaged in urban surveys.

L. G. Simmons,[9] Esq.—It is agreed that well-shaped figures with double determination in length are essential to high precision in geodetic triangulation. The writer does not agree on the importance that Mr. Hopkins attaches to the effects caused by the variations in his sample figure (Fig. 1). These effects are so small that they are likely to be completely obscured by more prominent effects arising from conditions entirely independent of figure design. It is

[9] Prin. Geodetic Engr., U. S. Coast & Geodetic Survey, Washington, D. C.

quite possible that the writer has missed the point, but to him it seems that Mr. Hopkins' reasoning does not follow a logical course.

For example, he begins with a symmetrical central-point hexagon and then assumes a set of observations closely approximating Fig. 1. As soon as he has assumed this set of observations, the perfect hexagon figure no longer has a place in the problem. It is nothing more than something he had in his mind before the analysis was started. The set of assumed observations is then adjusted by the method of least squares and the results tabulated as Δ-values or differences between the adjusted directions and the directions defined by the angles of the perfect hexagon. The significance of these Δ-values escapes the writer. There is no reason that the adjusted values of the angles approach those of a perfect central-point hexagon other than the fact that the assumed values approximated this figure.

Even if these Δ-values do have significance, it is not clear to the writer why the merit of the figure design should be judged by the closeness with which plotted values cling to a line drawn between the high and low values. On this basis, why does Mr. Hopkins state that stage 3, where complete double determination is first reached, is the most efficient figure design? Is it because the Δ-values, which have no meaning in the first place, occur in a uniformly ascending series of values? To the writer it is more important to keep the Δ-values low (if they do have a meaning), and on this basis it would seem that stage 0 is more efficient than stage 3. Moreover, the differences among all stages appear of small consequence, even if the assumed triangle closures were doubled.

As a practical proof of what figure design will do toward securing length agreement between measured bases, Mr. Hopkins cites several schemes of urban triangulation in which (in most cases) length closures were considerably better than 1 part in 1,000,000. The writer maintains that any length closures that are much better than 1 part in 200,000 are purely accidental and extra precision as implied by better figures is more apparent than real. The reason for this statement is twofold: First, lengths of the best standardized base tapes, with an accuracy of 1:200,000, are scarcely known. Certainly there are none more accurate than 1:500,000; and, second, the effects of systematic errors, which are present particularly in urban areas, preclude any certainty of a much better length closure. No amount of extra refinement in figure design will overcome the limitations already imposed by observing conditions (uncertainties in lateral refraction), and the limitations imposed by the ever-present systematic errors in triangulation work, too numerous to mention.

Of course, strong figures should be used and single triangles avoided where the highest precision is sought, but Mr. Hopkins is putting into figure design a refined value which cannot be extracted economically—if at all.

C. A. WHITTEN,[10] ESQ.—The selection of the type of mathematical analysis of a triangulation scheme is frequently dependent on the desires of the individual making the particular study. The possible types of investigations with all the variations which naturally develop present a problem for

[10] Chf., Section of Triangulation, Div. of Geodesy, U. S. Coast & Geodetic Survey, Washington, D. C

which there would be no end. When only one type of investigation or procedure is used, it must be established that the methods employed are rigid at least in principle.

A new method of analysis for a study of triangulation design is presented by Mr. Hopkins. In general, the results derived are not contradictory to established fact. Some of the author's conclusions are based no doubt on his experience, plus the "exercise of logic," rather than on the findings from a standard mathematical treatment. It is because of this that it seems necessary to caution those who would pursue this problem in further variations.

At the outset, the method of adjustment, whether by the angle or the direction method, should be established definitely. Both cannot be used simultaneously or interchangeably as Mr. Hopkins has done. Having established the method of adjustment to be used, it is permissible to make some assumptions. However, the writer questions the procedure of assuming a rigid figure and then assuming a set of observational errors. What will hold the true figure rigid? There could be a large number of mathematically consistent or rigid figures within the range of the assumed errors without creating an error greater than any of the original assumed errors. Thus, this method does not seem feasible for a general mathematical development. Even the distribution of the assumed errors was made in a systematic manner rather than according to probability. Why, then, use least squares?

Another unusual treatment is the development and tabulation of the Δ-terms. Since the assumed observational data are not truly observational, according to the laws of distribution, the graphs of the Δ-terms do not furnish conclusive evidence concerning the various stages. The ideal adjustment would be the one in which the Δ-values are small, and Mr. Hopkins has probably selected the wrong area of the graph for determining the "efficiency index." The mean Δ-term is a more logical value for an index.

The results obtained from the calculations of the seven stages of design should not be compared with each other without giving consideration to the mean of the assumed errors which were distributed by pattern. These mean errors are:

Stage of design	Mean error of angle (seconds)
0	0.067
1	0.088
2	0.097
3	0.113
4	0.122
5	0.126
6	0.127

Since there is a large change in the mean errors of the various stages, similar changes will be found in the probable errors and average corrections. However, the author has attributed the changes in probable errors and average corrections to the stages of design rather than to the magnitude of errors in the different figures. The mean errors have not been balanced sufficiently for a satisfactory comparison of the various stages.

Mr. Hopkins recognizes many of the difficulties that are encountered in determining the accuracy of any triangulation net or figure. When rigid specifications are used to limit the magnitude of errors of observations, the least squares method of adjustment will produce very satisfactory results. From a least squares adjustment, it is possible to determine the effect of an error of any one observation on the other lines of the scheme. Such a process as this, when applied to all lines of a scheme through various stages of development, would be very laborious and the value of the results obtained might not be worth the effort. However, such a method would produce results that could be interpreted with certainty since the procedure is rigid and conforms with accepted mathematical practice.

Ronald F. Scott,[11] Jun. ASCE.—It is hoped that this paper is the beginning of a new and wholesome approach to the problem of covering an area with triangulation of a more or less predictable accuracy. To this writer's knowledge all too little attention has been given to this very important phase of precise control surveys. The design of a triangulation scheme to provide uniformly precise control over a large area has been too much a matter of guesswork; or, perhaps, it has been classed as an art rather than a science. Much work has been done in adapting triangulation to the problem of a chain of quadrilaterals establishing control over long distances; but its use for an area has been insufficiently explored.

Those who have undertaken the design of a scheme for an area have too often been regarded as individuals apart from normal human beings with a special sense of things mathematical and geometrical. It will be very important to remove this phase of surveying from that highly specialized classification into the realm of things more common. Much work has been done to make the little-known facts of precise surveying available to a broader group of engineers. However, the profession is still a long way from providing the necessary and desirable tools to complete the numerous, carefully executed control surveys that will be required before the various systems of state-wide plane coordinates can come into general use. In the past decade some engineers have declined to undertake the supervision of precise-control projects involving triangulation simply because they have felt that the problems and techniques were far too involved for someone with ordinary engineering training. This concept of precise surveying can be done away with only by the development of design methods that will be suitable for widespread use.

The author's brief mention of a system of templets which will illustrate, graphically, the structural integrity in a triangulation scheme is the kind of thing which could well be expanded further. If engineers are required to take up this work they should be assisted to the greatest possible understanding of the significant factors, not only by mathematical reasoning but by utilization of all possible graphical and mechanical means. This relationship of geometric figures to one another in a triangulation scheme is the phase of the work that is the most difficult to understand. It is so intangible that it may too easily escape proper attention if, indeed, it receives any attention.

[11] Director Upper East Tennessee Office, Tennessee State Planning Comm., Johnson City, Tenn.

The hopelessly disorganized status of cadastral surveys, particularly in some parts of the eastern United States, will eventually bring about an insistent demand for sweeping reforms in surveying methods. It will be necessary for the engineering profession to have on hand, ready for use, the necessary criteria and design procedures in sufficient detail to enable the design of control surveys with the same assurance of success as can be had in the design of structures. Unfortunately, the advantages of sound surveying practice are apparent only to those who are most intimately connected with the very worst of the difficulties that arise from a short-sighted policy on control requirements. Even today a very few engineers, not to mention the laymen, realize the advantages and economy of a properly developed system of dimensional control for areas of extensive physical development.

CHARLES D. HOPKINS,[12] ESQ.—In concluding this paper, the writer wishes first to thank the persons who have contributed to the published discussion. A large measure of thanks is due, also, to those individuals whose advice continues to be a helpful factor in the development of a better understanding of the subject. It seems certain that every opinion that is brought to bear during the unfolding of the concept will materially aid progress.

The most significant reactions to this exploratory effort have come from the engineers in other fields. Without any doubt, the tenor of their remarks indicates a desire to understand this increasingly important subject and a belief that the subject material must be expressed in relative terms in the common language of the engineer. There is the "rub," since the person endeavoring to assist the growth of fellowship is confronted with the ever present difficulties: First, to conceive the nature of the problem and an approach to solution; and, second, to express findings so that the details and the relationships are clearly understandable.

It seems clear, in the light of knowledge acquired since this paper was written, that the first need for better understanding will be met when the subject material is properly classified in the conventional engineering manner—(*a*) the properties of the materials, (*b*) the structure in theory, and (*c*) the structure in place. The materials in triangulation, whose properties have been under close investigation for many years, are found in the field books recording the observations. The structure in place involves the use of the various projections to define the position of adjusted stations on the earth's surface and the data for projections are available in great detail through the long continued work of the mathematicians; but, to fully realize the relationship between the materials for construction and the structures in place, it is absolutely necessary to develop the theoretical concept for the structure. Otherwise, the engineer can never expect success in final results with any degree of certainty.

The writer appreciates to the full the complexities in the subject taken as a whole. That circumstance needs no elaboration. However, it is possible to reduce any subject to a degree of simplicity, given a point of attack and the required time. In this connection, an example of the reduction of a minor subject in this field, possibly encouraging, can be examined as follows:

[12] Geodetic Engr., Office, Chf. of Engrs., U. S. Army, Washington, D. C.

In the quadrilateral with both diagonals, the geometric conditions are found stated in four angle equations and five side equations. These can be put into the adjustment as three angle equations and one side equation, or two angle equations and two side equations, or one angle equation and three side equations. The number of combinations of the four equations required in this simplest type of completed unit figure is somewhat surprising—a total of 126 combinations has been identified, of which 120 are true and useful and six are false and useless; but, of the large number of useful combinations, only one combination is required, usually three angle equations and one side equation being the selected choice.

This comparison suggests that an understanding of the minimum working essentials can be grasped with relative ease. In other words, the engineer who builds roads does not necessarily need to remember the knowledge required to make the machines used in the operation.

In the light of experience, it is the writer's personal conviction (no doubt shared by many others) that unsuspected facts, indispensable to success, are present in triangulation. It does not seem reasonably possible to consider triangulation other than as a structure; since it can be defined as a structure, an arrangement of parts is involved—parts being the lines between stations. Therefore, since an arrangement of parts is an operation in fact, an orderly reasoned arrangement of these parts is logically necessary. This most strongly suggests an engineering treatment; and, the subject being treated as engineering, it becomes essential that every required principle in engineering be incorporated in the structure.

In view of the natural difficulties and the conflicting opinions relating to the geodetic field, it seems fitting to close this paper with an appropriate statement which will sum up the problem and point the way to an understandable solution. In one of the truly profound sayings of modern times, Sir Norman Angell poses the question: "How, out of complexity, to distill simplicity; out of knowledge, essential understanding; out of confusion, clarity." It seems entirely reasonable to state that the last mentioned attributes—simplicity, essential understanding, and clarity—applied to their limits would go far toward making the geodetic subjects more understandable, and certainly more attractive, to the engineering profession.

TORSION IN STEEL SPANDREL GIRDERS

By J. E. Lothers,[1] M. ASCE

With Discussion by Messrs. John E. Goldberg, I. Oesterblom, Robert V. Hauer, E. I. Fiesenheiser, Edward V. Gant, Oscar Hoffman, Phil M. Ferguson, and J. E. Lothers.

Synopsis

The computation of torsional stresses in rolled steel sections is not new. The application has been confined, however, to eccentric loads where the torque, or torsion moment, could be obtained by multiplying the load by the eccentricity. The case of hanger bolts suspended from a steel girder flange and supporting an intermediate stair landing might be cited as an example. A steel spandrel girder with a floor beam framed into its web presents a torsion problem of a different type. The deflecting floor beam twists the spandrel and a torque is introduced—the computation of which is analogous to that of the bending moment brought to a column by a rigidly connected beam. This torque has been neglected for the following reasons: (1) No simple method of computation has been advanced; and (2) it has not been considered of sufficient importance to justify an extended analysis.

The purpose of this paper is to propose simple formulas for the solution of the aforementioned problem and to justify them by the method of moment distribution. Simple empirical formulas are also proposed for computing approximate values of the torsional constant K for the design of rolled steel beams which involves only beam constants found in the ordinary steel handbook.

Introduction and Restatement of Principles

Notation.—The letter symbols in this paper are defined where they first appear, in the text or in illustrations, and are assembled alphabetically, for convenience of reference in the Appendix. Discussers are requested to adapt their notation to that of the paper.

Formulas Applicable to Cylindrical Beams.—In the ordinary textbook on mechanics of materials, torsion is applied to cylindrical shafts, that section being the most economical disposition of material to resist torsion. In other

Note.—Published in March, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Prof. of Architecture, School of Architecture, Oklahoma Agri. and Mech. College, Stillwater, Okla.

words, if a beam is to be designed, the chief function of which is to resist torsion, a circular section is chosen. The following two equations apply:

$$s = \frac{T\,r}{J} \qquad \text{(1a)}$$

and

$$T = \frac{J\,G\,\theta}{L} \qquad \text{(1b)}$$

in which s is the torsional shearing stress at the surface of a cylindrical shaft or beam; T is the torsional moment or torque; r is the radius of the shaft or cylindrical beam; J is the polar moment of inertia of the section; G is the shearing modulus of elasticity (usually assumed to be $0.4\,E$); θ is the total angle of twist; and L is the length of the shaft or cylindrical beam over which θ has been accumulated.

Eqs. 1 may be used for noncircular sections, such as I-beams or channels, subjected to torsion provided that proper values are substituted for r and J. If the thickness of that part of the noncircular section for which the torsional shear is desired is substituted for r and if the torsional constant K for the section is used instead of J, a close approximation of the desired result will be obtained by Eq. 1*a*.

The Torsional Constant K.—The torsional constant K may be defined as the measure of the torsional rigidity and twisting deflections of the beam.[2] For circular sections, J and K are identical. For noncircular sections, K is always less than J, but there is no direct relationship between the two. The use of K in connection with noncircular sections is analogous to that of J for circular sections. Therefore, the following equation holds:

$$K = \frac{T\,L}{G\,\theta} \qquad \text{(2)}$$

The value of K for any given beam may be found experimentally by observing simultaneous values of T and θ and substituting them in Eq. 2. For I-beams and H-beams it may also be found, for sloping flanges, by:[3]

$$K = \frac{b - t_w}{6}(m + n)(m^2 + n^2) + \frac{2}{3}t_w m^3 + \frac{1}{3}(d - 2m)t_w^3 + 2\,\alpha\,D^4 - 4\,U_s\,n^4 \qquad \text{(3a)}$$

and, for parallel-sided flanges—

$$K = \frac{2}{3}b\,n^3 + \frac{1}{3}(d - 2n)t_w^3 + 2\,\alpha\,D^4 - 0.42016\,n^4 \qquad \text{(3b)}$$

in which α is a factor that depends on two ratios, $\frac{t_w}{m}$ and $\frac{R}{m}$; and U is a factor depending on the $\frac{b}{n}$-ratio, with subscripts L and s to denote "large" and

[2] "Structural Beams in Torsion," by Inge Lyse and Bruce G. Johnston, *Transactions*, ASCE, Vol. 101 1936, p. 857.

[3] *Ibid.*, Eqs. 20 and 21, pp. 864–865.

"small" ends, respectively, of the flange. Symbol D is the diameter of the inscribed circle drawn tangent to the top of the flange and to the two adjacent fillets, and it may be computed or determined graphically by a large-scale layout of the beam.[3] The significance of the remaining symbols is shown in Fig. 1.

According to Saint Venant[2] and L. B. Tuckerman[4] the value of the torsional constant K for a structural steel section may be found approximately by dividing the section into three rectangular parts and taking one third of the long dimension times the cube of the short dimension for each part. By summation:

$$K = \frac{1}{3}\, d t_w^3 + \frac{2}{3}\,(b - t_w)\, t_f^3 \qquad (4)$$

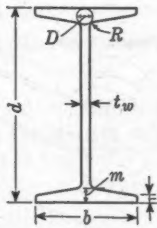

FIG. 1.—SYMBOLS

in which t_f is the mean flange thickness. Finding that Eq. 4 gave results that are too small, Mr. Tuckerman multiplied the right-hand side by a factor based on tests. In using Eq. 3*b*, Inge Lyse and Bruce G. Johnston,[2] Members, ASCE, applied corrections to take care of end effects, the stiffening effect of fillets, and the added rigidity due to the connection of the flange and web. In a like manner, Eq. 3*a* provides for the K-values of sloping-flange sections.

In an effort to arrive at simple formulas that would give practicable, approximate values for K and which would involve only those beam constants that are given in the ordinary steel handbook, the writer transformed Eq. 4 into the form,

$$K = c\, d t_w^3 + 2\, c\, (b - t_w)\, t_f^3 \qquad (5)$$

in which c is an empirical constant to be evaluated by substituting known values for the other constants in Eq. 5. Rolled steel beams were divided into three groups—(1) The square column or H-sections with parallel-sided flanges, (2) the remaining wide-flange sections, and (3) the American standard I-beams. A value for c was computed for each group, resulting in a formula for each group.

To arrive at reasonably representative values for c, beam constants for twenty-seven, well-distributed sections for each group were substituted in Eq. 5. The values substituted for K were taken from the "Bethlehem Manual of Steel Construction"[5] and were originally computed by Eqs. 3. The average value of c computed for each of the three groups resulted in the following equations:

For square column sections or H-beams with parallel-sided flanges—

$$K = 0.36\, d t_w^3 + 0.72\,(b - t_w)\, t_f^3 \qquad (6a)$$

for the other, nonsquare, wide-flanged beams, including both parallel-sided and sloping flanges—

$$K = 0.39\, d t_w^3 + 0.78\,(b - t_w)\, t_f^3 \qquad (6b)$$

[4] "Tests of I-Beams in Torsion," by L. B. Tuckerman, *Engineering News-Record*, Vol. 93, 1924, p. 882.

[5] "Bethlehem Manual of Steel Construction," Bethlehem Steel Co., Bethlehem, Pa., 1934, p. 279.

and, for American standard I-beams—

$$K = 0.43\, dt^3_w + 0.86\,(b - t_w)\, t^3_f \quad \text{. . . . .(6c)}$$

Torsional Shear Equations for Rolled Steel Sections.—For H-beams and I-beams, the following equations were suggested by Messrs. Lyse and Johnston:[6]

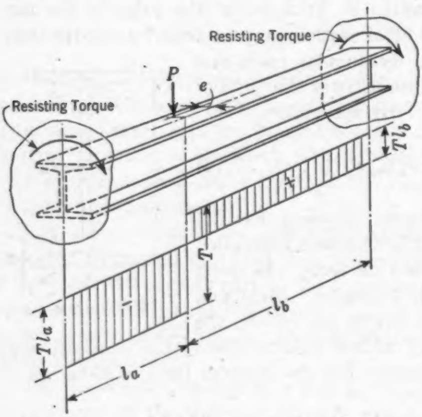

FIG. 2.—DISTRIBUTION OF TORQUE

$$s_w = \frac{T\,(t_w + 0.3\,R)}{K} \quad \text{. .(7a)}$$

and

$$s_f = \frac{T\,(n + 0.3\,R)}{K} \quad \text{. . .(7b)}$$

in which s_w and s_f are the torsional shearing stresses in the web and the flange, respectively.

Distribution of Torsion in a Beam.—A beam with a torsional load applied at some point along its length is subjected to a torsion or torque, T, which is distributed between the two ends of the beam in inverse proportion to the lengths of the two legs (see Figs. 2 and 3). This follows from the fact that the distribution of torque is pro-

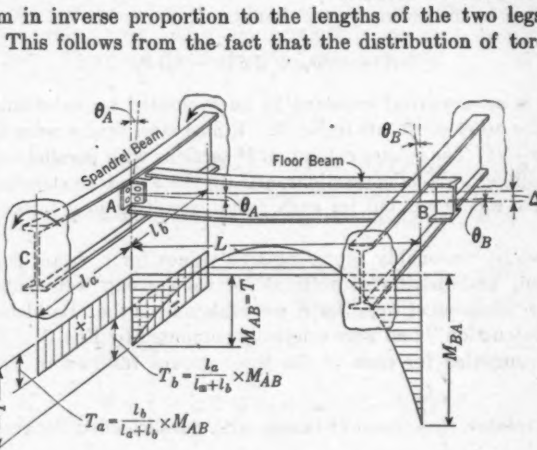

FIG. 3.—DISTRIBUTION OF MOMENT AND TORSION

portional to twisting stiffness which, in turn, is inversely proportional to length. The following equations apply and should be studied in conjunction

[6] "Structural Beams in Torsion," by Inge Lyse and Bruce G. Johnston, *Transactions*, ASCE, Vol. 101, 1936, Eqs. 27 and 28, p. 867.

with Fig. 2:

$$T = P\,e \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8a)$$

$$T_a = \frac{T\,l_b}{l_a + l_b} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8b)$$

and

$$T_b = \frac{T\,l_a}{l_a + l_b} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8c)$$

Torsion in Steel Spandrel Beams

Approach to the Problem.—In attacking the problem of torsion in spandrel beams several questions arise:

(1) How much moment can be developed at the end of a floor beam that frames into the web of a spandrel? In other words, what is the relative stiffness of the two beams, the one being in flexure and the other in torsion?

(2) How shall this moment be distributed among the two legs of the spandrel and the end of the floor beam?

(3) What assumptions shall be made as to the rigidity of end connections?

Relative Stiffness.—A beam is not nearly so stiff in torsion as it is in flexure. Therefore, since the end moment of a beam is proportional to its restraint, a relatively small moment is developed at the spandrel end of a floor beam. As shown in Fig. 3, the moment M_{AB} at the end of the floor beam must equal $T = T_a + T_b$. Also, assuming sufficient rigidity in the connection between the end of the floor beam and the spandrel web, the rotation θ_A of the end of the floor beam equals the angle of twist of the spandrel. From Eq. 3, $T_a = \frac{G\,K\,\theta_A}{l_a}$ and $T_b = \frac{G\,K\,\theta_A}{l_b}$. Therefore:

$$T = \frac{G\,K\,\theta_A\,(l_a + l_b)}{l_a\,l_b} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

The slope-deflection equation for the moment at end A of the floor beam is:

$$M_{AB} = \frac{4\,E\,I\,\theta_A}{L} + \frac{2\,E\,I\,\theta_B}{L} - \frac{6\,E\,I\,\Delta}{L^2} - (\mathrm{FEM})_{AB} \ldots\ldots (10)$$

Comparing Eqs. 9 and 10, it is evident that the same θ_A which gives rise to a torque of $\frac{G\,K\,\theta_A\,(l_a + l_b)}{l_a\,l_b}$ in the spandrel contributes $\frac{4\,E\,I\,\theta_A}{L}$ to the end moment M_{AB} of the floor beam. Hence, the relative stiffness or flexural stiffness of the floor beam becomes:

$$S_F = \frac{4\,E\,I}{L} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (11a)$$

and the torsional stiffness of the spandrel girder is:

$$S_T = \frac{G\,K}{l_a} + \frac{G\,K}{l_b} = \frac{G\,K\,(l_a + l_b)}{l_a\,l_b} \ldots\ldots\ldots\ldots (11b)$$

Moment M_{AB}.—The entire problem hinges on the moment M_{AB} at the spandrel end of the floor beam. This moment must be absorbed by the

spandrel girder; it produces the twist or torsion in the girder. Therefore, if a formula for M_{AB} can be found, the major part of the problem is solved. The following remarks are pertinent to this moment:

(*a*) The sum of the torques in the two legs of the spandrel must equal the moment M_{AB} (see Fig. 3).

(*b*) In view of the relatively low value of the torsional stiffness of the spandrel as compared to the flexural stiffness of the floor beam, the end moment M_{AB} of the latter is small and, by the same token, the ordinary standard connection between the two may be considered rigid. Any error in this assumption is on the conservative or safe side.

(*c*) The moment M_{AB} depends greatly upon the degree of restraint at the inner end or end B of the floor beam. Three different conditions of restraint will be assumed and a formula for M_{AB} given for each case.

Case I.—The inner end or end B of the floor beam is assumed to be fixed:

$$M_{AB} = \frac{S_T}{S_T + S_F} \times (\mathrm{FEM})_{\mathrm{AB}} \dots\dots\dots\dots\dots (12a)$$

Case II.—The inner end or end B of the floor beam is assumed to be free:

$$M_{AB} = \frac{2\,S_T}{S_T + S_F} \times (\mathrm{FEM})_{\mathrm{AB}} \dots\dots\dots\dots\dots (12b)$$

Case III.—The inner end or end B of the floor beam is assumed to be 50% fixed:

$$M_{AB} = \frac{3\,S_T}{2\,(S_T + S_F)} \times (\mathrm{FEM})_{\mathrm{AB}} \dots\dots\dots\dots\dots (12c)$$

In Eqs. 12, S_T represents the torsional stiffness of that part of the spandrel girder which resists the moment M_{AB}, and S_F signifies flexural stiffness and refers to the floor beam. The abbreviation $(\mathrm{FEM})_{\mathrm{AB}}$ denotes the fixed-end moment at end A of the floor beam. (See Eqs. 11 for values of S_F and S_T to be used in Eqs. 12.)

Eq. 12*a* holds for any type of loading on the floor beam so long as end B is fixed. Eqs. 12*b* and 12*c* for cases II and III, however, hold only for symmetrical loading on the floor beam AB. For unsymmetrical loading under cases II or III, moment distribution must be resorted to directly.

Distribution of Torsion.—The moment M_{AB} is divided in the form of torsion between the two legs l_a and l_b of the spandrel girder in the ratio of their stiffness factors. In other words, the torsion produced at end A in Fig. 3 by the member AB is divided between C and D in inverse proportion to their distances from end A. This is in accordance with Eqs. 8*b* and 8*c* and, in terms of M_{AB}, the following equations result:

$$T_a = \frac{l_b}{l_a + l_b} \times M_{AB} \dots\dots\dots\dots\dots\dots (13a)$$

and

$$T_b = \frac{l_a}{l_a + l_b} \times M_{AB} \dots\dots\dots\dots\dots\dots (13b)$$

in which the symbols have the significance shown in Fig. 3. The torsion is constant from end A to end C and from end A to end D, and of opposite sign on the two sides end A.

When two symmetrically placed floor beams frame into the spandrel girder both transmitting the same torsion, the distribution is as shown in Fig. 4. Each of the two equal outer legs of the spandrel carries all the torsion brought in by the floor beam and the middle leg has zero torsion.

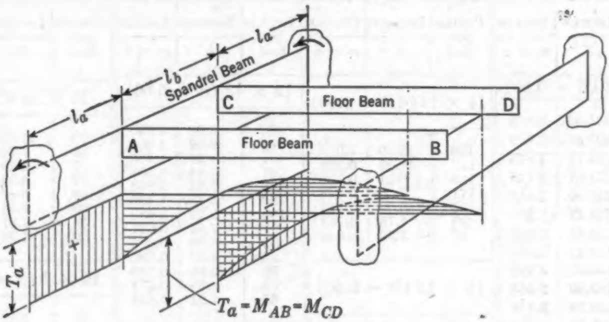

FIG. 4.—TORSION DISTRIBUTION FOR TWO SYMMETRICAL FLOOR BEAMS

Sign Convention.—A sign convention is indicated in Figs. 2, 3, and 4 which follows that of ordinary vertical shear. This convention was used to distinguish between the directions of twist on the two sides of the applied torque and to illustrate the analogy that exists between torsional and vertical shear. This sign convention applies to the spandrel beam only when the beam is treated as an isolated or separate beam. It does not apply when the spandrel is treated as a part of a space structure for the purpose of distributing moments among the end of the floor beam and the two legs of the spandrel.

Where a single floor beam frames into a spandrel, the entire length of the latter resists the moment brought in by the floor beam. Therefore, for the purpose of distributing moments in the resulting space structure, the signs of the torque on the two sides of the floor beam will be like, and will be opposite to, that at the end of the floor beam.

In the three examples below, cases I, II, and III applying Eqs. 12 are illustrated in that order. The M_{AB} for each example is first solved by the appropriate, proposed formula and then checked by the method of moment distribution (see Fig. 5, and subsequently Figs. 6 and 8). L. E. Grinter, M. ASCE, originated this scheme of applying moment distribution to space structures.[7]

ILLUSTRATIVE EXAMPLES

Example 1.—A 12-in. **WF** 106-lb spandrel girder is 10 ft long and has a 10-in. I 30-lb floor beam framing into its web 3 ft from one end. The floor beam is one of two continuous 20-ft spans rigidly connected at its ends and

[7] "Design of Reinforced Concrete in Torsion," by Paul Andersen, *Transactions*, ASCE, Vol. 103, 1938, p. 1503.

carries a uniformly applied load of 1,000 lb per ft throughout the length of both spans. Find the maximum torsional shear in the spandrel web.

This example falls under case I and, hence, Eq. 12a applies. From Table 1 values of R and K for the 12-in. **WF** 106-lb spandrel beam are found to be

0.60 and 9.23, respectively; and $G = 0.4\,E = 11{,}600{,}000$ lb per sq in. Since only the relative values of S_T and S_F are needed for Eq. 12a, 29 will be used for E and 11.6 for G in Eqs. 11. The torsional stiffness factors for the two legs of the spandrel are, $S_{T3} = 1/3 \times 11.6 \times 9.23 = 35.7$ and $S_{T7} = 1/7 \times 11.6 \times 9.23 = 15.3$ (see Eq. 11b and Fig. 5).

Also: $S_T = 35.7 + 15.3 = 51.0$; $S_F = \dfrac{4 \times 29 \times 133.5}{20} = 773.0$; (FEM) $= 1/12 \times 1{,}030 \times 20^2 = 34{,}333$ ft-lb; $M_{AB} = \dfrac{51}{51 + 773} \times 34{,}333 = 2{,}126$ ft-lb; $T_3 = 7/10 \times 2{,}126 \times 12 = 17{,}860$ in-lb; $T_7 = 3/10 \times 2{,}126 \times 12 = 7{,}650$ in-lb; and $s_w = \dfrac{17{,}860\,(0.62 + 0.3 \times 0.6)}{9.23} = 1{,}548$ lb per sq in. The values of M_{AB}, T_3, and T_7 are found by moment distribution in Fig. 5.

Example 2.—A 16-in. WF 64-lb spandrel girder, 21 ft long, has a 12-in. WF 36-lb floor beam framing into its web at each of the third points. The floor beams are 20 ft long, are freely supported at their inner ends, and each carries an applied load of 1,750 lb per ft. It is required to review the spandrel girder for maximum torsional shear in the web.

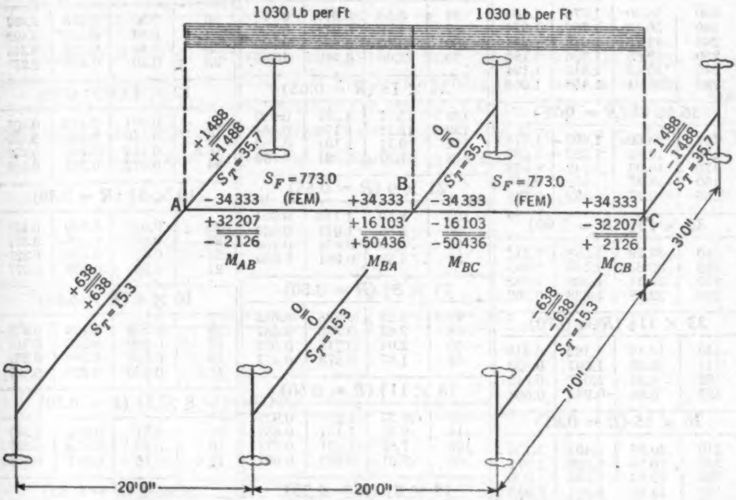

FIG. 5.—SOLUTION OF EXAMPLE 1 BY MOMENT DISTRIBUTION

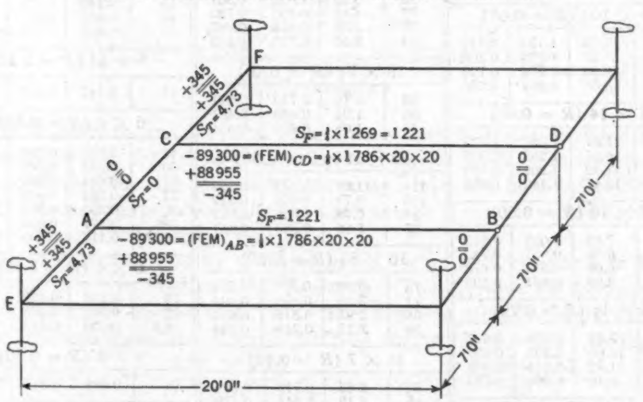

FIG. 6.—SOLUTION OF EXAMPLE 2 BY MOMENT DISTRIBUTION

As previously mentioned, only the torsional stiffness of one outer leg of the spandrel is opposed to the moment at the end of each floor beam in such a symmetrical arrangement of beams. This must be kept in mind when applying Eqs. 11*b* and 12*b*. For the 16-in. WF 64-lb spandrel (see Table 2), *R*, *K*, and t_w are 0.50, 2.85, and 0.443, respectively[5] (see Fig. 6).

[a] $R = 0.25$ for the 6×6 at 18-lb and the 6×6 at 15.5-lb beams.

The remaining solution then is: $S_F = \dfrac{4 \times 29 \times 280.8}{20} = 1{,}629$; $S_T = \dfrac{11.6 \times 2.85}{7} = 4.73$; $(\text{FEM}) = 1/12 \times 1{,}786 \times 20^2 = 59{,}533$ ft-lb; $M_{AB} = M_{CD} = \dfrac{2 \times 4.73}{4.73 + 1{,}629} \times 59{,}533 = 345$ ft-lb; $T_{EA} = T_{CF} = 345 \times 12 = 4{,}140$ in-lb; and $s_w = \dfrac{4{,}140\ (0.443 + 0.3 \times 0.50)}{2.85} = 861$ lb per sq in.

Example 3.—Fig. 7 represents a typical floor plan of a multi-story, steel-framed, light factory building. It has a story height of 10 ft and 8-in. brick curtain walls. All steel connections are assumed to be rigid. The floor consists of a 4-in., reinforced-concrete slab supporting a live load of 125 lb per sq ft. All beams and girders are fireproofed in concrete.

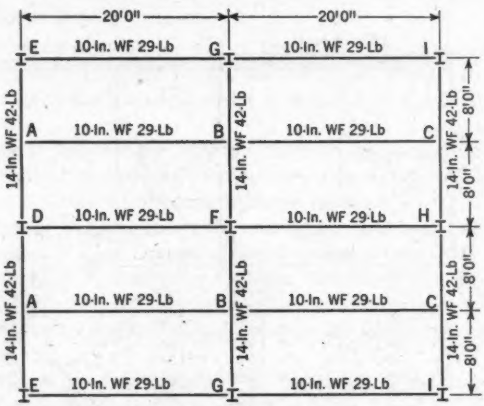

FIG. 7.—EXAMPLE 3

It is required to find the total maximum web shear in the spandrel girder DE (14-in. WF 42 lb) due to both direct and torsion loads. To insure maximum conditions the live load is to be omitted from the floor beam BC (see Fig. 8). It is required, also, to find the percentage of error involved in assuming this example to fall under case III.

The dead load carried by the floor beam, including fireproofing, is 520 lb per ft and the live load is 1,000 lb per ft. The K-value for the spandrel is 1.16 (see Table 2) and G is 11.6. The torsional stiffness factor for each end of the spandrel, the flexural stiffness factor for the floor beam, etc., are as follows: $S_T = \dfrac{11.6 \times 1.16}{8} = 1.68$; $S_F = \dfrac{4 \times 29 \times 157.3}{20} = 912.34$; $(\text{FEM})_{AB} = 1/12 \times 1{,}520 \times 20^2 = 50{,}667$ ft-lb; and $(\text{FEM})_{BC} = 1/12 \times 520 \times 20^2 = 17{,}333$ ft-lb.

From Fig. 8, M_{AB} is 246 ft-lb; the torque in the spandrel DE is 123 ft-lb on either side of the floor beam; and $s_w = \dfrac{123 \times 12\ (0.338 + 0.3 \times 0.4)}{1.16} = 583$ lb per sq in.

In computing the vertical shearing stress v in the web, the total shear V will be assumed evenly distributed over the web, the depth of the web being taken as the beam depth minus twice the mean flange thickness. That is,

$$v = \frac{V}{t_w\,(d - 2\,t_f)} \qquad (14)$$

It can be demonstrated that Eq. 14 gives values for the average rolled steel beam that are much closer to the maximum v given by the laborious ratio $\frac{V\,Q}{I\,b}$ than do the usual approximate formulas.

Treating the floor beam AB as a free body and taking the end moments -246 ft-lb at A and $+50{,}998$ ft-lb at B (Fig. 8) into consideration, the maxi-

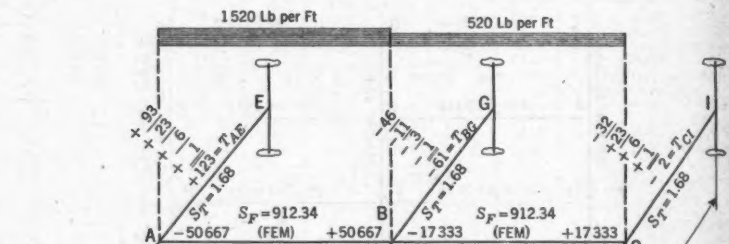

Fig. 8.—Solution of Example 3 by Moment Distribution

mum reaction that can be developed at A from the loaded floor beam AB is found to be 12,660 lb. The brick curtain wall weighs approximately 80 lb per sq ft of wall and the spandrel girder itself, including fireproofing, about 210 lb per ft; thus: $v = \frac{12{,}660 + 10 \times 16 \times 80 + 16 \times 210}{2 \times 0.338\,(14.24 - 2 \times 0.573)} = 3{,}257$ lb per sq in. The total shearing stress $= 3{,}257 + 583 = 3{,}840$ lb per sq in.

Short Method of Solving Example 3.—The assumption is made that loading one bay only with the live load will result in sufficient rotation of support B to give approximately 50% rigidity at that point and that, therefore, the example falls under case III. Then, $M_{AB} = \frac{3\,(1.68 + 1.68) \times 50{,}667}{2\,(1.68 + 1.68 + 912.34)} = 279$ ft-lb.

The percentage of error in M_{AB} is $\frac{279 - 246}{246} \times 100$, which is 13.4% on the conservative side. The shear is $s'_v = \frac{279}{246} \times 583 = 661$ lb per sq in.; and the percentage of error in total shear is $\frac{661 - 583}{3,840} \times 100$, which is 2.03% on the conservative side. The percentage of error involved in neglecting the torsional shear is $\frac{583 \times 100}{3,840}$, which is 15.2% on the side of weakness.

Derivation of Equations for M_{AB}.—Eqs. 12*a* and 12*b* follow directly as a result of distributing the fixed-end moment of the floor beam among the end of the floor beam and the two adjacent legs of the spandrel girder. Their derivation would involve the basic principles of moment distribution. They are based on the following premises:

(1) The moment M_{AB} at the end of the floor beam is resisted entirely by the spandrel girder. In other words, the combined torsional stiffness of the two adjacent legs of the spandrel girder is opposed to the flexural stiffness of the floor beam.

(2) In order to balance the joint by the laws of moment distribution, the fixed-end moment at the end of the floor beam is distributed between it and the spandrel in the ratio of opposing stiffness factors.

(3) The sum of the torques in the two adjacent legs of the spandrel must equal the moment M_{AB} at the end of the floor beam.

(4) It can be demonstrated by moment distribution that, if the inner or end B of the floor beam, AB, is released, the resulting moment at the spandrel end is virtually twice what it would be with the inner end fixed; hence the factor 2 in Eq. 12*b*.

(5) Case III assumes 50% rigidity at the end B of the floor beam. Since this is the average of conditions assumed in cases I and II, the factor 3/2 is used in Eq. 12*c*.

Concluding Remarks

It is not good engineering practice to neglect any computable stress. Torsional shear derived from the foregoing cause may be as little as 15% of the total shear as shown in Example 3. Where the floor beam frames into the spandrel near the column, however, the shear from torsion is much more important (see Example 1). Again, it is conceivable that an intermediate stair landing might be suspended from a spandrel girder by means of hanger rods so connected as to produce torsion in the spandrel additive to that brought in by the floor beams. To neglect the torsional shear from the latter in such a case could result in an overstress.

Although this paper primarily concerns torsion in a spandrel girder, it provides, at the same time, a method for determining the moment M_{AB} at the end of the beam framing into the spandrel. It is obvious, therefore, that a method is indicated for taking the "guess" out of the end moment and the required top steel of an outside reinforced-concrete building slab (or beam) poured monolithically with its supporting spandrel girder.

Direct stress from secondary moment due to torsion was not considered. It may be found just as readily as the torsional shear by substituting the torque found by Eqs. 12 and 13, inclusive, in the appropriate equations, not included in this paper. Equations for direct stress from torsion are based on the assumption that the ends of the twisted beam are boxed in and welded to the end supports in such a manner as to prevent warping of the end sections, as well as relative movement of the two flanges at the ends. This type of connection is not used in ordinary building construction at the present time.

Other methods than moment distribution might have been used in this demonstration. The method of slope deflections, for example, would be quite adaptable. Another point about which discussion might arise is that of rigidity or extent of elasticity of beam to girder connections. The question as to whether the ordinary standard end connection is sufficiently rigid to absorb the amount of end moment involved is a legitimate one for discussion.

Some of the beam constants used in torsion equations are not given in the ordinary steel handbook. The important ones are the torsional constant K and the fillet radius R. Eqs. 6 give reasonably close values for K and may be used where tables of K-values are not available. Results that are sufficiently close for most purposes will be obtained if the following approximate values for R are used:

Depth d (in.)	Fillet radius R (in.)
20 or more	0.7
10 to 20	0.5
10 or less	0.3

APPENDIX. NOTATION

The following letter symbols, used in this paper, conform essentially to American Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials (ASA—Z10a—1932) prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932:

b = width of section;

c = an empirical constant evaluated by substituting known values for other constants in Eq. 5;

D = diameter of a circle inscribed in a beam section (see Fig. 1);

d = depth of a section;

E = Young's modulus of elasticity;

e = eccentric distance;

(FEM) = "fixed-end moment";

G = modulus of elasticity in shear;

I = rectangular moment of inertia;

J = polar moment of inertia;

K = a torsional constant; the measure of the torsional rigidity and twisting deflections of a beam;
L = length of shaft or beam;
l = lengths along a spandrel beam; l_a and l_b are distances from a load point to either end of the beam;
M = moment; (FEM) = "fixed-end moment";
m = the greater flange thickness t_f;
n = the lesser flange thickness t_f;
P = a concentrated load;
Q = area under the moment diagram;
R = radius of fillet;
r = radius of a shaft or cylindrical beam;
S = stiffness, subscripts f and t denoting "flexural" and "torsional," respectively;
s = torsional unit shearing stress at the surface of a shaft or cylindrical beam, subscripts w and f denoting "in the web" and "in the flange," respectively;
T = torsional moment or torque;
t = thickness, subscripts w and f denoting "web" and "flange," respectively;
U = a factor depending on the $\frac{b}{n}$-ratio, subscripts L and s denoting "large end of flange" and "small end of flange," respectively;
V = total vertical shear;
v = vertical unit shear stress;
α = a factor that depends on the ratios $\frac{t_w}{m}$ and $\frac{R}{m}$;
Δ = linear displacement; and
θ = total angle of twist, with appropriate subscripts to indicate the point of application.

DISCUSSION

JOHN E. GOLDBERG,[8] ASSOC. M. ASCE.—By coincidence, the writer has been working on a paper covering the same problem as that presented by Professor Lothers, and the incidental study of the problem has disclosed several circumstances worthy of mention.

Professor Lothers has stated that the flange bending stresses due to the torsional moment (stresses which, under "Concluding Remarks," he designates as "direct stress from secondary moment") may be neglected on the ground that warping of the spandrel cross sections is not prevented. On the basis of this statement, only the torsional shearing stresses are considered by the author. In the opinion of the writer, the assumption of lack of warping restraint is erroneous, and is without practical and physical foundation. It is difficult to find a spandrel in which considerable restraint against warping does not exist. Consequently, an analysis which overlooks the effects of warping is likely to be very much in error, particularly when the torsion is applied a short distance from the end of the spandrel.

An excellent illustration is found in Example 3 of the paper. Assuming (as did Professor Lothers) that each spandrel may be analyzed independently of its supports, then the midpoint of each spandrel defines not only the location of the applied torsion but also a plane of symmetry. Clearly, this implies perfect restraint against warping at this location. Consequently, the flexural rigidity of the flanges must be considered. If this is done by the method used by the writer, it is found that the true torsional strength of the beam is approximately 2.22 times the value used by Professor Lothers.

The short method developed by the author can be used to obtain the approximate value of the torsional moments and thus to determine the approximate magnitude of the ultimate discrepancy. For the spandrels, Example 3:

$$K' = 1.16\ (2.22) = 2.57$$

$$S_T = \frac{11.6 \times 2.57}{8} = 3.73$$

$$M_{AB} = \frac{3(3.73 + 3.73)\ (50{,}667)}{2(3.73 + 3.73 + 912.34)} = 617 \text{ ft-lb.}$$

By the same short-cut method, but neglecting bending stiffness of the flanges, Professor Lothers obtained 279 ft-lb. Since it must be admitted that warping is prevented at the plane of symmetry (that is, the midlength of the spandrel), it follows that this procedure leads to an error of 338 ft-lb in the value of the end moment of the floor beam. The entire torsional moment induced in the spandrel beam must be resisted, at or near the ends of the spandrel beam, by torsional shearing stresses the maximum values of which

[8] Structures Engr., Consolidated Vultee Aircraft Corp., San Diego, Calif.

may be determined by Eqs. 7*a* and 7*b*, using the value of K taken from Table 1 or Table 2. As the analysis progresses from the end of the spandrel to the point of application of the torsional moment, a continuously smaller portion of the moment is carried by torsional shear stresses and an increased portion is carried by flange bending. At the midlength (the point of application of the torsional moment) practically the entire added moment of 169 ft-lb $\left(= \frac{338}{2}\right)$ is carried by flange bending and the distribution and magnitude of torsional shearing stresses are substantially as calculated by Professor Lothers.

The torsional moments increase as the length of the spandrel decreases. It may be noted that decreasing the spandrel of Example 3 from $L = 16$ ft to $L = 6$ ft (approximately) increases the torsional stiffness not to $16/6 = 2.67$ times its former value, but to 3.66 times that value.

The rotations at the ends of the spandrels are not necessarily zero and, therefore, have a great effect on the torsional moments distributed to the spandrel. A complete analysis should consider this effect which may be sufficiently great to reverse the torsional moment.

I. Oesterblom,[9] M. ASCE.—Many years ago it was known that the torsional effect on spandrel beams was severe; but designers were still thinking in terms of free static forces, and the procedure for computing these effects was very much a mystery. Slowly the idea that the strains in a structure were energy problems captured the consciousness of the engineers and they began to see ways out of many mystery problems—including the behavior of spandrels. It was a slow development, because most structures were highly indeterminate; and, even though one could write—if need be—any number of equations, it was only for simple cases that one was able to solve the system.

The spandrels are only a minor part of this difficulty; but—minor or major—the difficulty still exists, and the correct solution is well-nigh impossible if the designer is limited to classical theory and methods only.

Early in the writer's professional career he made attempts to find a solution of the torsion problem in concrete frames. He had to be satisfied with approximations. Nothing else at that time seemed feasible. Later, the subject was considered for steel spandrel beams by one of the large steel producers. Here also there was approximation in that one of the elements in the torque—namely, the eccentricity—was assumed. Although the scope was thus limited in both the foregoing attempts, and the methods were primitive, yet they were steps forward. There was a recognition not only that there was a problem, but that the problem was important. In fact it was discovered that torsional shears were heavy and often dangerous. It was important that they should be provided for.

Now Professor Lothers is urging—in fine style and with good practical sense—another step forward. He wants designers to evaluate the torsional effects of end restraints when secondary beams are framed into the spandrels. This is a very complicated problem if it is to be rationalized fully. Evidently, he knows this because he side-steps the difficulty by introducing an assumption.

[9] Engr., Carbide and Carbon Chemicals Corp., South Charleston, W. Va.

"Three different conditions of restraint will be assumed * * *," he states under the heading, "Torsion in Steel Spandrel Beams: Relative Stiffness (c)." Unfortunately, no one of the three (Eqs. 12) is likely to fit a specific problem very closely. In other words, it is again an approximation and not a rational solution. Although this is conceded it is not stated in a critical sense. The method is good; and with good judgment added in the selection of the proper case, the designer will be much closer to a safe and economic design than he would by the older method of judicious guessing—followed by a prayer that Providence would be kind in the matter of strain and stress.

With this grateful acceptance of the help that is offered in the paper, the structural engineer may yet be allowed to ask: Is that the best that can be done today? Does the profession have no means to fill the "wide open spaces" between the three cases offered?

In fact, such means are available; the problem of spandrels is merely a part of the larger problem of the space frame which can now be solved—if the designer can keep in good order the great mass of basic material from which he must start and the progressive steps in the process of relaxation that follow. So far, the torsional moments and reactions, and their behavior in an elastic framework, have been woefully neglected by authoritative writers of texts and technical papers. Can it be that these writers are still suffering from the confusion that attends the efforts of a novice to keep signs and computations in order during the process?

Surely that should not apply to experienced pundits of engineering science. This paper, therefore, is a challenge to the younger pundits to whet their imaginations, and take the next step forward courageously and in full stride. The ground ahead is neither soft nor hard; it is just fair to the one that has the wits and the will.

ROBERT V. HAUER,[10] ESQ.—The method of computing torsional stresses in spandrels, as described by the author, is sufficiently accurate, if applied to a concrete construction with the necessary modifications; but it is not satisfactory in the case of steel beams.

Even if the spandrel is assumed to be connected to the columns in such a way that the end cross sections are free to warp, there must be one section in the central part of the spandrel which remains plane and which is therefore the origin of a certain stress irregularity. In steel beams this causes a considerable increase of the torsional stiffness, changes the distribution of the shear stresses, and gives rise to normal stresses in the middle of the girder. The latter are of much more interest than the shear stresses, because they are additional to the bending stresses that generally govern the design of the spandrel.

Checking Example 3, by the use of the approximate method[11] of S. Timoshenko, shows that the torsional stiffness of the spandrel is 2.11 times as great as that computed by the author and that the additional normal stresses in the flanges amount to 2,780 lb per sq in.—a quantity which can hardly be considered negligible. The shear stress in the web due to torsion alone is found to be 43% higher than the value given by the author.

[10] Structural Engr., Albert Kahn, Inc., Detroit, Mich.
[11] *Zeitschrift Mathematik Physik*, Vol. 58, 1910, p. 361.

In principle, the behavior of a rectangular spandrel as used in concrete is the same. However, the difference is that, in a rectangular beam, a stress irregularity in a certain section practically disappears within a very short distance from this section and therefore does not materially affect the member as a whole, whereas an I-beam, because of its particular shape, emphasizes such irregularities. In the quarter points of the spandrel investigated in Example 3—that is, at a distance from the center equal to about three and one-half times the depth of the beam—the additional normal stress in the flanges due to torsion is still 35% of its maximum value. It might be stated that an I-beam is somewhat reluctant to follow the well-known principle of de Saint-Venant.

Since the torsional stiffness of any part of an I-spandrel depends on the degree of restraint against warping of its end sections, this stiffness cannot generally be determined in advance, but is governed by the final distribution of the torsional moments in the entire spandrel. Therefore, both the method of moment distribution and the slope-deflection method fail in problems like those discussed by the author, except in the cases where only one floor beam or two symmetrical floor beams frame into the spandrel. In all other cases only the classical method of redundant moments offers a solution.

E. I. Fiesenheiser,[12] Assoc. M. ASCE.—The profession is indebted to Professor Lothers for presenting a method of analysis for torsional stresses in steel spandrel girders and particularly for Tables 1 and 2, which give torsion constants for use in design.

The analysis of steel frameworks for torsional stresses is a refinement not often used in steel building design, partly because shear stresses do not usually govern in the selection of floor beams. Ordinarily, attention is directed mainly to analysis for moment. Moreover, it is the writer's opinion that torsional analysis is not justified unless another factor of equal importance is also considered.

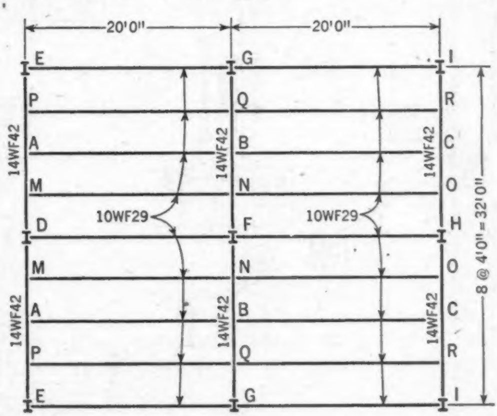

Fig. 9

The manner in which the ends of filler beams are connected to their supporting girders in actual practice is fully as important if greater refinement in design is to be used. Standard, riveted connection angles will probably be adequate to transmit the torque of a spandrel girder to its supporting column;

[12] Associate Prof. of Civ. Eng., Illinois Inst. of Tech., Chicago, Ill.

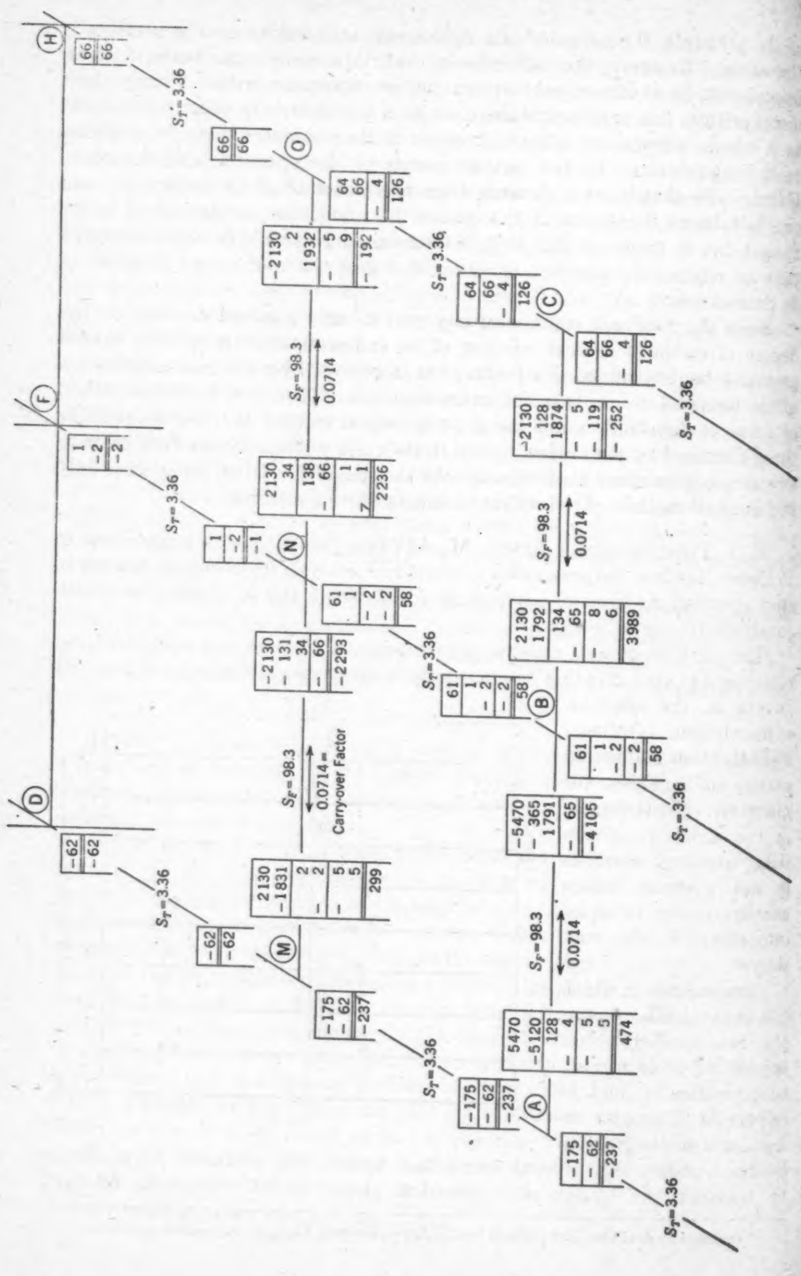

FIG. 10

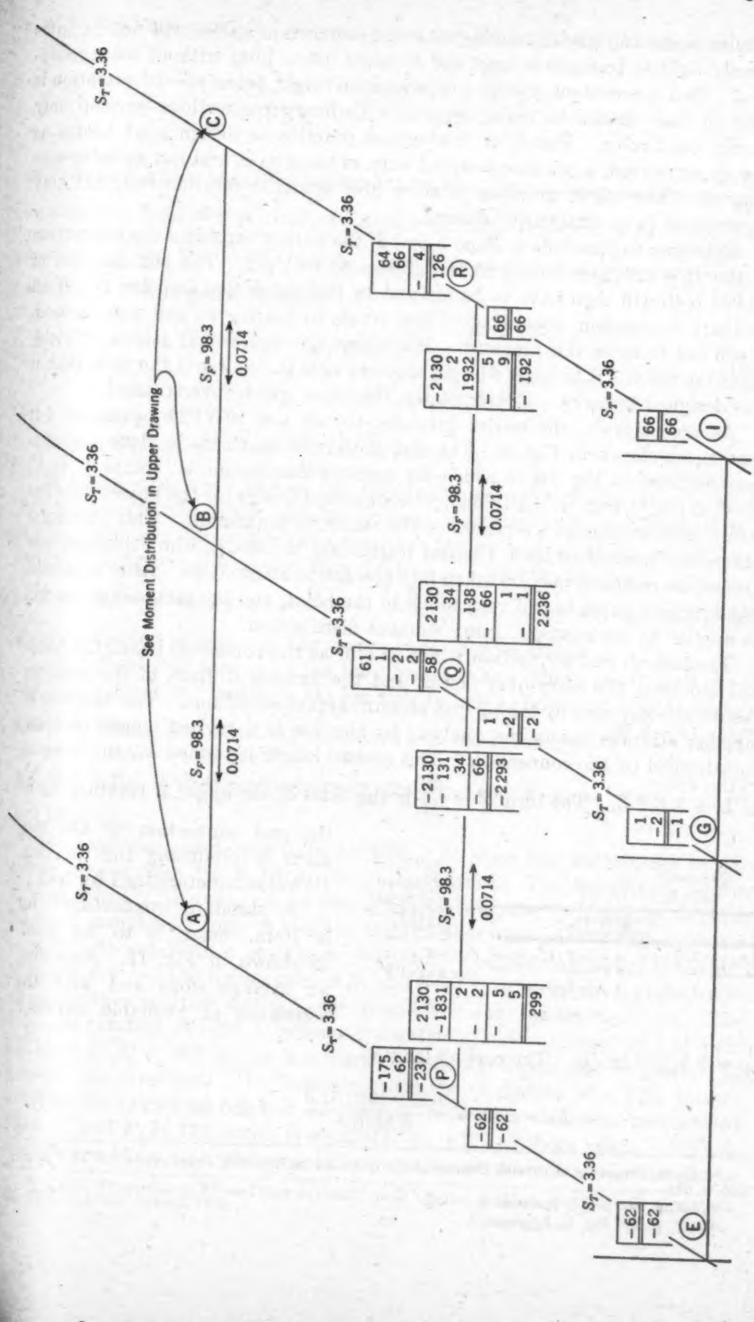

FIG. 10.—(*Continued*)

but, in beam and girder framing, the end connection angles will not be sufficiently rigid to transmit a large end moment into a joint without some reduction. End connections should not be assumed rigid unless special attention is paid to their design to make them so. Ordinary connections develop only partial continuity. Hence, it is common practice to design steel beams as simply supported, a practice justified only as being safe, and not as being economical. The writer proposes to show how actual connection restraint may be included in an analysis, if desired.

Referring to Example 3, Figs. 7 and 8, the author considers the connection of the 10WF29 filler beams to the girders to be rigid. The end moment of 50,998 ft-lb will then have to be resisted by the connection at point B. If an ordinary connection, consisting of four rivets in bearing on the web, is used, it will fail to resist this moment. The connection angles will deform or yield, requiring beam AB to resist a larger moment near the center of the span than it was designed to carry. Consequently, the beam will be overstressed.

As an example, the writer proposes to use the 10WF29 beams at 4-ft centers, as shown in Fig. 9. The distribution of moments in three cycles is demonstrated in Fig. 10, in which the order of distribution is: Joints A, B, C, M, P, N, Q, O, and R. Although an economical design for the beams does not result, neither does an overstress of the standard connection. This particular connection was tested by J. Charles Rathbun,[13] M. ASCE, who explained how connection restraint may be taken into account in an analysis. After a decade, this excellent paper is still very much to the point, and the methods given will be applied to the example, using moment distribution.

Because an end connection is not as stiff as the connected beam, the fixed-end moment, the carry-over factor, and the flexural stiffness of the member should be computed by taking into account actual conditions. The decrease in member stiffness enters the analysis by the use of a revised length of span, transformed by the connection. This revised length is termed L_2, and is equal to $L + 3\,E\,I\,Z$. The term $Z = \frac{\theta_M}{M}$ is the ratio of the angle of rotation θ_M of the end connection to the moment M producing the rotation. Its value is determined by test.

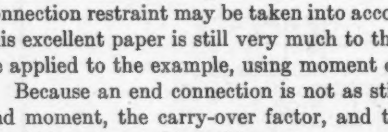

FIG. 11

A standard connection[14] for a 10-in. beam is to be used, as shown in Fig. 11. Assuming an average slope and with the assistance of available curves,[15] $\frac{1}{Z} = 9.5(10)^6$ in.-lb. The revised length,

$$L_2 = 240 + \frac{3(29)(10)^6 157.3}{9.5(10)^6} = 1{,}680 \text{ in.}$$

[13] "Elastic Properties of Riveted Connections," by J. Charles Rathbun, *Transactions*, ASCE, Vol. 101, 1936, p. 524.

[14] *Ibid.*, p. 527, Fig. 1, Specimen 2.

[15] *Ibid.*, p. 538, Fig. 13, Specimen 2.

The fixed-end moment for symmetrical loading is given by the expression:

$$(\text{FEM}) = \frac{6\,Q}{L}\,\frac{2\,L_2\,\frac{L}{2} - L\,\frac{L}{2}}{4\,(L_2)^2 - L^2} \qquad (15)$$

in which Q, the area under the moment curve for a simple beam, is equal to $\frac{w\,L^3}{12}$ for a uniform load of w per unit of length. Substitution yields a fixed-end moment of $\frac{w\,L^2}{60}$ for the 10WF beams. The carry-over factor $\frac{L}{2\,L_2} = \frac{240}{2 \times 1{,}680} = 0.0714$. The flexural stiffness—

$$S_F = \frac{3\,E\,I}{L_2 - \frac{L^2}{4\,L_2}} \qquad (16)$$

—yields $0.431\,\frac{E\,I}{L} = \frac{0.431 \times 29 \times 157.3}{20} = 98.3$.

In applying moment and torque distribution for space frame structures to to this example, the writer uses the process described by L. E. Grinter,[16] M. ASCE. The sign convention for moment or torque assumes that a moment or torque tending to produce clockwise rotation of a joint is positive.

The stiffness factor $S_T = \frac{G\,K}{L} = \frac{11.6 \times 1.16}{4.00} = 3.36$ for the 14WF 42 girders subjected to torque. The carry-over factor for torque is -1.0.

The revised load carried by the filler beams is now 320 lb per ft dead load, and 500 lb per ft live load. In the example to follow, beam AB only is loaded with live load. For this beam the fixed-end moments are $\frac{(320 + 500)(20)^2}{60} = 5{,}470$ ft-lb. For the other beams the fixed-end moments are $\frac{320\,(20)^2}{60} = 2{,}130$ ft-lb.

The numerical work was done by slide rule since any refinements in accuracy greater than 1% or 2% are of no significance. The distribution begins at joint A in Fig. 10 and proceeds through three complete cycles. The original fixed-end moment at joint A is 5,470 ft-lb. When this joint is released, it is permitted to rotate in a clockwise direction. The accompanying balancing moments are $-5{,}120$ for member AB, and -175 for members AM and AP, which are in proportion to the S_F-factor and S_T-factor for the members. The clockwise rotation at joint A induces a counterclockwise moment at end B of $0.0714 \times 5{,}120 = 365$, which is written in with the minus sign at joint B to indicate the direction. The balancing moment or torque of -175, accompanying the clockwise rotation at joint A, induces a clockwise moment at joints M and P, of 175, which is written in as $+175$ at these joints. A single straight line is drawn under each balancing moment to indicate completion of

[16] "Elastic Properties of Riveted Connections," by J. Charles Rathbun, *Transactions*, ASCE, Vol. 101, 1936, Vol. 103, 1938, p. 1512.

distribution. After all moment and torque have been balanced, a double line is drawn before adding the columns at the various joints.

The maximum end moment to be carried by any connection is 4,121 ft-lb at end B of member AB, which is not too high for the ordinary connection to withstand.

The method of moment distribution applied to the analysis of space frames is more tedious, although scarcely more complicated, than is moment distribution applied to planar structures. Its use is justified in the investigation of torsional shearing stresses and in the study of connections.

EDWARD V. GANT,[17] Assoc. M. ASCE.—As the author has stated, one of the problems that arises in investigating the torsion of steel spandrel girders is the assumption regarding the rigidity of the connection between the floor beam and the spandrel girder. There is not much experimental information on this point available; but, according to recommendations made by the Steel Structures Research Committee of Great Britain,[18] no allowance should be made for a restraining moment at the end of a beam which frames into the web of a girder unless there is a similar beam framing into the girder on the opposite side at the same point. Thus, with ordinary steel construction there would seem to be little moment developed at the spandrel end of a floor beam, and consequently torsion in the spandrel girder from this source could be neglected. However, where welded connections are used, or where special provision is made for a restraining moment at the spandrel end of a floor beam, some moment may be developed; and an investigation of the resulting torsion in the spandrel girder would be desirable. In any case, a definite answer to the question of the rigidity of the connection between the spandrel girder and the floor beam would seem to await additional experimental evidence.

Assuming that the connection between the spandrel girder and the floor beam is rigid enough to transmit moment, Professor Lothers has proposed simple formulas (Eqs. 12) for the moment at the spandrel end of the floor beam. It should be emphasized that these formulas do not allow fully for the facts that the spandrel girder and the floor beam are units of a structural frame and that deformation of other members may influence their deformation. For instance, the rotation of the ends of the spandrel girder is a function of column deformation and could either relieve or increase the torsion in the spandrel girder, depending on the direction of rotation.

Another factor that may influence the validity of Eqs. 12 is the relative vertical deflection of the ends of the floor beam that frames into the spandrel girder. The effect of this deflection would be to add algebraically a moment to the fixed-end moment $(FEM)_{AB}$ in Eqs. 12. From Eq. 10 and a similar equation for the moment M_{BA} at the inner end of the floor beam, the corrections would be

$$\pm \frac{6\,E\,I\,\Delta}{L^2}; \quad \pm \frac{2\,E\,I\,\Delta}{L^2}; \quad \text{and} \quad \pm \frac{3.3\,E\,I\,\Delta}{L^2} \qquad (17)$$

[18] "Final Report of the Steel Structures Research Committee," Dept. of Scientific and Industrial Research, His Majesty's Stationery Office, London, 1936, p. 552.

for Eqs. 12*a*, 12*b*, and 12*c*, respectively. In many cases the magnitude of the correction will be small. However, the possibility of a large relative deflection modifying the moments in Eqs. 12 should not be overlooked.

OSCAR HOFFMAN,[19] M. ASCE.—A better understanding of the actual behavior of structural frameworks, beyond that which is given by simple two-dimensional analysis, is contributed by this excellent paper. The methods presented are very straightforward and workable in cases similar or closely related to those illustrated by the author; but they would become somewhat impracticable and cumbersome for a larger number of floor beams, say, three or more, within a single spandrel girder span.

The writer wishes to call attention to the possibility of using finite difference equations in handling such cases. The fundamentals of the calculus of finite differences, and some interesting applications of it to structural problems can be found in a book by Theodor von Kármán and M. A. Biot[20] published in 1940.

The method of approach to the spandrel girder problem can best be illustrated by its application to a comparatively simple case—a single-span spandrel girder with fixed-end supports (which may be visualized as an interior span of a continuous girder supported by infinitely rigid columns) carrying a number of floor beams, placed at constant intervals, a. The girder span is $l = N\,a$, in which N is an integer. The floor beams are so arranged that there is one of them at the center line of each supporting column. All floor beams are assumed to be fixed at their inner ends, to have the same moment of inertia, I, and to carry the same uniform load, w, per unit length. Fig. 12(*a*) shows a view of the spandrel girder. Figs. 12(*b*), 12(*c*), and 12(*d*) show the torques, M_x, acting on the girder at each floor beam intersection; the torsional moment, T_x, along the girder; and the angle of twist, θ_x. Fig. 12 shows a complete analogy with the load diagram, shear diagram, and moment diagram of an imaginary simple beam having the span length l and being loaded with the imaginary concentrated loads, M_x. Fig. 13(*a*) represents the forces acting on a typical floor beam and Fig. 13(*b*) is the corresponding moment diagram.

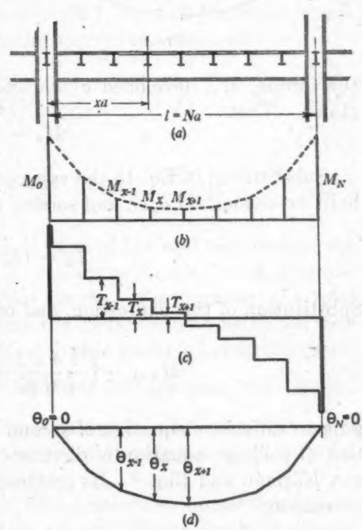

FIG. 12

[20] "Mathematical Methods in Engineering," by Theodor von Kármán and M. A. Biot, McGraw-Hill Book Co., Inc., New York and London, 1940, p. 437.

The relationship between the difference in the torsional moments between x and $x - 1$ and the change in the angle of twist between these points follows from the elastic properties of the spandrel girder, by using Professor Lothers' notations, G and K:

$$\theta_x - \theta_{x-1} = T_x \frac{a}{G K} \quad \text{.....................(18)}$$

At the same time, θ_x represents the outer end slope of the floor beam x, and M_x represents the outer end moment for the same floor beam. The relationship between those two quantities, readily obtained, for instance, from the slope-deflection equation, is:

$$\theta_x = \left(\frac{w L^2}{12} - M_x\right) \frac{L}{4 E I} \quad \text{..(19)}$$

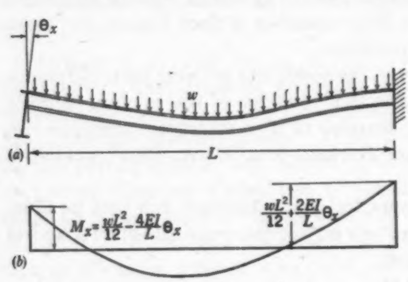

FIG. 13

A third basic relationship is that the change in torsional moment from a point to the left to another point to the right of the intersection of a floor beam with the spandrel girder is equal to the torque, M_x, developed by the rigid connection of the floor beam with the girder. Then:

$$M_x = T_x - T_{x+1} \quad \text{.......................(20)}$$

Substituting in Eq. 18 the expression for θ_x given in Eq. 19 and a similarly built expression for θ_{x-1}, and solving for T_x, one obtains:

$$T_x = (\theta_x - \theta_{x-1}) \frac{G K}{a} \quad \text{....................(21)}$$

Substitution of this expression, and of a similar one for T_{x+1}, in Eq. 20 yields:

$$M_{x-1} - \left(\frac{4 a E I}{L G K} + 2\right) M_x + M_{x+1} = 0 \quad \text{............(22)}$$

a linear difference equation of second order. The method of finding the solution of such an equation is discussed and abundantly illustrated by Messrs. von Kármán and Biot.[20] Its application to the present problem leads to the expression:

$$M_x = \frac{w L^2}{12} \frac{\beta^x + \beta^{N-x}}{\beta^N + 1} \quad \text{....................(23)}$$

in which

$$\beta = 1 + \frac{2 a E I}{L G K}\left(1 + \sqrt{1 + \frac{L G K}{a E I}}\right) \quad \text{............(24)}$$

The assertion that Eq. 23 satisfies Eq. 22 and the boundary conditions of the problem ($\theta_0 = 0$ and $\theta_N = 0$) can be verified by simple substitution.

The expression for the torsional moment between the floor beams $x - 1$ and x is to be mentioned because of a subsequent use of it:

$$T_x = \frac{w L^2}{12} \frac{\beta^{N-x+1} - \beta^x}{(\beta^N + 1)(\beta - 1)} \qquad (25)$$

Eq. 23 has some general implications. It shows that the behavior of spandrel girders depends on β, which is given by Eq. 24 as a function of the stiffness ratio $\frac{a E I}{L G K}$.

A survey of the possible range of practical limits of values for the stiffness ratio in steel structures, with the usual low torsional stiffness of the spandrel girder, shows that, in general, β can be approximated satisfactorily by the expression:

$$\beta \approx \frac{4 a E I}{L G K} \qquad (26)$$

and, as the stiffness ratio is seldom less than 15, β will be larger than 60 in most cases.

In such cases, the end moment of the floor beam 1, M_1, and the end moment of the floor beam 0, M_0, will be related by the approximate formula:

$$M_1 \approx \frac{M_0}{\beta} \qquad (27a)$$

and, similarly,

$$M_2 \approx \frac{M_1}{\beta} \approx \frac{M_0}{\beta^2} \qquad (27b)$$

In other words, M_1 drops to less than 2% of M_0 and the end moments of the floor beams with order numbers from 2 to $N - 2$ are negligible, for all practical purposes, irrespective of the number of floor beams. Furthermore, the total torque transferred by the spandrel girder into the column can be estimated with an error of less than 2%, as being equal to M_0. In the example herein discussed, $M_0 = \frac{w L^2}{12}$ results from the assumption of infinitely stiff columns, but the foregoing considerations indicate the possibility of taking into account, with a fair approximation, a finite column stiffness in conjunction with a single floor beam —the one that frames directly into the column.

An essentially different situation arises with reinforced-concrete structures because of the higher torsional stiffness of the spandrel girders and of the consequently lower values of β. For such structures, β can vary from a little more than 1 to 5; but it seldom passes the latter limit. As a consequence, the moment, M_x, decreases slowly from its maximum value, at the columns; and its magnitude is no longer negligible in the design of the floor beams, even at the center of the spandrel girder span.

The total torque, transferred to the column, which forms an intermediate support for a continuous spandrel girder, is $M_0 + 2\,T_1$, and, in the specific

example considered herein, the following expression can be found for it:

$$\frac{w\,L^2}{12}\,\frac{(\beta^N - 1)\,(\beta + 1)}{(\beta^N + 1)\,(\beta - 1)} = \frac{w\,L^2}{12}\,\nu \qquad (28)$$

In Eq. 28, the factor:

$$\nu = \frac{(\beta^N - 1)\,(\beta + 1)}{(\beta^N + 1)\,(\beta - 1)} \qquad (29)$$

is evidently the number of floor beams that develop the fixed-end moments to be transferred fully into the column. The product $\nu\,a$ can be considered as the width of the tributary strip of floor which is to be taken into account in cases of finite column stiffness, with its moment of inertia equal to $\nu\,I$.

The writer wishes to emphasize the simplifying assumptions upon which the foregoing specific example is founded, and which are primarily responsible for the reasonably simple results obtained; yet, the writer feels strongly that the method of approach illustrated herein may have some broader applications, although the mathematics involved in such applications might prove to be somewhat more formidable.

PHIL M. FERGUSON,[21] M. ASCE.—The writer has watched the development of the torsion formula for steel beams and the attempts to apply it to practical problems with a great deal of interest. A solution of this problem is needed in many situations and the trend of architectural development each year adds to the need; yet the freestanding steel beam subject to torsion is relatively a rare condition. In building construction, there is nearly always a restraint present that is not considered in the conventional treatment of the problem, for example, a concrete floor slab or a stiff wall encasement.

The author's solution of the problem is interesting and helpful. However, it should be emphasized that its field of usefulness is limited to cases in which the girder is free to rotate in accordance with the simple torsion formula (Eq. 2). This eliminates most cases in which a concrete slab frames into the girder, including all cases where the girder is encased in concrete, and probably most cases where the slab is simply poured on or around the top flange of the girder.

In ordinary design the assistance that the slab gives to the beam may be, and generally is, ignored. The slab is likewise considered as an entirely separate unit for design purposes. However, a concrete slab resting on a steel beam increases the stiffness and reduces the deflection of the beam very materially, even when not accompanied by concrete fireproofing of the beam. It would thus seem necessary, in dealing with spandrel girder torsional stresses that depend chiefly on beam deflection, to consider the probable composite action of steel beam and concrete slab. The slab modifies the beam action in several ways:

1. The stiffness of the composite beam is much greater than that of the steel beam alone;

[21] Chairman, Dept. of Civ. Eng., Univ. of Texas, Austin, Tex.

2. The increased stiffness greatly reduces the beam deflection and the end rotation that results, whether the spandrel girder is similarly reinforced or not; and

3. The neutral axis of the composite beam lies much higher—above the middepth of the steel beam.

The effect of these differences will be discussed after the action of the girder is considered.

The slab also modifies the girder action. Even when the girder is not encased, and the web and bottom flange are thus left almost entirely free from concrete restraint, the top flange is usually interlocked with the concrete. Lateral movements of the girder top flange that can result are largely determined by the movements of the concrete; these movements depend on the slab deflection and the extent to which the slab is shortened by its action as part of the compression flange of the beam.

A comparison between the author's assumed girder flange deflection and the probable deflection when a concrete slab is present will reveal the difference. The simple torsion formula assumes that the upper girder flange is displaced laterally by the end rotation of the beam it carries, and that this displacement decreases to zero at the end of the girder at essentially a linear rate. In other words, a plan view of the deflected flange is assumed to be essentially a straight line between the beam connection and the end of the girder. The concrete slab, on the other hand, shortens lengthwise, with the beam axis and perpendicular to the girder, in an amount that is dependent upon the extent to which it serves as a compression flange for the beam. Generally this flange action will correspond to nearly perfect adhesion between the concrete and the steel beam. It is not probable that this concrete shortening will decrease directly with the distance from the beam, as would be required to permit the steel girder to satisfy the simple torsion formula. Instead, it might be expected that this shortening would be nearly uniform for a considerable distance on each side of the beam. The upper girder flange must be displaced to conform to this concrete pattern, as if the beam had a very wide connection tied in to the top girder flange. The result seems to be that the top girder flange is displaced almost uniformly over a considerable length, leaving a much shorter length within which it must return to its normal position (if it does so return at the end of the girder). At the same time, the bottom flange retains greater freedom of action. The resulting torsional resistance to this type of rotation and displacement must be considerably different from that indicated by the simple torsion formula.

It would also appear that the rotation impressed by the connection of the composite beam is a twisting about an axis at the level of the composite beam axis, and this is several inches above the middepth of the beam and the girder.

The rotation of the girder over most of its length thus seems to be about an axis which varies from point to point, and which is generally not through the centroid of the cross section. The torsional stiffness will surely be increased by this shifting of the center of rotation, since it adds a lateral displacement of the girder to the rotation about an axis through the centroid. This aspect of

the problem seems to have been largely neglected in the engineering literature that has come to the writer's attention. In the related field of beams curved in plan, elaborate formulas have been developed which assume a beam to be free to twist about a centroidal axis; but no mention is made of the concrete slab which usually enforces entirely different deformations. This seems more serious than approximations for the value of K.

The effect of the concrete slab can be evaluated more definitely in its relation to the bending stiffness of the beam, which is greatly increased even when the beam is not encased. Although the exact amount of increase may be subject to some uncertainties, a 4-in. concrete slab added to Example 2 would at least double the beam stiffness. This increase in beam stiffness would result in a reduction of approximately 50% in the total rotation of the girder envisioned in this paper; and girder web shears created by torsion would seem to be reduced proportionately. However, the writer is disturbed by the feeling that the complex type of rotation described herein would have a considerable effect on the resulting torsional stiffness and torsional stresses. For this reason, he does not state that torsional shears are necessarily less serious than those Professor Lothers would find; but they may be quite different.

If the spandrel girder is encased in concrete, its torsional action would be greatly modified, and an entirely different analysis would be necessary. Especially in this case, the slab moments on a section parallel and adjacent to the girder flange (caused by the deflection of the slab relative to the girder) would seem to be of considerable importance. When strictly considered, these slab moments complicate, very materially, the moment-distribution process indicated in Fig. 6.

If there is objection to the use of a composite beam as not the usual method of steel design, a different problem is presented, but one that is still without a simple solution. If the slab does not act as a flange of the beam, it would seem to follow that it would act as a relatively rigid spacer which would tend to hold the top flange of the girder in its initial position; and any girder rotation would be rotation about the top flange, not about the centroid of the girder.

In the form presented by Professor Lothers, the solution is thus subject to considerable question when concrete floors connect to the girder. Nevertheless, there are cases in which this analysis is directly applicable, such as open steel frameworks, timber flooring on steel beams, and the like. It is a step in the larger problem that must ultimately be solved, and the author is to be commended for presenting this step so clearly.

It seems to the writer that Eq. 12*b* is not mathematically correct, although the practical difference is not important. For Case II the effective stiffness of the beam (from joint A) is $\frac{3\,S_F}{4}$ and the end moment, before joint A is allowed to rotate, is $\frac{3}{2}\,(\text{FEM})_{AB}$. Then a moment distribution would give

$$M_{AB} = \frac{S_T}{S_T + \frac{3}{4} S_F} \times \frac{3}{2}\,(\text{FEM})_{AB} = \frac{2\,S_T\,(\text{FEM})_{AB}}{\frac{4}{3} S_T + S_F} \quad \ldots\ldots\ldots (30)$$

Eq. 30 differs from Eq. 12*b* only in the first term of the denominator, and this term is often so small that its complete omission would do slight damage.

J. E. LOTHERS,[22] M. ASCE.—The able discussion of this paper has been no mean contribution to structural engineering literature and its courteous flavor has been most flattering and gratifying. The paper itself was an attempt to present a more or less simple method for computing torsional shear in steel spandrel girders. The discussion was a masterful job of providing details and embellishments, calling attention to shortcomings and exceptions, and indicating the mitigating effects of fireproofing and other factors encountered in practice. In his closing discussion the writer can do little else, aside from expressing his appreciation to these accomplished writers, than to agree with most of the hypotheses.

Professor Fiesenheiser is correct, of course, in stating that a standard riveted connection would not suffice at joint B, Figs. 7 and 8. He gives a very complete demonstration of the application of Prof. J. Charles Rathbun's method of correcting for connection restraint to torsional analysis. In his introductory remarks Professor Fiesenheiser mentions that the ratio Z of the angle of rotation θ_M of the end connection to the moment M producing it is determined by test. The constant Z may be computed and the writer hopes to have equations for that purpose published. It can be demonstrated, for example, that the small connection mentioned by Professor Fiesenheiser may be subjected to a moment of 5,780 in.-lb without exceeding the allowable bending stress of 20,000 lb per sq in. in the outstanding legs. This condition would seem to refute Professor Gant's contention that a standard riveted connection would not develop the torsion in a spandrel girder.

Eq. 17 (Professor Gant) for correcting for the effects of deflection and Eqs. 18 to 29 (Professor Hoffman), inclusive, illustrating the application of the calculus of finite differences to the torsion problem are gratefully acknowledged.

Professor Ferguson calls attention to the modifying effects of the enveloping concrete slab and fireproofing. Since a steel beam without fireproofing is rarely found in important steel construction, his discussion is very pertinent. The writer "laid himself open" when he specified concrete fireproofing in Example 3. In so doing, however, he was endeavoring to arrive at practical and readily computed loads, and the stiffening effects of the resulting composite beams and girders were neglected for the purpose of simplicity in demonstrating the proposed method of solution.

Professor Ferguson also called attention to the fact that Eq. 12*b* is not mathematically correct and stated that the practical difference is not important. Eq. 30 can be further simplified to:

$$M_{AB} = \frac{6\,S_T}{4\,S_T + 3\,S_F} \times (\text{FEM})_{AB} \ldots\ldots\ldots\ldots\ldots\ldots (31)$$

The derivation of Eq. 31 was demonstrated in the oral presentation of the paper

[22] Prof. of Architecture, School of Architecture, Oklahoma Agri. and Mech. College, Stillwater, Okla.

before the Oklahoma Section at Tulsa on April 28, 1945.[23] Undoubtedly, the derivation (indicated in Professor Ferguson's discussion) should have been included in the published version. It will be noted, however, that Eq. 12*c* was given for a condition of end fixity that was the average of the conditions covered by Eqs. 12*a* and 12*b*. To have averaged Eqs. 12 and 31 would have led to an awkward form for Eq. 12*c* that would not have been justified in view of the rather rough assumptions of end fixity for the three cases covered by Eqs. 12. As Professor Ferguson has stated, S_T is very small as compared with S_F; and, accordingly, the coefficient of S_T in the denominator of Eq. 31 may be changed from 4 to 3 without affecting slide rule computations. Eq. 12*b* results if this substitution is made.

LANDSLIDE INVESTIGATION AND CORRECTION

By Hyde Forbes,[1] M. ASCE

With Discussion by Messrs. T. W. Lambe, Jacob Feld, George S. Harman, Robert F. Legget, Rush T. Sill, Earl M. Buckingham, Alfred V. Bowhay, D. P. Barnes, and Hyde Forbes.

Synopsis

The occurrence, cause, and correction of landslides and earth movements in the San Francisco Bay region of California are described in this paper. Examples are cited of (1) a shear slide in which hydrostatic uplift on an unbalanced slope resulted in mass movement of the unconsolidated slope material; (2) a shear slide caused by the overstress of clayey material on a slope that had absorbed a water load; (3) a slide that developed along the contact between two rock formations; (4) a detrital slide caused by the seasonal saturation of soil; (5) a detrital slide resulting from a geochemical breakdown of rock cut slopes; (6) a slide of street fills founded upon soils subject to movement when saturated; (7) a detrital slide generated by earthquake shock; (8) slides started by ground-water pressure; and (9) soil creep.

The methods used for investigation, the procedure followed, the costs involved in the corrective work, and the results obtained are described in the instances where economic factors required the investigation and correction of slides. The geological and ground-water conditions that generate slides and earth movements are treated in the paper, which demonstrates that such conditions can be recognized and their effect predetermined. Plans for engineering construction in such locations can include the corrections.

Introduction

A localized, surficial movement of earth severe enough to destroy the structure of the soil, earth, or rock mass involved, and any structure in its path commonly compose a landslide. Landslides differ in intensity and characteristics because of variance in the natural conditions through which they are generated.

Ordinarily, the geologic structure and mineralogical characteristics of the

Note.—Published in February, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Cons. Engr. and Geologist, San Francisco, Calif.

rock or soil formations affected by a landslide will contain a clew as to the cause of movement and the corrective measures to be adopted. The bedding planes within one formation and contact planes between two formations or types of material are frequently the planes of slippage. In geology the term "plane" is used to denote "surface of separation," and the sliding surface, although it is seldom a geometric plane, is commonly called the "slip plane." Under the influence of certain forces and conditions slip planes are developed, and the material above the slip plane moves from one position of stability or condition of equilibrium to a new position and condition of equilibrium.

When a rock mass is fractured, as through earthquake fault movement, or when it disintegrates through weathering, loose material may accumulate in sufficient unbalanced weight to produce "detrital" slides of dry material; or water may penetrate the loose material and accumulate to the extent that a sudden "shear" slide is generated.

All manner of ground-water occurrence, movement, and pressure phenomena is found involved in generating slides. The minerals present in some rock formations become readily hydrated in contact with water, producing a clayey material that deforms under load or begins to flow in a plastic state. The same is true of residual clay subsoil which retains moisture normally to within a small percentage of its lower plastic limit, and the limit is reached by contact with very little additional water or by subjecting the mass to pressure or additional loading.

Soil technology, including a study of the physical and mechanical properties of the mass, may be of value in the solution of a problem involving the stability of materials on slopes as they exist in nature and as modified by construction. However, most of the laws and experimental data in this field have been developed through the use of dry sand composed of from 95% to 99% stable silica. Sand is seldom found disassociated from silt and clay, which are largely composed of unstable hydroxides and hydrous silicates, and most generally found containing water. Furthermore, most products of rock disintegration are subject to physical change under the geochemical processes of oxidation, carbonization, and hydration. This change occurs more rapidly than is generally realized and results in the accumulation of unstable masses.

The stability of slopes, determined from experimental data and assumed values, is of obvious significance; but, in the case of sliding ground and the prevention of earth movement, in loading slopes or excavation of cuts proposed in engineering construction, the experimental determination or assumption of stability factors is not recommended as a substitute for either thorough preliminary investigation of all other determinate facts or the use of judgment based upon experience under similar conditions.

Landslides

Landslides may be classed as "shear" or "break in the ground," and "detrital" or "flow of loose earth," or "deformation of plastic material," according to the character of the material involved and the type of movement in a given case. Shear slides develop as the result of well-defined breaks through the soil

or earth along which the mass has been sheared. The surface of shear is the slip plane and a single area may have one or several such surfaces along which the material is sliding. Shear slides are frequently associated with the unbalanced slopes that remain after material has been removed from natural slopes. The shearing force may be entirely the pull of gravity—that force for the particular slope being greater than the resistance offered by the cohesion and friction within the material involved. More often, however, ground water is the principal generating factor, especially when large bodies of material are involved.

For example, when a stable mass of material, protected from water seepage by a cover of topsoil and vegetation, is disturbed by excavation or grading, rainfall will penetrate and thus increase the ground-water content. Also, a well-drained mass of material may have its natural drainage outlet obstructed by construction activities with the result that ground water backs up behind the obstruction, thus increasing the ground-water content.

The weight of the added water alone may overstress the material in such cases; the fluid may reduce cohesion and friction within the mass; the percolating water may reach bedding planes or contact planes, acting as a lubricant to generate slides; ground-water levels may rise, causing increased hydrostatic pressure with resulting uplift forces and blowouts; and absorbed moisture may create geochemical changes that weaken and swell the solid particles so that they cannot support loads.

Experience has shown that the variety of conditions under which slides are generated are numerous. No two slides are the result of conditions exactly alike; nor can any one slide be classed as typical. Once generated, shearing occurs throughout the sliding mass destroying its structure. Movement of the loosened mass along the main plane results in an upper scarp and a lower heave or bulging which is characteristic. Borings show that, as a rule, slip planes are cylindrical in shape and a segment of a circle in longitudinal dimension, but within the moving mass, as stated, there may be several such planes.

Each slide requires the determination of the conditions unique to the area before plans are formulated for correction; but methods successful in one case may generally be adapted successfully to meet the conditions encountered in other cases. For that reason it may be of value to detail the conditions and corrective measures applied in connection with several landslides in the vicinity of San Francisco, Calif.

Shear Slides

Examples of shear slides, caused by unbalanced slopes, usually with a change in moisture conditions, are afforded by experience along Monterey Boulevard; Parker Avenue at Lone Mountain; at Market and Glendale streets in San Francisco; along the State Highway, north and south of San Francisco; and in some residential districts of Oakland, Berkeley, and Crockett in the San Francisco Bay area.

Parker Avenue Slide in San Francisco.—This slide occurred in the latter part of December, 1935. The maximum movement, shown in Fig. 1(a), was

FIG. 1.—THE PARKER AVENUE SLIDE, SAN FRANCISCO, CALIF., DECEMBER 24, 1935

sudden. The noise was tremendous, the street was disrupted, and the million-dollar building of the San Francisco College for Women just above the scarp was threatened seriously. This movement produced a semicircular escarpment having a maximum height of 30 ft at the uphill boundary, with a corresponding heave of the downhill part. The downhill heave carried that section of Parker Avenue to a maximum of 20 ft above the finished grade, as shown in Fig. 1(*b*). The area affected extended about 450 ft east to west along the axis of the slide (at right angles to the street) and from 200 to 250 ft north to south.

In the preliminary investigation and exploration period of seven months, seventy-nine holes, totaling 2,855 ft, were bored. The drilling program was expanded or modified as the work progressed, to obtain an accurate picture of all subsurface conditions that may have influenced the movement. Water levels were measured in 2-in. pipes set in a gravel backfill of the boreholes at frequent intervals to determine the dynamic forces acting on the mass.

This investigation revealed that the original, somewhat stratified material was broken by internal shearing and movement—a given strata not being subject to the same amount of displacement from point to point, but the mass moving along a well-defined sliding plane. Movement continued throughout the period of investigation so that the main slip plane was located definitely. Ground-water levels indicated three different water horizons, each affected by its own drainage characteristics. Consequently, no single cross section could be drawn, and the position of the strata and water levels were studied by plotting contours of equal elevation from time to time. The approximate contour of the area before and after the slide is shown in Fig. 2(*b*).

The landslide was produced by a combination of causes, both natural and artificial. The natural causes were: The mineralogical and physical character of the serpentine bedrock of the region; the topographic development of that bedrock under the attack of ground water; the character, weight, and water content of the sand overburden; the position of the clay and other relatively impervious material, developed in the overlying mantle of unconsolidated material; and the effect of rainfall and other accretions to ground water upon the whole.

The artificial causes can be defined best by giving the sequence of engineering events affecting the area. During 1919 the right of way for Parker Avenue was excavated to grade through the base of the west slope of Lone Mountain. No movement had been recorded for fifteen years. Tile drains were placed along the right of way and the street pavement was completed that year. During 1931 the top of Lone Mountain was graded for the site of the San Francisco College for Women, and the excavated material was spread over the upper slope. In January, 1933, the construction of the college building was completed, and the grounds were landscaped, with provision for watering the lawn by a sprinkling system. Apparently, this construction work on the hilltop and upper slope did not overstress the supporting material or disturb its condition of stability, since no movement was noted in the succeeding three years. The accumulative effect of water applied by the sprinkler system may have been a contributing factor as it seeped through the surface and found its way underground.

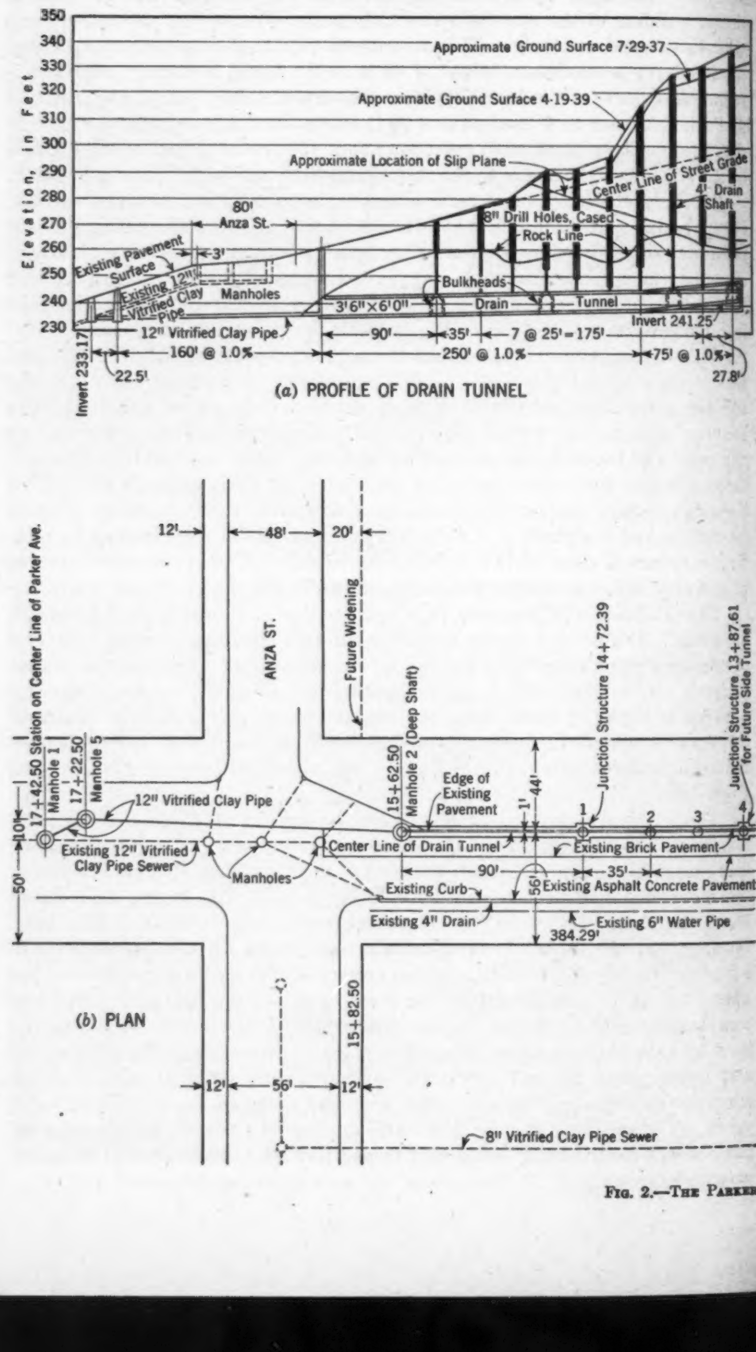

FIG. 2.—THE PARKER

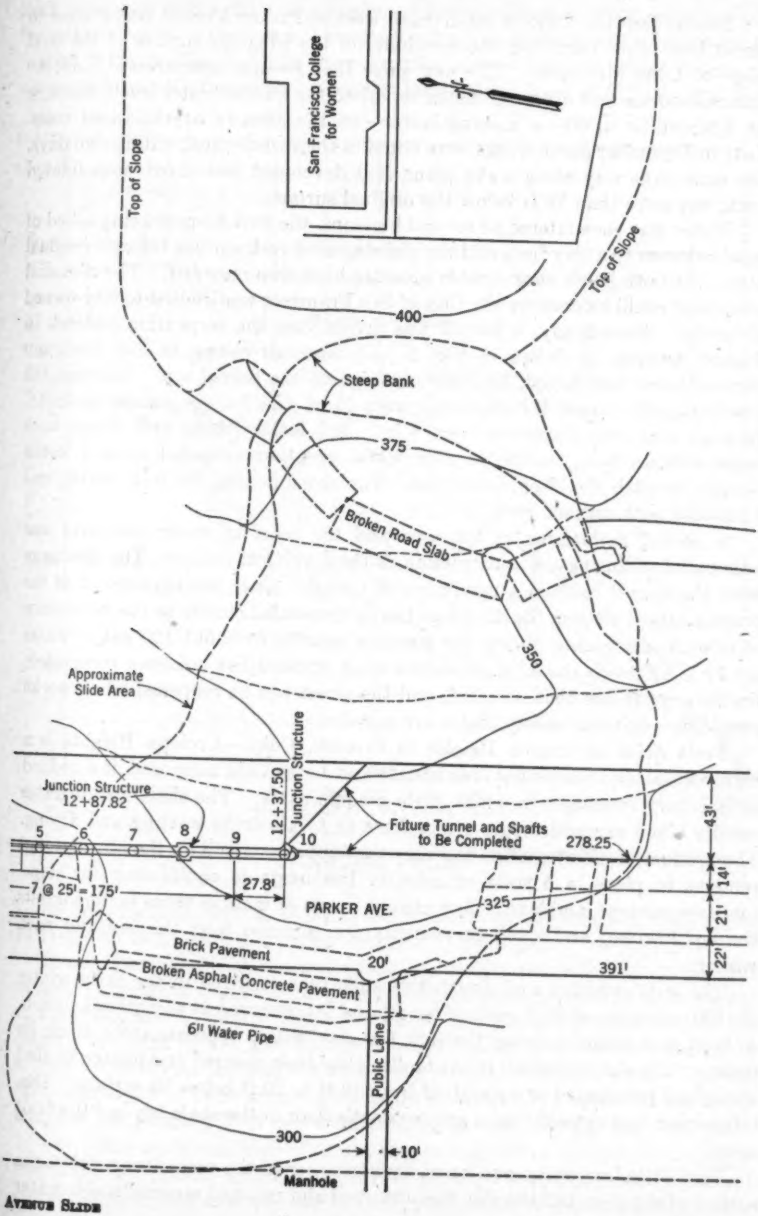

Avenue Slide

During October, 1935, a subdivision west of Parker Avenue was graded to street level, thus removing the remainder of the irregular surface of the west slope of Lone Mountain. The new slope then became overstressed, and the first rainstorms that occurred thereafter raised the ground-water levels, exerting an hydrostatic uplift—a moving factor—on the already overbalanced mass. Late in December shear cracks were noted in the surface; and, within two days, the mass gave way along a slip plane that developed just above consolidated rock, not more than 70 ft below the original surface.

Water was encountered at several horizons, the two deepest being a bed of sand between two clay beds and the disintegrated rock surface below a residual clay. At both levels considerable pressure head was recorded. The remedial work that could be done by the City of San Francisco was limited to city-owned property. Accordingly, a tunnel was driven into the serpentine bedrock in Parker Avenue, as shown in Fig. 2. At intervals shown in Fig. 2(*a*), ten vertical holes were bored, from the surface into the tunnel top. Through the overlying soil to rock the diameters were 36 in. and for the remaining depth, through rock, the diameters were 8 in. The latter (churn-drill holes) were cased with an 8-in., perforated pipe, which was then extended upward to the surface through the 36-in. boreholes. The space behind the 8-in. casing was backfilled with crushed rock.

A partial dewatering of the area and the relief of water pressures was accomplished during the construction of these vertical drains. The discharge from the tunnel reached a maximum of 1 mgd. Since the completion of the present tunnel section, the discharge has corresponded closely to the occurrence of rainfall, decreasing during the summer months to about 100 gal of water per hr. Although the total corrective work planned has not been completed, the movement has been arrested, and the street can be reopened when works providing additional safety factor are installed.

Earth Slide at Crolona Heights in Crockett, Calif.—Crolona Heights is a highly developed residential area situated on a steep hill composed of a bedded sedimentary formation in which shale predominates. The shale disintegrates rapidly when exposed to the atmosphere or to alternate wetting and drying. The product of disintegration is a clay that appears as soil on the hillsides and remains in place in a state of more or less unstable equilibrium for slope moisture content, and load. Any change in one or more of those factors upsets the equilibrium, and small movements are common over the hillsides each winter.

The large, sudden, and destructive slide that occurred in the early winter of 1936, was the result of geologic conditions not observed at any other location. A fault was found passing through the clay shale, approximately along its strike. The shale involved in the faulting had been sheared and jointed so that water had penetrated to a depth of from 10 ft to 20 ft below its surface. Disintegration had extended to a greater depth than in the shale beyond the fault zone.

Very little free water was found by boring, or in the excavations below the surface of the clay; but the clay had absorbed and retained a considerable water

load. Samples taken from the boreholes on November 5, 1936, were tested for water content. The average results for the cross sections are noted at their central point in Fig. 3. The same samples were tested for other moisture characteristics with the following results: Plastic limit, from 20.27% to 26.27%;

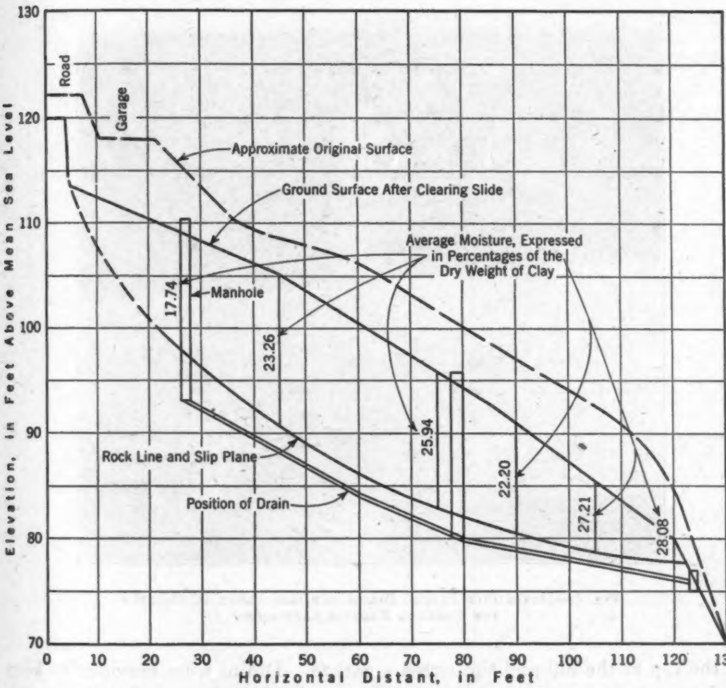

FIG. 3.—CROSS SECTION ALONG THE DEEPEST TROUGH OF THE CROLONA HEIGHTS LANDSLIDE AT CROCKETT, CALIF.

liquid limit from 35.79% to 38.96%; and moisture equivalent, from 22.39% to 32.11%—all in relation to the dry weight of the samples.

It was concluded that the water load had finally reached proportions that caused the material to shear. Cracks developed, allowing rainfall to penetrate to the shale, and a sudden slide occurred along a slip plane developed in the clay above sound rock. The borings made it possible to determine the depth to rock in place and the position and conformation of the slip plane. The slip plane was found to be at a maximum depth of about 15 ft below the surface of the slide and possibly 20 ft below the original ground surface (Fig. 3).

Corrective work consisted of excavating to rock below the slip plane (which was easily recognized by its striated and polished surface), installing a well casing preperforated over one half of its circumference in the sound rock below

the slip plane (see Fig. 4), and backfilling with crushed rock to within 3 ft of the surface.

Vertical ventilating shafts, consisting of perforated corrugated pipe, were left in the backfill to aid in drying the clay. Reinforced concrete posts poured in holes bored 12 ft into the shale retained the fill for the main access roadway

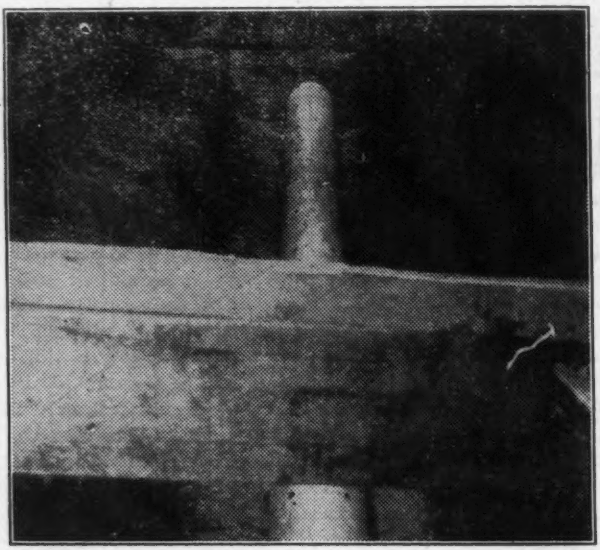

FIG. 4.—DRAIN PIPE PLACED BELOW THE SLIP PLANE TO CORRECT THE CROLONA HEIGHTS LANDSLIDE

to the top of the hill and supported a garage. Drains were provided to keep surface water from accumulating in the area, and the loose material over the toe and street and sidewalk areas was removed; but the upper slope below the roadway was not brought back to its original grade and loading. During the intervening wet winters many small slides have developed at other points on Crolona Heights, but there has been no movement of the corrected slide.

Plastic Material at Market and Glendale Streets, San Francisco.—The slide movement which occurred on Market and Glendale streets in San Francisco was also one caused by geologic conditions unique to the area. Market Street was graded through solid rock in a low cut on the slope of Twin Peaks. For several years the rock mass sheared and moved during the winter months, disrupting the pavement and blocking traffic on an important artery of the city. Each summer the street was regraded and the pavement replaced. The usual procedure for investigating subsurface conditions by borings was not adapted to the hard rock involved in the movement. In 1940 and 1941 surveys were made of the surface, the escarpments of the slide, and the movements of

the ground. The results of these surveys are given in Fig. 5; and the remedial works, the limits and contours of the slide, and the reference line for measurements in Fig. 5 are shown in Fig. 6.

The axis of the slide was approximated from the results of Fig. 5, and exploration pits (an upper pit 6 ft by 8 ft and a lower pit 8 ft by 10 ft) were

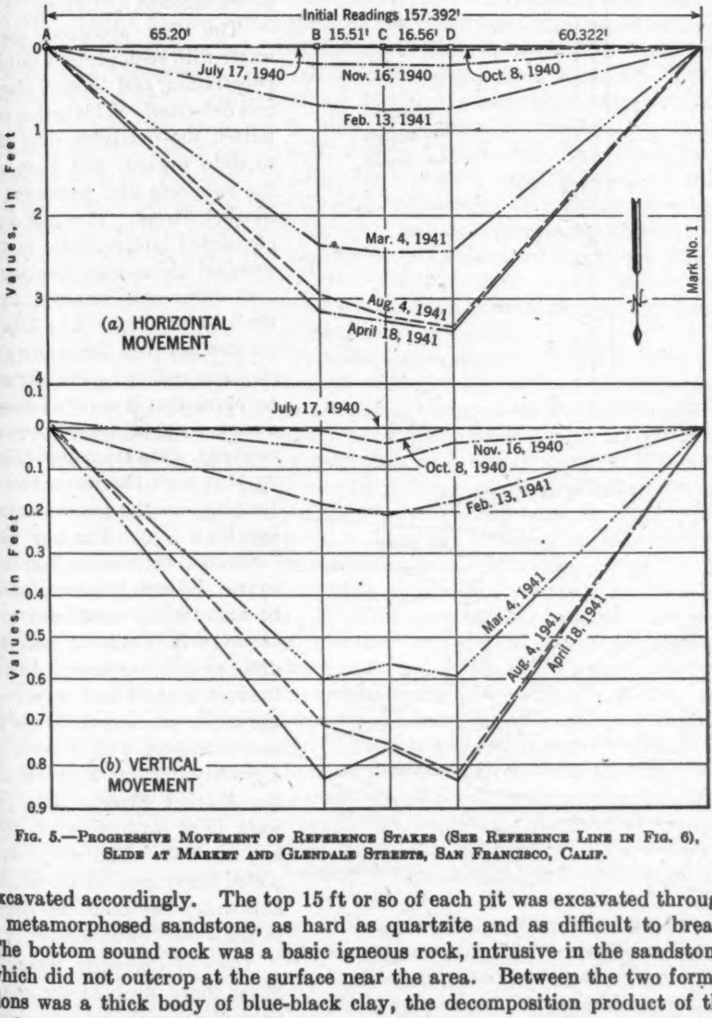

FIG. 5.—PROGRESSIVE MOVEMENT OF REFERENCE STAKES (SEE REFERENCE LINE IN FIG. 6), SLIDE AT MARKET AND GLENDALE STREETS, SAN FRANCISCO, CALIF.

excavated accordingly. The top 15 ft or so of each pit was excavated through a metamorphosed sandstone, as hard as quartzite and as difficult to break. The bottom sound rock was a basic igneous rock, intrusive in the sandstone, which did not outcrop at the surface near the area. Between the two formations was a thick body of blue-black clay, the decomposition product of the basic rock. Surface water had penetrated to the lower rock formation causing it to hydrate and swell with such force as to fracture the overlying quartzite.

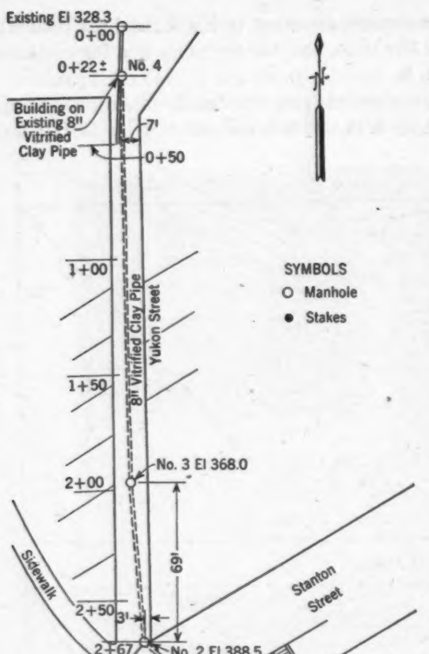

Fig. 6.—Limits of the Market and Glendale Slide, Showing Contours of the Slide, Reference Line for Observations, and Remedial Works

These fractures allowed a more ready access of water and contact with the basic rock and the process continued until the thick intervening clay had been produced through hydration.

The clay absorbed excess water with each winter's rainfall penetration, and became plastic and deformed. This action permitted the overlying rock load to slide toward, and push up, the subgrade and pavement of Market Street. The pits were completed late in 1941, as the seasonal rains were beginning, and water was pumped from them that winter. The time of contact between the water and clay was reduced materially and no movement was noted except during a 36-hr period, over a weekend, when the pumps failed. At that time the water rose in the pits and the pavement rose less than 1 in. The pits were connected by a drain laid in a tunnel and their bottoms, cleared to sound rock, were lined with concrete in 1942. A collector drain system was extended along the rock contact both ways from the upper pit, and the lower pit was connected with a sewer by a gravity drain in a tunnel under Market Street. The pits were filled with crushed rock and covered. The work completed has arrested all movement and water has been discharged to the sewer continuously.

Costs of Corrective Works.—Shear slides involve large quantities of material, and a considerable area, and the cost of corrective work applicable for a given

case varies with the magnitude of the area in motion and with the extensions necessary to meet subsurface conditions and to provide drainage outlets. The hard serpentine rock encountered in tunneling below the Parker Avenue slide becomes slacked and swelled in the presence of air, so that a reinforced concrete lining was required. This raised the estimated total cost of the tunnel to about $100,000, the incompleted installation as of December, 1945, costing $65,000. At the Market Street slide, on the other hand, the cost of sinking, timbering, bottom lining, and backfilling the pits, on a unit bid basis, was $2,466. The tunnel connection and the intercepting drain connection to the sewer on Yukon Street (see Fig. 6) cost $5,126 on a lump sum contract.

A surface survey alone could not have revealed the geologic conditions affecting the Market Street slide, but several other shear slides have been analyzed as to the cause and to determine corrective methods by a geological survey. The experience of the City of San Francisco, in landslide correction work, has shown that a geological survey of surface exposures is a first requirement in directing the subsurface exploration and that such a survey can always shorten the time and thus control the cost of boring. Boring records and samples are of little value if they are not collected by an experienced geologist who can analyze them in light of the problem presented.

Preventive and Precautionary Measures.—Because the City of San Francisco had frequently been sued for property damage resulting from landslides and because, more frequently, the owner had no recourse in the event that his property suffered damage, the late A. D. Wilder, M. ASCE, then Director of Public Works, was prompted to require that plans be approved by his department in relation to surface and subsurface drainage, stability of fills, and street subgrade of proposed subdivisions whose streets would be taken over by the city for maintenance. Among projects submitted to the writer for investigation in October, 1941, was an area covering the slope between Silver Avenue and Alemany Boulevard, six blocks wide and about a quarter of a mile along Alemany Boulevard, with streets and utilities serving three hundred and eighty dwelling units. The slope, which was then being graded, gave some evidence of landslide material in several places and a few springs issued from the surface.

The cost of the preliminary investigation was divided between the city and the subdividers. The borings revealed the fact that alternate beds of dune sand and silty clay overlie a bedrock with an outcrop at an elevation 300 ft above the upper street level. Each sand bed contained water and the lower beds developed water under pressure at several points in line up the slope from spring outlets. The need for drainage works to stabilize the area and to prevent landslides and the saturation of street fills was anticipated. This work was begun before the street and building construction of the subdivision was completed.

The drainage system consisted of a continuous perforated tile 900 ft long laid in a trench from 4 ft to 8 ft below the surface in the sidewalk area of the highest street of the subdivision and rising 35 ft to El. 180 city base. The trench intercepted the water in a series of horizontally bedded sands and clays which yielded about 90 gal of water per hr in September, 1942. Three relief wells, 50 ft apart, were bored at the higher end of the trench—one to bedrock

at El. 140 from which water flowed under pressure into the trench, one to a sand bed at El. 160 from which water also flowed, and one through clay to sand at El. 170 in which the water level just rose to the bottom of the trench. This work increased the discharge of the system to 180 gal per hr.

During the winter months, the discharge of the drain increased until in March, 1943, it was 515 gal per hr, decreasing again through the summer until in November, 1943, it was 225 gal per hr. That the effective radius of the drain is increasing is evidenced by the fact that the discharge in January, 1944, was 301,500 gal as against 172,700 gal in January, 1943. The comparable February measurements revealed a total of 357,200 gal for 1944 as against 204,800 gal for 1943 although the 1944 rainfall was less than that of 1943.

The drain is located close to the foot of the upper cut slope. The total cost of the drain construction was $3,350 on a lump sum contract, which was very economical insurance. No saturation of fills, heaving of pavements, or other forms of instability have been noted, but those experienced in these matters in the office of the city engineer know that the saturation of fills and development of water pressure would have resulted in slides if the quantities of water drained away had been allowed to accumulate underground in the area.

Detrital Slides

Detrital slides in natural earth masses have several causes. Masses of material will move after heavy rains have saturated or swelled them. Under certain conditions rainfall will penetrate to, and will lubricate, surfaces of contacting material such as soil or clay over rock (or soil over clay), which thus allows the top material to slide. This action frequently exposes the subsoil material to moisture penetration that generates slides. Weathering of, or geochemical changes in, earth or rock slopes so weakens the material that it moves under the force of gravity. Earthquake shock has been the cause of an initial movement in loose or sheared material of fault zones on the West Coast of the United States. Examples of each of these types of movement are to be found in the San Francisco Bay region.

O'Shaughnessy Boulevard Slides.—During construction, and after completion in 1941, two detrital slides of considerable extent occurred during the winter months along O'Shaughnessy Boulevard in San Francisco. The surface material became saturated, expanded, lost its cohesive properties, cracked, and slid to the boulevard right of way. One area is retained by a high and heavy wall, but the material flowed over and around the wall. Another area involves the subgrade of the boulevard and the wetted material moving along a solid surface has forced the pavement upward during the winter and spring months—a hazard to traffic which had to be corrected.

The exact contour of the solid rock or clay over which the latter slide recurred each winter could not be determined without an extensive and costly boring program. Surface surveys were made and, upon the basis of the experience gained in the correction of similar slides, specifications were prepared and a unit price contract was let in the fall of 1945 under which exploration and corrective work were done simultaneously. Three shafts were first excavated at the estimated location of the axis of the slide.

The material that was within from 10 ft to 12 ft of the surface consisted of loose soil and clay, carrying considerable rock float which had originated in the dumps from old quarry operations at the top of the slope and had moved as much as 500 ft down the slope. There was a definite sliding plane at the base of this material which curved to meet the pavement close to curb line. Movement along this plane had sheared a tile drain parallel to the roadway at a maximum depth of 7 ft below ground surface.

The bulge under the greater area of the pavement, however, was caused by the action of a clay subsoil when its moisture content increased above its plastic limit each year. Apparently, the top detrital material became saturated with rainfall penetration and seepage, allowing the water to reach the top of the clay subsoil, and thus lubricating its surface and generating surficial movement. Water was then in contact with the clay subsoil and absorbed by it; and this clay became viscous. Movement, causing the bulging up of the pavement, resulted from the integration of minute slippages between clay particles in plastic deformation.

The depth to which water had been drawn into the clay and the bottom of the clay involved in movement was clearly perceptible in the shaft walls. The solid, dry clay into which the shafts were driven exhibited its original residual structure and characteristics whereas that involved in movement was obviously "remolded." The lowest point in the latter material was determined from the first three shafts. A manhole was constructed at that point, and thirty-four shafts, averaging 20 ft in depth, and two additional manholes were excavated. The line of shafts was located along the axis and grade of the slide, as its location and depth were revealed by excavation from point to point. The function of the shafts and of their crushed rock backfill was to draw the ground-water levels down below the top material and to consolidate the clay through evaporation of its excess moisture.

TABLE 1.—UNIT COSTS ON CORRECTIVE WORK, 1945; O'SHAUGHNESSY BOULEVARD SLIDES

Item	Description	Unit cost
1	Drain shafts; including excavation, hand finishing the bottom to fit the drain pipe, sheeting and bracing, disposing of surplus material, and backfilling with from ¾-in. to 1½-in. crushed rock (per linear foot of depth)........................	$ 9.50
2	Drain tunnels, minimum section 15 in. by 15 in., connecting bottom shafts and manholes; including excavation, hand finishing the bottom for pipe installation, and tamping the crushed rock backfill (per linear foot of tunnel)..................	$ 6.00
3	Perforated drain; furnishing and installing 8-in. vitrified clay pipe; including the grout and mortar work necessary to produce a tight bottom and a rigid support (per linear foot of drain)..	$ 3.00
4	Manholes, 4 ft in diameter; constructed complete with concrete foundation, steps, and other features in accordance with City Standard Specifications (per linear foot of depth)..	$20.00

The shafts were connected by short tunnels through which a perforated drain tile was laid, in a manner similar to that illustrated by the Crockett slide drain (Fig. 4). The system was extended across the boulevard through solid clay and road fill to discharge on a rock slope. The unit costs were as given in Table 1. The total cost, units plus extras, is about $11,000.

The bedrock core of the San Francisco Peninsula is a geologically ancient complex (Franciscan formation) in which rock of sedimentary origin is metamorphosed to varying degrees through both intrusion of basic igneous magmas and crustal pressure. The basic igneous dikes, principally serpentine, characterize areas in which gulleys have developed in the bedrock through the geochemical breakdown of the rock. Two such areas in the cliffs facing the Golden Gate are producing slides that involve the El Camino del Mar subgrade and Phelan Beach recreation area, the serpentine hydrates forming a clay which, with the further absorption of moisture, becomes a viscous mass moving down the slope and carrying its overburden of dune sand and road fill.

The Franciscan formation has been subjected to many periods of faulting, which is the fracture relief of enormous compressive stress although, for the most part, the faults have been long "dead" and healed. In the area of the O'Shaughnessy Boulevard slide, however, a healed fault zone was found in which the fault gouge, although consolidated through time and pressure, was subject to comparatively rapid breakdown in the presence of ground water, resulting in a blue plastic clay. Free water was found in the jointed rock of the old fault zone and under pressure beneath the gouge clay, which made it necessary to stabilize a considerable part of the material by excavating shafts to depths as great as 27 ft and by flattening the gradient of the drainpipe across the zone.

There is nothing unique about the rock formations of the San Francisco Bay area that makes them particularly susceptible to the development of landslides other than the slopes resulting from the topographic development. All geologic formations contain zones of structural weakness and are subject to the attack of ground water and weathering agencies. Ground water occurs at such zones of weakness, in varying degrees, conditions, and quantities, often sufficient to produce local unstable masses in which slides are readily generated. In fact, the ground movement along the slope that supports O'Shaughnessy Boulevard is the normal process of topographic development common to all slopes and was initiated long before the boulevard was constructed.

Rock slopes disintegrate under the attack of weathering agencies to produce soil in place; or soil is moved to rock slopes by wind action (as in the dune sand areas of San Francisco) and the underlying rock then is disintegrated and decomposed by the geochemical action of ground water held in the overlying blanket. When the rock decomposes, the subsoil develops in place as a residual clay. The soil cover moves down the slope whenever its moisture content reduces cohesion and friction to less than the pull of gravity. This exposes fresh rock surfaces to weathering or underlying subsoil or residual clay to seepage, the clay then being subject to some form of plastic flow. The process is continuous until a new slope is formed upon which the material will remain in a stable position. However, detrital slides have been generated in San Francisco when fresh rock surfaces were exposed to weathering agencies and when lateral support for bedded materials was removed in excavating for streets or building sites.

Joost Street Slide in San Francisco.—Removal of lateral support was the

cause of the Joost Street slide in 1928, when two layers of material of different character (sandy topsoil and sandy clay subsoil) moved at different rates down a slope whose lower toe had been disturbed by excavation on Monterey Boulevard. The material adjoining the excavated surface lost its lateral support and the topsoil started moving. The structure of the topsoil was broken and movement was accelerated during the winter when the topsoil absorbed an unusual quantity of rainfall. Water then could reach the clay subsoil to generate a plastic flow over solid material. The movement extended up the slope until the foundations of houses on Joost Street, parallel to and above Monterey Boulevard, were affected and the houses slid down the slope.

Broadway Tunnel Approach in Oakland.—Detrital slide development on cut slopes occurs frequently in the San Francisco Bay region even when roadways are cut through seemingly solid material. Dry soil, clay, shale, or rock composed of basic minerals all become weathered when they are subjected to temperature changes, alternate wetting and drying, and exposure to the atmosphere. The resultant disintegration allows the penetration of rain water, adding weight to the mass as well as weakening and lubricating the material. The cut for the approach to the Broadway Tunnel in Oakland, Calif., was one of those investigated.

The fresh cut, made in 1934, on a slope of 1 on 1, presented a rocky surface. It was brown in color because, in this crushed and sheared fault zone, there was an iron-oxide coating on many joint faces of the hard blue rock. Moist areas on the slope were characterized by the presence of partly decomposed rock. These clay pockets contained material that had developed polished and grooved joint faces (slickensided) produced by the force of the internal swell in hydration.

Samples of the crushed rock were obtained and tested for their action under hydration. The moist clay from the clay pockets was placed on sloping surfaces and further wetted. It was concluded, from these tests, that the rock fragments would break down to clay when subjected to rainfall penetration and that the clayey material would slide on slopes at angles greater than 25°. The material of the cut slope did reduce to clay and slide when wetted each winter, exposing new rock faces. This process was repeated until a predicted slope of 25° was reached. The progressive development, from 1934 through 1941, toward the predicted stable slope is shown by three typical sections in Fig. 7. The character of the slides generated and the breakdown of the property on the parallel and higher Buena Vista Avenue, with the destruction of trees, as it appeared in 1941 are shown in Fig. 8. This process occurs frequently along California highways. The rock at some cut faces decomposes with comparative rapidity and breaks down to clay when exposed to weathering and when penetrated by water. The clay retains moisture and increases in volume to a much greater extent than the rock from which it is derived. The inevitable result is that the clay cover slides progressively, each time uncovering fresh surfaces of rock. The process of deep disintegration and decomposition advances with each cycle until the slope becomes stable for the conditions prevailing at the time.

Street Fills Placed on Unstable Materials or on Soils Subject to Saturation.—Detrital slides develop slowly as compared with shear slides and are seldom as destructive to streets and property. However, damage results when material subject to such movement is utilized as a foundation for fills or for the sub-

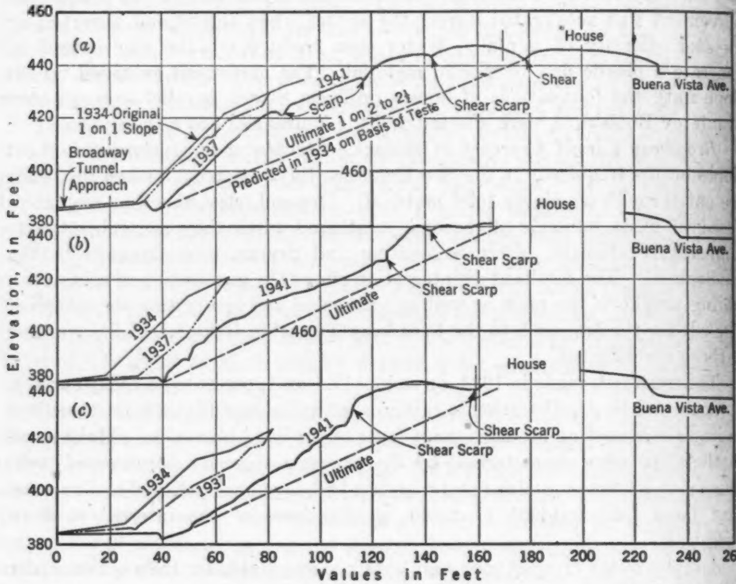

FIG. 7.—PROGRESS OF SLOPE STABILIZATION, APPROACH TO THE BROADWAY TUNNEL, OAKLAND, CALIF.

grades of streets. An instance is afforded in San Francisco from experience on Monterey Boulevard. The fill-supported pavement settles on the downslope side in many places; and, at Detroit Street, a fill to street grade slid down the slope, destroying one house and damaging two other properties.

Burnham Street and 24th Street Slide.—A fill required for 24th Street and Burnham Street on the east slope of Twin Peaks settled from 2 ft to 4 ft each winter, disrupting the Burnham Street roadway to its center line. When the fill slid down the slope to force a wave of saturated soil ahead of it, the foundations of three houses on 24th Street were destroyed, and the material piled against the foundation of a fourth house at the end of the block.

Test boring in 1942 revealed a clay and rock fill 22 ft deep at the intersection, decreasing to 12 ft down and along the crossing streets. Water under pressure was encountered at various levels, the pressure being developed by the restraint exerted by the overlying clay fill on the original surface soil. The moisture content of soil samples recovered from parts of the fill, in July, 1942, was greater than the plastic limit, but no plastic deformation was found to have occurred; the street surface had settled when the downslope part of the fill had

sheared; in other words, the displacement occurred because of the unstable underlying material. The base of the fill as well as the underlying soil—a total thickness of from 4 ft to 5 ft—was saturated and yielded free water. In many of the boreholes along Burnham Street, the water rose to within 4 ft of the street level when the original soil was penetrated.

FIG. 8.—VIEW OF SLOPE, APPROACH TO THE BROADWAY TUNNEL IN 1941

The remedial works had to be installed within the city-owned street and sidewalk area. A total of thirty-five 4-ft by 5-ft shafts, varying in depth from 18 ft to 35 ft up the slope of 24th Street and both ways from the junction manhole on Burnham Street were excavated by a half-yard clamshell bucket on a 44-ft boom. The shafts were 6 ft apart so that a column of earth was left as a protection against movement. Tunnels about 3 ft by 3 ft in section connected the shafts, and 450 ft of perforated tile drainpipe were laid as a continuous drain along the bottom.

The drain was covered with a backfill of $\frac{3}{4}$-in. to 3-in. crushed rock in the tunnels and to within 6 ft of street level in the shafts. Three manholes were constructed to give access to the drain and to act as air vents at differing levels. The lump sum contract price for this work and for a short, trench-laid connection to a sewer, was $18,750 in 1943.

The water pressures were relieved by the drainage outlet, as evidenced by the lowering of the free surface water levels in the boreholes. The discharge of the system was as much as 300 gal per hr during construction; after the completion of the project and before the winter rains (November, 1943) the discharge was 100 gal per hr. The movement has been arrested and no recurrence of the settlement has been noted. With the passing of time, as the circulation of air causes water to evaporate, the fill will become consolidated and permanent pavement will be placed.

Construction Control and Preliminary Investigation in Private and Public Work.—Litigation with private parties, concerning private property, is a costly factor in city government. To correct this condition in San Francisco, legislation was initiated in 1941, by Director Wilder and John J. Casey, M. ASCE, then city engineer, to require that private parties obtain city permits to excavate, place fill, or dispose of waste material of specified minimum quantities. The need for such legislation was demonstrated in February, 1942, when two persons were killed in a house destroyed by flowing mud. A body of waste material dumped in a gully above the house had become saturated and flow of a considerable quantity of mud so formed was the result. Many slides could have been avoided, final slopes of excavations could have been determined in advance, the city could have been protected from damage suits and excessive maintenance costs, and the property owner could have been protected—if the facts determined later, by necessity, in the correction of such occurrences had been determined before construction was undertaken. Such considerations led to the adoption of a program of preliminary geological and subsurface investigation in connection with the city's plans for street, boulevard, and free way construction.

Earthquake Shock.—The Pacific Coast of the United States is a region of seismic activity. Small earthquake shocks occur frequently, and the shattered rock of fault zones has provided material for slides on natural slopes. The typical landslide topography along known fault lines in California is evidence of the fact that surficial ground movements accompany shock. These are the so-called "moving mountains" which receive newspaper publicity and are of general interest from time to time. One such slide was investigated because its effect brought about a damage suit. It occurred in 1936 along the right of way of the Western Pacific Railroad in the Altamont Pass. Its cause and effect may be of interest in connection with West Coast highway cuts.

The railroad cuts in that vicinity are excavated in hard, thin bedded shale at right angles to the bedding planes and with their dip 14° from the horizontal at the slide. The shale consists of cemented fines rather than of compacted fines as it contains intergranular binder, does not slack nor disintegrate readily in the presence of moisture, nor does it absorb moisture. Furthermore, the slide occurred on November 21, 1936, before any rain had fallen that season, and no water was encountered in boring. The usual conditions that cause slides were lacking in this instance and no slide had occurred there since the railroad cut was completed thirty years previously. It was reasonable to conclude that the slope adopted in excavation was safe, that no deformation or slide would develop as a result of the excavation, and that the cut slope would remain stable except for superficial sloughing.

The shale formation is faulted locally, due to varying compression in the geologic folding and distortion of the entire area. These faults are numerous and of minor importance as a rule, having little significance in the stability of the entire mass. For the most part, they cause no trouble in the cuts. However, at mile post 60 an extensive fault with considerable displacement of the beds cut across the shale beds in both the railroad cut and a fresh State High-

way cut on the opposite side of the pass (see Fig. 9). The west fault of the zone made up the west slip plane of the slide. Vertical shears at the head of the slide were cross faults of the zone, and the shale within the fault zone was sheared and jointed. Even then, considerable stress must have been required, under those conditions, to overcome the stability inherent in the mass due to

FIG. 9.—FAULT ZONE IN ALTAMONT PASS AS REVEALED BY A STATE HIGHWAY CUT

its natural state and position. The character of the dry slide material, after the main body had been removed, is shown in Fig. 10.

In order to observe subsurface conditions, a number of holes were bored after the loose material was removed by bulldozer. Seven of them were 30 in. in diameter, ranging from 10 ft to 20 ft deep. The line of break was located; and, because the dip of the displaced shale beds could be observed from the top to the bottom of these holes, it was possible to reconstruct the history of the movement. The flow of dry material occurred as an outward movement at the toe of the cut slope of the right-of-way excavation. This was followed by flow along the west fault boundary and a breakup of unsupported material toward the east boundary. The rotary movement continued, involving a mass of material overlying a bedding plane common to all boreholes and below which the material was still in place. The entire mass of shale fragments spilled on to the tracks from a wide hillside area as through a funnel. The flow would have continued if approximately 10,000 cu yd of loose material had not been removed in clearing and protecting the tracks.

A week before the main slide, a trackwalker reported a heaving and cracking of the soil that loosened fence posts and destroyed the right-of-way fence. This led to the conclusion that the stress involved was in the nature of an earthquake shock or series of shocks. The records of the nearest seismograph, at Berkeley, Calif., showed two shocks with an estimated epicenter not far

from the location to have occurred about a week apart, the second one at the time estimated for the slide. The first shock is believed to have overcome the stability of the mass, loosening it and causing it to heave and then to settle. The shock that followed a week later caused the actual flow of material, rendered loose by the first, to be shifted from its position to the tracks.

FIG. 10.—FAULT ZONE MATERIAL IN A SLIDE OF THE RIGHT OF WAY OF THE WESTERN PACIFIC RAILWAY

SLIDES DUE TO WATER PRESSURE

Ground-water pressure is one factor in the generation of many slides, and it is the principal and only factor in some slides. Road cuts and grading operations on slopes have the effect of intercepting subsurface channels or zones through which underground water passes from higher to lower levels to be discharged as springs in a state of nature. Localized slides will develop in such areas, due to the pressure exerted by the water.

Bernal Avenue Cut Slide Corrected at Arlington Street.—A localized slide of this kind occurred in the Bernal Avenue cut in San Francisco. The surface of the slopes of the cut revealed an apparently uniform material. However, landslides occurred at two points on the west side. As a temporary expedient, timbers were driven into the slope and connected to concrete anchors by horizontal tie rods. Bulkhead timbers were bolted to the upright timbers. This arrangement failed and the slide continued. The disturbed material was saturated and moisture emerged from the scarp of undisturbed material at points above the slide.

A line of test holes was bored through the slide into the underlying material, and water flowed from a number of the lower holes. Local saturation and water pressure produced deformation that had weakened and unstablized the material to well below the timber bulkhead and the bottom of the cut. Continued

sliding ground destroyed a retaining wall and some of the test borings. The latter were supplemented by others in which pipes were set for future water-level observation; and the borings were continued in line up the slope of the hillside for a distance of three blocks. The water level in the holes bored through clay into the disintegrated rock on the upslope sides of Arlington, Chenery, and Laidley streets, parallel to Bernal Avenue, rose to from within a few inches to within a few feet of the sidewalk level. A profile along this line to Arlington Street is shown in Fig. 11. By observing the water levels in these pipes, the hydraulic gradient of the water that caused the slide condition was found to intercept the slope of the cut, inducing flow from the lowest installed pipe at an elevation 25 ft above the pavement of Bernal Avenue. The water-table gradient before and after the installation of the Arlington Street drain, in relation to the position of the drain, is shown in Fig. 11.

Additional holes were bored at right angles to the first line, along the parallel, and next higher, Arlington Street; and water was found to be under pressure head in seams of fractured rock and along the disintegrated rock surface in line with the slide areas of Bernal Avenue cut. An intercepting drain, similar in construction to that described in connection with the Burnham Street and 24th Street slide, was laid in shafts and tunnels at a maximum depth of 26 ft (25 ft above the cut grade opposite the Bernal Avenue slide areas) along Arlington Street. The length of the drain, in shaft and tunnel, was 460 ft, with an additional 340 ft of trench-laid pipe connecting with a sewer in Bernal Avenue. The work, which included three manholes, cost $16,880 on a lump sum contract.

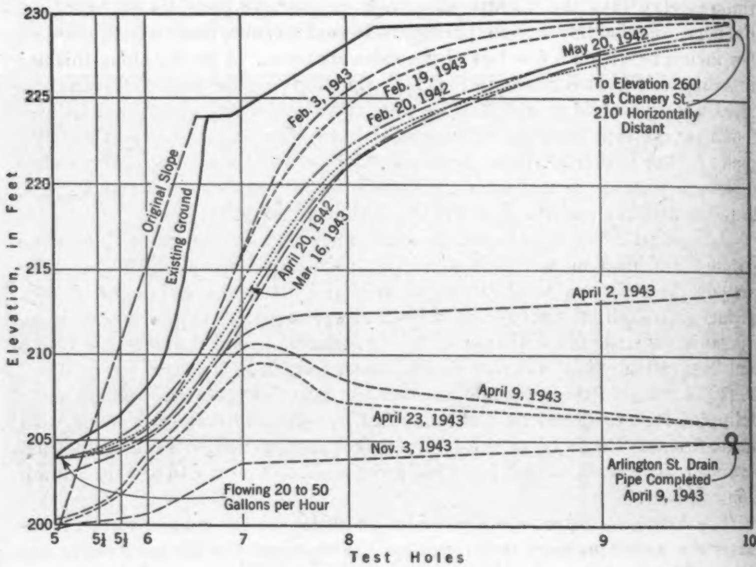
The Arlington Street drain provides an outlet for the ground water; it releases the water pressure that produced the slides on the Bernal Avenue cut slope. The discharge amounted to 300 gal per hr when the works were completed in April, 1943, decreasing through the summer months to 133 gal of water per hr in November, 1943. The water levels in the observation pipes were lowered almost immediately when the drain excavation and installation approached their vicinity. The saturated slide material was drained slowly by a shallow trench extended into it in 1944. Plans are being made for the replacement of the cut slope.

St. Mary's Playground Slide.—Another common form of landslide that results from water pressure concerns fills. Loose or compacted fills have been placed to provide streets or other level areas on hillsides without provision for draining all the natural spring flow or normal ground water. Such water finds its way through the soil along the contact of the base of the fill material or through disintegrated rock below that soil. The hydrostatic uplift exerted by the confined water against the base of the fill is the principal factor causing the fill to slide in some instances.

The St. Mary's Playground slide was the largest slide of this type that has occurred in San Francisco. The original fill was constructed as a project of the U. S. Work Projects Administration (WPA). Loose material was dumped over an area of about 80,000 sq ft, varying in thickness to 60 ft. Each winter parts of this fill slid down the slope until 15,000 sq ft of the highest parts of

the fill were lost. The result of this movement, with large parts of the fill intact but displaced, is shown in Fig. 12.

Preliminary borings showed that the fill material was practically impervious



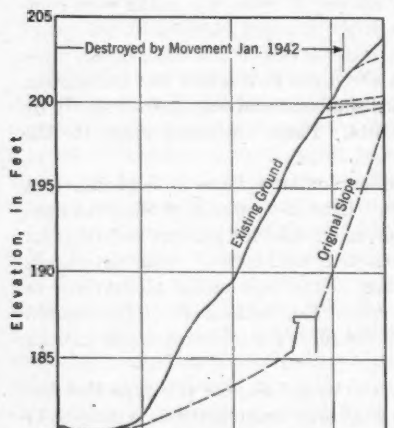


FIG. 11.—HYDRAULIC GRADIENTS AND PROFILE OF LANDSLIDE, WEST SIDE OF BERNAL AVENUE, 1942 AND 1943

and contained no free water; but, when the old surface soil or disintegrated rock was penetrated, the water rose in the boreholes, in some holes to within a few feet of the surface of the fill. The depth to bedrock, its elevation, and the elevation of the water levels, varied greatly in the boreholes. The contour of the original surface was not known. Its determination and the determination of the source and occurrence of the ground water and water pressures would have required an extensive boring program. A combination involving exploration and correction was adopted to meet these conditions, and the writer accepted a professional service contract for investigation and progressive design

and direction of a work contract let on a unit basis. This procedure proved to be satisfactory and economical.

The work was started in the fall of 1941 before the winter rains. An exploration trench was first excavated from one side a distance of 25 ft into the slide area, shown in Fig. 12. This trench revealed a buried contact of ser-

FIG. 12.—LANDSLIDES IN ST. MARY'S PLAYGROUND, SAN FRANCISCO, CALIF.

pentine rock with the siliceous sandstone making up the slope beyond the playground area. Decomposition of the serpentine rock had produced a "gully" in the bedrock surface which would not have been evidenced in the contour of the surface soil. The gully underlay the easterly toe of the fill and was an important factor in the instability of the whole. Ground water was concentrated in this region and was moving downward under head. The disintegrated serpentine rock below a blue clay was found to carry the greater quantity of water under pressure, although seepage occurred from the original soil cover of the slope underlying the fill.

The depth to rock prohibited further trenching, and 30-in. holes were bored at 5-ft centers, 20 ft to 35 ft deep, through the slide material and through 2 ft of disintegrated serpentine rock to sound rock. Grades were established after drilling four holes. The fill material was dry and stood without casing, but water encountered at the rock line rose to varying heights in each hole. A 6-in. red-iron casing perforated one half of the circumference, was laid as a drain pipe in the trench, and was carried on grade from hole to hole through short tunnels so that water was drained off as the work progressed. The boreholes and trench were backfilled with crushed rock to 6 ft above the base of the fill and were finished with excavated material. The first twelve holes and the

trench crossed the subsurface "gully" and produced a flow of 50 gal of water per hr in November, 1941.

The varying depth to sound rock below the original soil surface made it impossible to predetermine the line of the holes and still maintain the necessary grade. The location of each borehole depended upon conditions found at grade in the preceding holes projected. The irregular route[2] so determined, was such that the drain did collect all the water and relieve water pressures, which varied in amount from place to place. A second gully was encountered between holes 20 and 23 and the flow increased to 72 gal per hr. The most extensive gully development was found at about the axis of the slide where the westerly contact of the intrusive serpentine rock with the silicious sandstone was found. The holes bored in the sandstone were dry, so a turn was made to follow the gully up the scarp of the slide on to the undisturbed fill terrace. At this point the discharge had been increased by 86 gal per hr.

The St. Mary's Park area consisted of three terraces on fills, the middle terrace being 25 ft lower than the upper terrace. The lowest terrace was 40 ft still farther down the slope above Alemany Boulevard. The drain system was completed by locating the line of boreholes along the edge of the upper terrace and placing the drain in rock at depths decreasing from 30 ft to 15 ft below the surface in a horizontal distance of 200 ft. An intercepting drain, consisting of a 6-in. corrugated drain pipe, was laid from 4 ft to 6 ft below ground surface along the upper cut slope of the top terrace. The line of boreholes in the axis gully were discontinued at the division between fill to cut, and it was connected to the intercepting drain by a pipe laid in open trench. The discharge of water from the completed system has varied from 140 gal per hr at the end of summer to more than 500 gal per hr during the rainy season. No further movement of the fill has occurred.

The quantities and unit costs of the St. Mary's slide contract let in 1941 were as follows:

Item	Description	Unit cost
1	3,200 ft, 30-in. drain shaft; per linear foot of shaft.	$ 2.95
2	400 ft, connecting tunnels; per linear foot of tunnel.	$ 1.40
3	800 ft, 6-in. perforated casing; per linear foot of of casing.	$ 1.50
4	450 tons, crushed rock ($\frac{3}{4}$ in. to $1\frac{1}{2}$ in.); per ton. .	$ 2.35
5	Two manholes, including 40 lin ft of 30-in. steel casing and covers; each manhole complete. . . .	$32.00
6	600 ft, 6-in. perforated drainpipe; per linear foot of pipe.	$ 0.65
7	200 cu yd of excavation 4 ft to 8 ft deep, and back-fill for item 6; per cubic yard.	$ 2.40

The length of the connecting tunnels was limited by the difficulty of working, by the tools that had to be used in the cramped quarters at the bottom of 30-in. boreholes, and by the problem of disposing of the material removed

[2] "Pipe Drains Stop an Earth Slide," *Engineering News-Record*, April 9, 1942, p. 67.

from the tunnel with a man working in the space. However, the borehole system, even with borings spaced close together, is relatively economical and is best adapted to the correction of large active slides which would require a considerable number of preliminary borings to establish the grade and contour of the contact between moving and undisturbed material or costly shoring to protect workers and adjoining property if open excavation were used.

Success of Remedial Measures.—The success of remedial measures is demonstrated by the fact that the slides have been arrested. To December, 1945, the corrected slides described in this paper have passed through one or more winter rainy seasons without any further movement or signs of instability. The slides in which water was the moving force have been observed continuously, and the discharge of their drainage systems has been approximated from periodic measurement. The results of such determinations, and the corresponding monthly rainfall record at the San Francisco weather bureau station, are listed in Table 2. For the Parker Avenue slide, in addition to the values given in Col. 2, Table 2, the following data for 1939 are presented to complete the record and to simplify Table 2:

Month	Rainfall (in.)	Discharge (gal. per month)
July	Trace	69,200
August	Trace	55,500
September	1.06	48,800
October	1.17	45,700
November	0.20	32,700
December	1.05	41,700

Soil Creep

Soil creep is the type of movement characteristic of all soil-covered slopes in excess of 25° from the horizontal. Soil creep takes place on natural slopes such as topographic canyons, and is entirely the result of internal forces. During rainy seasons saturated or wet soil cover, over rock surfaces, gravitates downslope when the forces of cohesion and friction are reduced below that of gravity. Downhill soil creep ceases when soil dries sufficiently to overcome the pull of gravity—that is, as the forces of cohesion and friction increase. This common form of earth movement is evident over large sections of every sidehill and, next to stream-bed erosion, is the main factor in the geologic history of canyon or sidehill topographic development.

As a general rule, this movement is slow and is only destructive where the soil involved in movement supports a fill, roadway, or structure. Retaining walls alone may serve no useful purpose because the soil can creep to, and overflow, the wall. This was found to be the case with the Turk Street slides in San Francisco, and it is a natural action under natural processes. However, the City of San Francisco has been involved in damage suits as the result of such natural action. A sliding condition that developed on the slope above Laidley Street before 1925 resulted in litigation; and the city, at that time, was required to purchase the property and the houses damaged in the movement. The slopes were flattened by the removal of part of the accumulated soil;

shallow drains were installed; and an extensive area was covered with asphalt to shed rain water. This area is two blocks up the slope above, and half a block west of, the drain completed on Arlington Street in April, 1943. No water has discharged from the Laidley Street drain since May, 1943, which would indicate that soil creep can be controlled if the moisture content is

lowered by diverting water into underlying natural drainage ways that are kept dewatered by works installed at lower levels.

CORRECTION SHOULD BE BASED UPON A THOROUGH INVESTIGATION

Experience is the only basis upon which landslides and earth movements can be predicted. In excavation or foundation work, they occur under certain recognizable conditions. Data concerning the distinctive characteristics of movement, and the topography developed through slides, are informative; but correction can be planned in detail only after the subsurface geologic and ground-water conditions are determined. Each type of slide and each set of conditions will present a particular problem in drainage, lateral support, or rebalancing of slopes with or without retention. Corrective works will have to be designed to meet the determined elements of a given problem, and no general treatment can be prescribed.

A geological survey, together with exploration boring, is the first requisite in the determination of the subsurface conditions and physical characteristics of the material involved. The saving in ultimate cost of the corrective work will repay such preliminary work many times. For example, drainage works were designed for the slide at Market Street near Glendale in San Francisco,

for St. Mary's Playground (Col. 3) was 46,800 gal. In December, 1941 it was 108,700 gal; and in January to April, surface water was diverted into the drain.

described previously; and their cost was estimated at $25,000 before adequate investigation was made of the problem. After careful investigation, by standards described in this paper, the corrective work was finally done at a cost of one fifth of that of the original estimate.

For determinations of moisture content and drainage characteristics, under some conditions of sliding ground, soil samples should be taken which are representative of the full soil column over the area. Ground-water sources and the seasonal water levels and pressures should be determined. If slip planes are observed in an upper scarp, throughout, or at the toe of a slide, they should be watched for in the borings. A series of such planes should be followed down carefully so that the bottom planes or the base of the present or prospective slide is recognized or so that the plane along which shearing has occurred, or is to be expected, is located definitely. Geologic conditions are controlling factors in the occurrence of ground water, and borings should be

made sufficiently deep to determine those conditions and the condition and the occurrence of the contained ground water. Landslide corrective works have failed in a number of instances for lack of definite information on this score.

Continuing Investigation During and After Construction.—Considerable preliminary borings have been made in slide areas known to the writer, a plan of works has been designed on the basis of such borings, and later the subsurface was found to vary materially from that assumed on the basis of the borings. Excavation for the construction of subsurface works should always be considered as a continuation of the investigation. The writer requires three contracts or service orders in slide corrective work for the City of San Francisco: One covering the preliminary investigation, direction, and analysis of the exploration boring and a report with recommendations; one covering time spent in consultation with the City Engineering Department in design, preparation of specifications (which are always made sufficiently broad so that work needed to meet conditions as they are revealed can be done on a unit basis or as an "extra"), and cost analysis of alternate plans; and the third covering time spent in examining and directing the work of the contractor.

Subsurface work in engineering construction must be considered in the nature of research, and it is necessary for the investigator to "feel his way." The data resulting from subsurface observation, boring, or excavation are necessary in the preparation and adjustment of plans, for drainage, sloping, retention, or stabilization. Frequently, boreholes in sliding ground will be cut by movement on two or more planes in their depth. If the boreholes are closed by the movement of any part of the soil column along any plane, such planes and movement must be recognized and provisions must be made to meet the deepest movement as well as the moving horizons in the column.

In slide corrective work much depends upon whether the slide is one of shear or detrital movement. Shear slides must be stabilized by providing works below the slip plane. Detrital slides can often be stabilized by: (*a*) Drainage ways in the upper slope; (*b*) shallow drainage facilities below the ground surface; (*c*) excavation to reduce the slope; or (*d*) retaining walls along the toe of slope to reduce the slope.

However, when the earth's structure is once ruptured by movement and its surface is cracked so that water has ready access to the interior of the mass, causing it to swell and become unstable, or causing bedding or contact planes below installed shallow drains to become lubricated, movement will recur. In all cases, once a slide is generated under a force great enough to overcome stability due to structural compactness and position of the material, it will continue or recur under forces much less than the initial force. Earth slides are a menace to the safety of life and property in urban localities or along roadways until they are corrected, properly and permanently.

DISCUSSION

T. W. LAMBE,[3] JUN. ASCE.—Water has several effects on slopes: It erodes the slope; it changes the strength properties of the soil; it makes possible a liquefied condition when the soil undergoes certain volume changes upon shearing; and it exerts forces on the soil. The author describes the water forces in general terms which, to the engineer, do not present a clear picture of the true nature of the effects. He mentions (see heading, "Landslides") that "The weight of the added water alone may overstress the material in such cases * * *." This thought, which is expressed in several places in the paper, needs some clarification, since a slope submerged, with no seepage, is safer than one that is not submerged although the "weight of added water" is much more. The seepage forces—the forces tending to cause slope failure—result from the difference in water pressures (that is, a sloping water table). If a flow net can be drawn for any slope, the seepage forces can be evaluated.

The question as to whether a slope is safe against rupture is one of mechanics: Failure occurs when the forces actuating the possible failure exceed the forces resisting such a failure. There are several types of slope movement that do not lend themselves to a quantitative analysis because of the difficulty of evaluating, accurately, the actuating or resisting forces. An example of an indeterminate actuating force is the force that an earthquake exerts on a slope. Likewise it is sometimes impossible to determine the shearing resistance of the soil that exists at incipient failure. Geology is a science that is helpful in formulating a more complete understanding of factors affecting these two types of forces.

To present a picture of the forces acting on a slope, an element of soil from an infinite slope will be analyzed, first without seepage forces and, second, with seepage forces. (A description of the methods of analyzing slopes has been presented elsewhere by D. W. Taylor,[4] Assoc. M. ASCE.)

In Fig. 13, H is the height of a soil element; α is the angle of inclination of the slope; γ is the unit weight of soil; and ϕ is the angle of internal friction of soil. The actuating unit forces, which are shown by solid lines in Fig. 13(b) are then:

$$W = \frac{\text{weight of soil}}{\text{area}} = \frac{\gamma \times H \times 1 \times 1}{\sec \alpha \times 1} = \gamma\, H \cos \alpha \quad \text{(1a)}$$

$$W_n = \text{normal component of } W = \gamma\, H \cos^2 \alpha \quad \text{(1b)}$$

and

$$W_s = \text{shearing component of } W = \gamma\, H \cos \alpha \sin \alpha \quad \text{(1c)}$$

and the resisting unit forces, which are shown by dashed lines in Fig. 13(b), are: C equals unit cohesion; and

$$F = \text{frictional resistance} = W_n \tan \phi = \gamma\, H \cos^2 \alpha \tan \phi \quad \text{(2)}$$

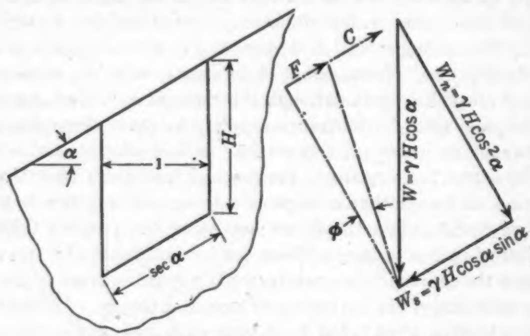
[3] Instructor of Soil Mechanics, Civ. Eng. Dept., Mass. Inst. Tech., Cambridge, Mass.

[4] "Stability of Earth Slopes," by D. W. Taylor, *Journal*, Boston Soc. of Civ. Engrs., July, 1937, p. 197.

For stability the resisting forces must exceed the actuating forces along the plane of failure; that is, $F + C > W_s$. The factor of safety (FS) with respect to strength is equal to

$$\frac{F + C}{W_s} = \frac{\gamma\, H \cos^2 \alpha \tan \phi + C}{\gamma\, H \cos \alpha \sin \alpha} = \text{FS} \ldots\ldots\ldots\ldots\ldots (3)$$

The only effect of complete submergence, with no seepage, in the expression for FS is to change γ (submergence may cause minor changes in ϕ). The value



(a) INFINITE SLOPE (b) FORCE POLYGON

Fig. 13

of γ for a slope above the water table is the unit weight of soil, plus any capillary moisture, as this total weight is carried by the soil structure. When the slope is submerged, the effect of buoyancy can be taken care of by using the submerged, or buoyed, unit weight of soil.

The two limiting types of soil are the cohesionless type (which is approached by clean sands) and the highly cohesive type (which is approached by stiff clays). If the soil in question is cohesionless, C is equal to zero and Eq. 3 becomes

$$\frac{\cos \alpha \tan \phi}{\sin \alpha} = \frac{\tan \phi}{\tan \alpha} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

The only criterion for stability of a cohesionless slope is that ϕ be greater than α; submergence or height of element has no effect.

If the soil is highly cohesive, submergence makes the slope have a higher FS against movement. This can be demonstrated from the fact that submergence decreases both F and W_s by replacing γ with the buoyed unit weight, whereas C remains unchanged in the expression $\text{FS} = \frac{F + C}{W_s}$. When F and W_s are decreased, C remaining constant, the factor of safety increases. Since all soils fall between the two limiting cases, the effect of submergence, without seepage, varies from not changing the FS to making the FS larger. This effect of submergence with no seepage is common knowledge that can be checked easily in the laboratory.

The water content of a soil can be increased by capillary action; this water content would make the slope less safe as the increased weight would have to be carried by the soil structure. In Eq. 3, F and W_s would be increased because of the increased γ although C remained unchanged. Drains within the slope would not remove the capillary moisture. This condition is not to be confused with analyzed conditions of complete submergence.

The detrimental forces of water are the seepage forces which the water imparts to the soil. Seepage forces act in the direction of the seepage and are equal to

$$J = i\,\gamma_w \quad \text{(5)}$$

in which J is the seepage force per volume; i is the gradient, or head lost per distance traveled; and γ_w is the unit weight of water. This seepage force when directed upward, having reached a magnitude greater than the weight of the soil, causes "quicksand." Seepage forces may be evaluated in one of two ways—(1) by consideration of the actual seepage force, or (2) by consideration of the boundary water pressures, which are the pressures that make up the seepage force. In most soil problems it is more convenient to use the boundary water pressures. The results obtained from the two methods are identical.

To show the fundamentals of the seepage force, an element from an infinite slope in which seepage is taking place throughout the mass parallel to the slope (that is, the top flow line coincides with the slope surface) will be analyzed by both methods. Any slope for which a flow net can be drawn can be analyzed, but the very simple infinite slope is selected as it shows the fundamentals clearly without unnecessarily complicating the problem. The forces acting on the element in Fig. 14(a) are determined by the two methods and superimposed in the force polygon shown in Fig. 14(b).

The forces on the element are first set up using the actual seepage force. Let γ_t be the total unit weight of soil and water; γ_s, the submerged, or buoyed, unit weight of soil; and γ_w, the unit weight of water. The actuating unit forces, shown by solid lines in Fig. 14, are then:

$$W_s = \frac{\text{submerged weight of soil}}{\text{area}} = \gamma_s\, H \cos\alpha \quad \text{(6a)}$$

$$W_{sn} = \text{normal component of } W_s = \gamma_s\, H \cos^2\alpha \quad \text{(6b)}$$

$$W_{ss} = \text{shearing component of } W_s = \gamma_s\, H \sin\alpha \cos\alpha \quad \text{(6c)}$$

$$J = \text{unit seepage force} = \frac{i\,\gamma_w \text{ volume}}{\text{area}} = \gamma_w\, H \sin\alpha \cos\alpha \quad \text{(6d)}$$

and the resisting unit forces, which are shown by dashed lines, are: C equals unit cohesion; and

$$F = \text{frictional resistance} = W_{sn} \tan\phi = H\,\gamma_s \cos^2\alpha \tan\phi \quad \text{(6e)}$$

The forces on the element are now set up using the total soil weight and boundary water pressures. The actuating unit forces shown by the dotted

lines are then:

$$W_t = \frac{\text{total weight of soil and water}}{\text{area}} = \gamma_t H \cos\alpha \ldots\ldots\ldots (7a)$$

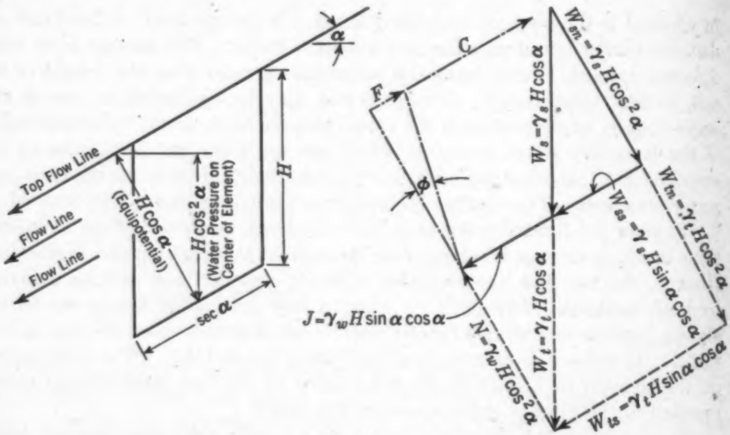
$$W_{tn} = \text{normal component of } W_t = \gamma_t H \cos^2\alpha \ldots\ldots\ldots\ldots (7b)$$

$$W_{ts} = \text{shearing component of } W_t = \gamma_t H \sin\alpha \cos\alpha \ldots\ldots\ldots (7c)$$

$$N = \text{boundary water pressure} = \gamma_w H \cos^2\alpha \ldots\ldots\ldots\ldots (7d)$$

and the resisting unit forces, which are shown by dashed lines, are: C equals unit cohesion, and

$$F = \text{frictional resistance} = (W_{tn} - N) \tan\phi = H (\gamma_t - \gamma_w) \cos^2\alpha \tan\phi \ldots (7e)$$



(a) INFINITE SLOPE (b) FORCE POLYGON

FIG. 14

Since $\gamma_s + \gamma_w = \gamma_t$, the seepage force plus the shearing component of the submerged, or buoyed, soil equals the shearing component of the total weight. For the same reason the friction components by the two methods are alike. The force polygon shows that the two methods give identical results. As before the criterion of failure is whether or not the sum of actuating forces exceeds the sum of the resisting forces.

The force polygon in Fig. 14(b) clearly indicates the effect of seepage. In this case seepage has added an actuating force of about the same magnitude as the gravity force since for most soils γ_s is close in value to γ_w.

The slope on the "West Side of Bernal Avenue," of course, is made much safer by the instalment of the "Arlington Street Drainpipe" (see heading, "Slides Due to Water Pressure: Bernal Avenue Cut Slide Corrected at Arlington Street"); but this added safety is provided by the removal of seepage forces, or differences of water pressure—not simply from the "release of water pressure." This is apparent from the fact that had the entire slope been submerged, although the water pressures have been increased, the slope would have been made more safe by this submergence than by the installation of the drain.

JACOB FELD,[5] M. ASCE.—The landslides reported in this paper are spectacular demonstrations of adjustments often occurring within soil bodies because of load changes or modifications of physical conditions. The internal adjustments result from (*a*) an increase in either static or dynamic loading externally, (*b*) a decrease in a lateral resistance or support, or (*c*) a modification of the soil constituents causing a decrease in physical resistance characteristics. Such internal adjustments very often do not exhibit any exterior result. When an exterior displacement becomes visible, it is called a landslide. However, the same phenomenon is encountered in engineering work and treatments similar to those described by the author become necessary even for cases which are not designated as landslides. For instance, when the fills in back of retaining walls or abutments settle because of either changes in external load or changes in internal characteristics, when structures and pavements along the side of railroad cuts and subway operations move either laterally or vertically, and when buildings constructed on hillsides or on filled-in ground covering sloping original surfaces show sign of distress—all these phenomena are landslides.

In general there are two types of correction: (*a*) The physical lateral resistance or support to a mass of soil can be increased by adding a retaining wall, sheet piling, or other structural additions; (*b*) further change of the physical make-up of the soil can be prevented by control of internal water, or by chemical injections, or by other methods that have been developed to alter the property of weak soils. For a number of cases in which building movements resulting from internal soil failures occurred, the methods of correction were published by the writer elsewhere.[6]

No general rules can be devised for sufficient and necessary methods of altering the physical characteristics of soils. Before any decision on such work can be reached, it is necessary to obtain complete information about the soils that exist in the locality; to know how these soils react with different moisture conditions under varying pressure and varying temperature; and to realize the effect of local chemicals that may be brought into the picture by the soil moisture. It is known that different chemical constituents in clays can be recognized and that the success of chemical control of clays depends upon the chemical constituents in the clays.

The effect of added absorbed moisture is described by the author (under the heading, "Landslides") as a weakening of the soil particles so that they cannot support loads. This is not always the case, as is exemplified in the description under the heading, "Shear Slides: Plastic Material at Market and Glendale Streets, San Francisco." The hydration of some soils retained within the materials which are not affected by water may increase the bearing capacity of the mass. This condition occurs when a formation swells from the absorption of water and integrates with adjacent layers. Some of these mixtures are similar to hardpans in their resistance to excavation.

Filling up cracks in clays overlying rock or other unalterable surfaces with rain water (under the heading, "Shear Slides: Earth Slide at Crolona Heights

[5] Cons. Engr., New York, N. Y.

[6] "Several Foundation Repair Jobs," *Proceedings*, Brooklyn Engrs. Club, April, 1930, p. 47.

in Crockett, Calif.") is identical with the cause of failure of basement walls built in clay areas if surface waters are not properly collected. In both the Hartford, Conn., and Detroit, Mich., areas, the writer has seen basement walls pushed in by the pressure of water filling in a narrow but continuous crack when clay backfill dried out and left a gap along the exterior face of the wall. The use of underground stone drains in soils of this nature is only a temporary correction, since the clay soils find their way into the stone and seal up the ground. The only solution is to eliminate the water.

In attempting to prophesy where slides, either of the spectacular type or of the equally troublesome internal adjustment type, may occur, it is necessary to have a complete picture of subsurface ground conditions. Trouble will almost always occur in areas where natural drainage channels have been buried. Near Newburgh, N. Y., where some fills almost 60 ft deep had been placed under proper supervision and by heavy equipment, an internal adjustment occurred quite suddenly, forming a crack similar to that resulting from earthquakes. Fortunately, the crack developed one day before a concrete pavement was placed on a prepared subgrade which had been tested for bearing capacity and had been approved. Borings taken of the soil adjacent to the point of failure indicated that an old drainage channel at the bottom of the fill was still in operation and that the material at a depth of 60 ft was too soft to obtain any kind of sample.

A reliable method of determining the nature, thicknesses, and direction of the slope of the subsurface layers of soil is by means of test pits. The cost of such procedure is much more than the cost of borings and the accuracy of the information obtained is proportionate to the cost of the two methods. In connection with the methods of determining subsurface conditions, it is difficult to agree with the author in his statement (under "Shear Slides: Costs of Corrective Works") that boring records and samples are of little value if they are not collected by an experienced geologist. In some soil locations, boring records are of little value regardless of who collects them. The presence of an experienced geologist does not increase the value of the soil sample which has been improperly taken. The writer has found a collective history of the vicinity and especially a comparison of maps showing topographical conditions over a period of years to be of great value. Such information has permitted the design of necessary corrective work for several subway operations in New York, N. Y., since the data indicated the direction and, to some extent, the amount of movement over a period of years. In this way artificial resistance can be provided to prevent incipient movement of adjacent structures. For instance, the record of surface elevations in the vicinity of 8th Avenue and the Harlem River in Manhattan (an area adjacent to the Polo Grounds) was a history of slowly decreasing movements in certain directions. Later excavations and test pits as well as borings provided sufficient information to prepare comprehensive subsurface maps indicating the slopes of the various layers. The movement predicted by this study agreed almost exactly with that found from the previous collection of data—on movement of monuments, amount of settlement of adjacent structures built at different times, and movements of streets. Movement of streets is not an unusual condition in cities built along

waterfronts where almost always the marginal streets are on filled-in ground. In such locations corrective methods are often necessary and the methods used by the author in the correction of landslides in the San Francisco Bay vicinity have yielded very valuable data.

George S. Harman,[7] Assoc. M. ASCE.—The Recreation Commission of San Francisco, Calif., from time to time has acquired parcels of land which, because of topography, instability, or both, are not particularly adapted to commercial or residential development. However, playgrounds, which supply a space for children to play in an otherwise highly congested district, can be built on these lands.

In designing a playground, the recreation profession and recreation leaders desire areas as large and with as few levels and terraces as possible. Thus, since San Francisco is a very hilly city, some heavy cuts and fills are necessary when grading a parcel of land for playground purposes.

When it became incumbent on the writer to determine engineering policy for developing such lands into playgrounds, it soon became evident that special knowledge in geology and experience in underground water were required. This need was filled when Mr. Forbes was employed as a consultant; and, since the writer followed the investigation and construction phases closely, he is most pleased that the unique conditions and methods used to solve the problem at St. Mary's Playground have been presented to the Society as a whole.

One of the principal benefits to be derived from the section on "St. Mary's Playground Slide" is the very practical approach to the solution of a problem of engineering geology in a hilly area with very complex soil and rock composition. The fact that investigation of the problem and remedial engineering construction work were combined in one project saved time, work, and money. The construction itself was quite novel in that it allowed the author to feel his way and to control the underground water as soon as it was encountered. Many ideas were considered in trying to overcome the slide conditions, but all of them were discarded in favor of the method used because neither the depth of the underground water nor the location of the source were known.

Precise surveys and levels over a period of a year after the work on St. Mary's Playground have shown that the slide has been stabilized, whereas, previous to construction, each winter the slide was moving progressively many feet south.

The author mentions briefly the cause of the sliding at James D. Phelan Beach. Before this site can be used as a recreational area, the slide must be totally stabilized and a sea wall constructed to control the sandy beach and to prevent undercutting by high tides and wave action. As the author states, the underground water is causing the underlying serpentine rock to deteriorate and to disintegrate into a blue clay, thus producing a slip plane. This disintegration is not apparent on the surface, but borings and preliminary investigation have shown that this is the case. Sufficient remedial work has been done to prove that this slide can be stabilized by properly controlling the underground water. However, the partial installation also showed that time and money can be saved by having the advice of a consultant geologist during construction.

[7] Engr., Recreation Comm., San Francisco, Calif.

ROBERT F. LEGGET,[8] M. ASCE.—The description, presented by Mr. Forbes, of a number of landslides typical of the San Francisco area is a most valuable addition to the published records of earth movements affecting civil engineering works. Since, as the author rightly observes (under the heading, "Correction Should Be Based Upon a Thorough Investigation")—"Each type of slide and each set of conditions will present a particular problem * * * and no general treatment can be prescribed"—it is impractical to offer any useful general comment upon the individual cases included in the paper. However, it is especially significant that serpentine is apparently predominant among the rock types encountered locally, being referred to (under the heading, "Shear Slides: Parker Avenue Slide in San Francisco") as "the serpentine bedrock of the region" and later (under the heading, "Detrital Slides: O'Shaughnessy Boulevard Slides") as "basic igneous dikes, principally serpentine." Accordingly, it is puzzling to read the author's statement (also under the heading, "Detrital Slides: O'Shaughnessy Boulevard Slides") that "There is nothing unique about the rock formations of the San Francisco Bay area that makes them particularly susceptible to the development of landslides * * *." In the strictly literal sense, serpentine cannot be described as unique, but it is encountered as bedrock in built-up areas so infrequently that this statement seems to require some qualification.

Serpentine has long been recognized as one of the most treacherous of rocks, at least by the civil engineer. The author himself comments (under the heading, "Detrital Slides: O'Shaughnessy Boulevard Slides") on "* * * the serpentine hydrates forming a clay which, with the further absorption of moisture, becomes a viscous mass moving down the slope * * *." (Presumably this is what is meant by the "landslide material" mentioned under the heading, "Shear Slides: Preventive and Precautionary Measures.") Very fortunately, there are few if any other varieties of solid rock which possess the undesirable features of serpentine. Therefore, it may be suggested that some of the earth movements so ably corrected and described by Mr. Forbes were due, at least in some measure, to a special cause—the presence of serpentine.

If this suggestion is true, it is even more difficult to draw any general conclusions from this study of selected cases. Despite such a limitation the author has suggested a classification of earth movements which has little to commend it as compared with previously published classifications.[9,10] Only unusual local circumstances could be held responsible for having led the author to make statements in the "Introduction" which are not quite in agreement with a large body of informed opinion previously expressed and recorded.

The great value of the factual descriptions presented by the author make the submission of any critical comment an invidious task. However, for example (see heading, "Introduction") it would be singularly unfortunate if it were recorded in the publications of the Society, without refutation, that "* * * most of the laws and experimental data in this field [soil mechanics] have been de-

veloped through the use of dry sand composed of from 95% to 99% stable silica." The contents of the *Transactions* of the Society alone suffice to question this assertion. Although, it may be true (see heading, "Introduction") that, in the San Francisco Bay area, "Sand is seldom found disassociated from silt and clay, * * *" there are at least a few other parts of North America where even this statement is not quite correct. Other statements in the "Introduction" could be questioned, and there would surely be few engineers who would urge the use of slope stability calculations "as a substitute for * * * thorough preliminary investigation of all other determinate facts." Rather such calculations can only be used in conjunction with a thorough study of site conditions. There are many valuable publications which substantiate this suggestion, of which only two need be mentioned—that by A. W. Skempton in 1945[11] and that by Alex Collin in 1846.[12]

With Mr. Forbes' emphasis upon the importance of ground water in many cases of earth movement, there will be very general agreement. Not the least valuable part of the paper, therefore, is the statement of actual costs for the several types of drainage installations used by the author. The actual records of drainage discharge are similarly interesting and show in no uncertain manner the significance of ground-water movement at the slides in question. When plotted graphically, the discharges show somewhat erratic correlations with rainfall records; it would be interesting to know the author's explanation of this condition. Water can affect slope stability in ways other than those outlined by the author. Another paper, published in 1945, gives useful relevant illustrations.[13]

Rush T. Sill,[14] Esq.—An extremely well-presented treatment of the causes of landslides and their correction is contained in this paper.

The writer had the opportunity to study and suggest corrective measures in a slide in which the movement took place along faults occurring in a large mass of homogeneous rock.

Water over a large surface area percolating through the soil entered the fault and softened the gouge material transforming it into softened lubricated mass on which the rock moved.

The spillway cut at the El Capitan Dam built by the City of San Diego, Calif., on the San Diego River, as a part of its water collecting and storage system, was made through the much faulted, fractured, and altered granitic rock which forms the north abutment of the dam. Along lines of rock weakness, fault, shear, and fractured planes, weathering had progressed, developing near the surface the boulder type of weathering so common to granite. The results of this type of weathering are boulders of almost fresh, unaltered granite surrounded by weathered and altered granite less durable than the boulders.

North of the dam area, in the spillway cut about opposite the west end of

the weir is a prominent fault striking north 16° east with a dip of 69° to the south. Some distance below the top of the hill, this fault had been cut by a steep westerly dipping shear plane, and Fig. 15 shows a slide of several hundred tons of the crushed material in the fault zone. This slide occurred soon after the excavation in the spillway cut had progressed below the westerly dipping shear plane.

A mass of rock estimated to be 150,000 cu yd rested on a westerly steeply dipping fault plane which extended southeasterly along the spillway cut from this fault on the north to a small gulley formed on a shear zone to the south end of the spillway cut and east 400 ft to the first prominent shear planes strike north 58° west dipping steeply to the north. The wedge-shaped block of ground was left unsupported on the lower or big end of the wedge by the excavation of the spillway (see Fig. 15). During construction, in the winter wet season, this block of ground moved approximately 6 in. down the westerly dipping shear plane, opening a series of almost continuous cracks over the crest of the ridge between the small gully formed on the north fault and the gully formed along the south shear plane.

Fig. 15.—View of Slide, North Abutment, El Capitan Dam, San Diego, Calif.

These cracks in the surface soil are from 2 in. to 4 in. wide and some of them can be followed for a distance of from 40 ft to 50 ft. Continued slippage would have resulted in the movement of this 150,000 cu yd into the spillway cut. Its subsequent removal would have been a very expensive operation. Had the slide occurred and the spillway been plugged during a flood, overtopping of the dam might have resulted.

It was recommended that this block of ground be protected by well-constructed ditches to keep the water from entering this fault plane to lubricate it with resulting possible further movement.

The El Capitan Dam is in a dry section of Southern California, and further movement of this block of ground has been arrested.

The following investigations were instigated by the contractors to classify the material in the spillway cut and to confirm the surface indications as to the cause of this movement.

Crushing, specific gravity, and percolation tests were made on samples of the partly decomposed granite surrounding the boulders. This was done to establish the classification into which the material fell—solid rock (ledge rock in place that cannot be loosened except by wedging, barring, or blasting); detached masses of solid rock more than 1 cu yd in volume; or earth, or overburden. Samples were taken from seven sections spaced approximately at equal intervals along the north face of the spillway, none of which were free of fracture lines and thin gage seams which greatly reduced their strength. For permeability tests, samples of rock were cut to a thickness of 4 in. These were placed in a circular side form composed of galvanized sheet iron; then a mortar composed of one part of Portland cement and two parts of sand was puddled around the stone, which gave a finished specimen in the shape of a disk 4 in. thick and 8 in. in diameter. The metal side forms remained on the disks during the tests. The specimens were placed in a moist room as soon as they were molded to insure proper curing of the mortar.

The disks were placed for testing between cast-iron top and bottom pieces of holders to bring water under pressure in contact with the upper surface, and to retain for measuring all water passing through the disk.

These castings were made to make contact or bearing with the disk for a width of 1 in. around the circumference; a small chamber for water was left both above and below the disk; the water was free to pass through the center of the 6-in. disk; and the castings were drawn together by tightening the six bolts in the flanges.

The upper cap was provided with a water gage and air vent; the lower cap had an outlet valve and an outlet tube leading to a glass tube graduated to cubic centimeters.

In testing, water was poured into the lower chamber; outlet valves were filled and no air was present. The outlet valve was closed so that any water passing through the disk was caught in the graduated tube. Water was then admitted to the upper cap, excluding all air. The reservoir was so arranged that the head of water was kept constant throughout the test.

Readings of the water level in the container were taken at 15-min intervals, and the amount of leakage calculated. The results of these tests (Table 3) show a porous condition of this weathered granite to depths of between 200 ft and 250 ft. Near the surface percolation rates of 1,149 ft per yr were obtained from sample 4C.

TABLE 3.—AVERAGE LEAKAGE RATE THROUGH TYPICAL SAMPLES

Flow, in cubic centimeters	Specimen 1B	Specimen 4C	Specimen 5A
For a head of 80 in.	206	2,967	388
Per hour	824	11,868	1,552
Per day	19,776	284,832	37,248
Per sq in. per day	695	11,508	2,763

In making the tests on voids in rock fragments, the rock was first crushed into particles passing a No. 4 screen. The sample was poured loosely into a

steel cylinder 6.17 in. in diameter and 7.93 in. high which was filled to about ½ in. below the top. A steel piston was placed on the rock fragments and brought to level bearing without pressure except its own weight; the specimen was placed in the testing machine and successive loads applied. After each load was applied and the piston had come to rest, measurements were taken of the height of the material in the steel cylinder. The increase of the load on the piston caused the rock material in the cylinder to be compressed; from the heights of the material in the cylinder, the volumes of the material at various loads were calculated; and the weights of the material per cubic foot were then calculated from the actual weight of the samples used. The apparent specific gravity of each sample (see Table 4) was determined by the "Standard Method of Test for Approximate Apparent Specific Gravity of Fine Aggregate" of the American Society for Testing Materials (A.S.T.M. C—68—30).

TABLE 4.—CHARACTERISTICS OF FINE MATERIAL

Description	Sample 1A	Sample 5C	Sample 6B
Specific gravity (approximate, apparent)	2.39	2.76	2.76
Percentage of Voids, Under Loads (Lb per Sq Ft) of:			
Piston only	44.46	44.16	43.54
2,500	44.76	43.12	42.85
5,000	43.74	42.50	42.22
7,500	42.93	41.91	41.74
10,000	42.18	41.30	41.32
12,500	41.49	40.89	40.99

The percentage of voids under each condition was determined according to the "Standard Method of Test for Determination of Voids in Fine Aggregate for Concrete" of the American Society for Testing Materials (A.S.T.M. C—30—22).

The soft decomposed granitic material from the spillway cut disintegrates rapidly when excavated and placed in the waste pile. In order to test the percentage of voids and apparent specific gravity of the material in the waste pile, parts of the rock samples 1A, 5C, and 6B were crushed to pass a ¼-in. opening. The compaction, under 12,500 lb per sq in., equal to a height of dump of 100 ft, varied from uniform grading of the crushed material, as shown in the screen tests. Grading of stone voids in the fragments before testing was made on all the samples from the north spillway cut, the results of sample No. 1 being as follows:

Sieve No.	Individual sieve	Cumulative
200	6.3	6.3
100	4.2	10.5
80	2.8	13.3
50	7.1	20.4
40	5.6	26.0
30	8.5	34.5
20	12.8	47.3
16	7.4	54.7
10	18.3	73.0
8	7.7	80.7
4	19.3	100.0
	100.0	

The weight per cubic foot was made on samples from the spillway cut as follows: Sample 5B, 136.66; sample 1B, 160.99; and sample 5C, 166.61.

The compression tests (see Table 5) were made on all the samples. Rocks with crushing strength of 388 lb per sq in., etc., represent material that can be excavated without blasting, but that in quarrying operations is drilled and blasted for economy and speed of operation.

TABLE 5.—SELECTED TESTS FOR TOTAL COMPRESSIVE STRENGTH OF STONE

Strength	Sample 4B	Sample 1B	Sample 5C
Pounds	38,220	38,220	10,380
Pounds per square inch	1,333	2,389	353

Where nests of boulders and hard-rock ribs are interspersed in this decomposed granite, it is necessary to drill and blast before excavating by a steam shovel, and should be paid for as rock.

EARL M. BUCKINGHAM,[15] Assoc. M. ASCE.—A very practical approach to a difficult problem is evidenced by the data in this paper, and it is not the intent of the writer to criticize the author for his excellent presentation. Rapid progress has been made in soil mechanics in recent years; much has been learned that is of value in slide investigation; but the fundamental problem is still one of determining the structure of the hill and the nature of the materials involved. Mathematical analysis has its place, particularly in dealing with slides that cannot be drained. However, in most cases the problem is simply one of locating and removing water. If this can be done, the increase in the strength of the soil will nearly always be more than sufficient to insure stability, and a stress analysis becomes merely an interesting academic exercise. No slide investigation is complete without a thorough determination of underground conditions, but it is frequently possible to simplify the boring program and materially reduce its cost.

Topographic Shape.—The landslide is a natural phenomenon, and one of the processes by which topographic forms are sculptured. An experienced topographer can frequently study the shape of the slide and the adjacent hillside and predict with considerable success the underground conditions that will be discovered by borings.

A long narrow shape, with movement approximately parallel to the original surface, indicates a shallow source of water, and a shallow bedrock which is also roughly parallel to the surface. (In this connection the writer broadens the term bedrock to include a firm and impervious clay.) Although it is easy to draw conclusions after the result is known, the St. Mary's Playground slide in San Francisco, Calif., appears to be typical of this class.

A broad sweeping curve at the head of the slide indicates a deep source of water, particularly if the outline of the slide is poorly defined and formed by a number of parallel cracks. This condition may be accompanied by a distinct rotary motion of the slide mass. The McKillop slide, in Oakland, Calif., shown in Fig. 16, falls in this class. The extreme breadth of the slide indicates either an unusually broad sheet of water or several more or less independent channels.

[15] Draftsman, City of Oakland, Oakland, Calif.

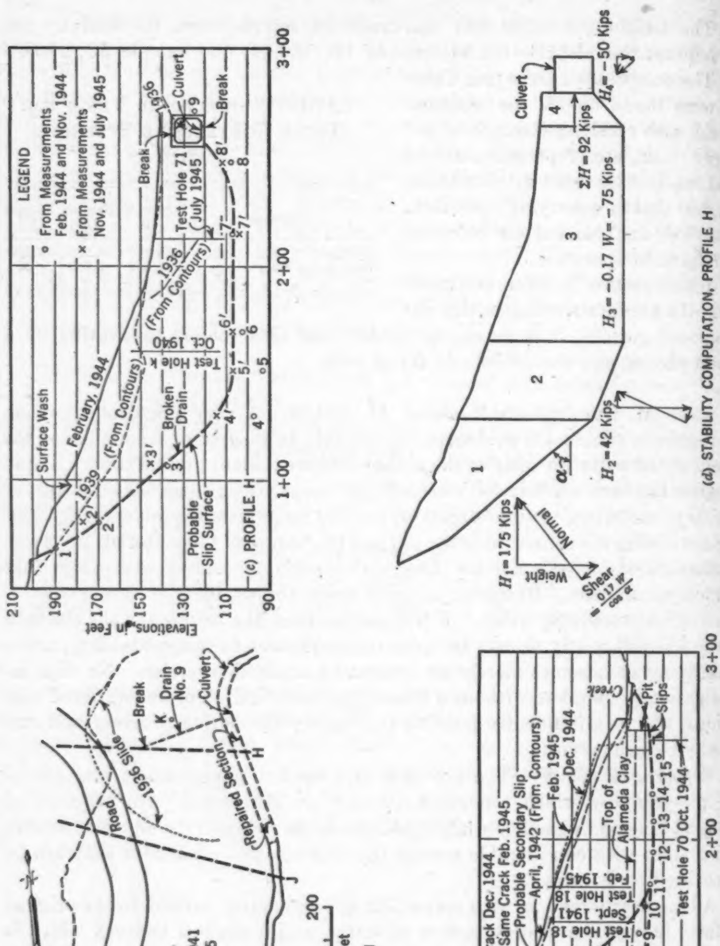

FIG. 16.—MAP OF MCKILLOP SLIDE

At least four separate deep channels were located by borings. The small apex opposite the north arrow indicates an independent shallow channel. Shallow water was found in the slide mass, and opposite this point in the next street to the west, but the connection was not followed through private property to the head of the slide.

The almost semicircular outline of the head of the Parker Avenue slide (San Francisco) indicates a deep and fairly concentrated source, located near a luxuriant growth of shrubbery about midway between the "5" of the 375-ft contour and the head of the loop of the 350-ft contour in Fig. 2. The depth below the original surface is confirmed by the extent of the movement that has occurred; but it would be interesting if the author could comment on the location and relative importance of the channels that he found.

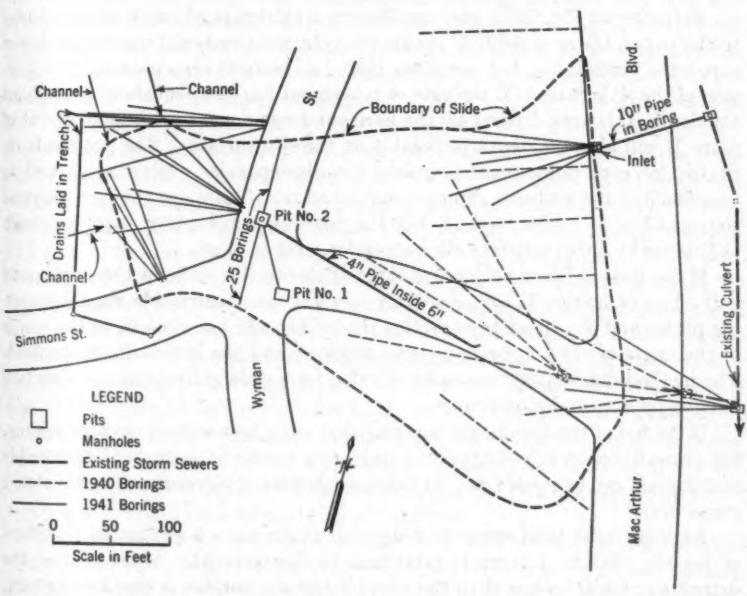

FIG. 17.—SIMMONS STREET SLIDE

A sharp apex forming the head of a slide indicates a narrow, shallow channel feeding into the apex. If the slide broadens considerably in the lower part, it is likely that either the slip surface is deep or there are other feed channels part way down the slide, or both.

Irregular embayments at the head of a slide are almost certain indications of more than one source of water; channels sometimes can be located within a few feet by this method alone. The Simmons Street slide, in Oakland, shown in Fig. 17, is a good example; the three channels shown were strongly suspected

before they were located by borings. The apparent embayment on Simmons Street above Wyman Street is an upheaval or secondary toe, and does not indicate a channel.

The terms "shallow" and "deep" are relative, of course, and must be considered with respect to the other dimensions of the slide.

Displaced Volumes.—Under favorable conditions it is frequently possible to compute the shape of the slip surface with a fair degree of accuracy from surface surveys. The method is by no means infallible, but the writer has found it to be of considerable value, and when it fails the error will usually be obvious. The field work consists of running one or more profiles as nearly as possible in the direction of the slide motion, using marked points, and repeating the measurements after an appreciable movement has occurred. The McKillop slide will be used to illustrate the procedure.

Referring to Fig. 16(*b*) and considering a thickness of unity perpendicular to the paper, the area ABB′A′ equals the volume of material which has moved across the vertical line B-4, provided there has been no expansion or consolidation of the slide mass. If the rate of movement has been constant throughout the depth, this area divided by the horizontal component of the movement of point B will give the depth to point 4 on the slip surface. The process is repeated for each point on the survey, the discrepancies evaluated as well as possible, and the probable slip curve sketched in. There are obviously several sources of error in the method, but the operator can rapidly acquire enough skill to make fairly accurate allowances for most of them.

If the slide is fairly uniform at right angles to the plane of the profile and if the line of motion is comparatively straight, any reasonable skew between the profile and the direction of motion should not affect the result, as the cosine of the angle of skew appears in both the area and the horizontal movement. The method does not appear to be of value for a slide of irregular cross section moving on a meandering course.

If the toe of the slide is not being carried away by a stream or other agency, the over-all change in volume of the slide mass can be determined; a reasonable distribution can be made from the evidence presented by open cracks, shattered areas, etc.

An important local error may develop at an abrupt change in the slope of the slip surface if there is rotational motion present. Movement of the survey point will be less than the mean if the slip surface is concave upward, and the computed depth will be too great. This condition is illustrated by points 5, 6, and 15 of Fig. 16(*b*) and 4, 5, 6, and 8 of Fig. 16(*c*). Rotation may or may not be relieved by the development of a vertical crack such as formed at C and moved to D (Fig. 16(*b*)), apparently breaking the slide into two blocks moving on different slopes. A similar condition developed on a smaller scale over points 4 and 5 of profile H during the second measurement period, and may account for the apparent lack of rotational effect on points 4′, 5′, and 6′. In the somewhat unusual case of a slip surface which is convex upward, it is possible that the computed points would be too high, although expansion due to tension at the surface might introduce another type of error.

If there are two or more major slip surfaces separated by any considerable distance, the motion will not be uniform and neither slip can be located by

computation. If the two slips join, the error will be localized, as at points 8, 9, and 10 of profile I. The occurrence of two or more parallel slippages within a narrow zone would not seriously affect the result; the computed position would fall between the actual surfaces and would be well within the zone of slippage. The existence of multiple slippages sufficient to cause appreciable error usually will be indicated by surface disturbances.

After the slip surface has been sketched, the result can be verified by a comparatively few borings. The major part of these can be sunk by ordinary drilling methods, with core samples required for only a few feet in the vicinity of the slip surface. As shown in Fig. 16, the check may be quite close. Point 2 of profile I is known to be too high because of a zone of multiple cracking at the head of the slide; if a similar allowance had been made at point 3, the sketched slip would have been very close to the known shear in test hole 20. The loss of depth of hole 18 is believed to be due to the infiltration of sand, and this well apparently does not reach the main slip surface. Point 15 is obviously too deep because of rotation at the toe; a smooth curve drawn from point 14 to the known toe in the creek passes directly through the upper of two slips found in hole 70. The checks on profile H are not so definite, but are reasonably certain. The broken drain was installed by boring, and may not be exactly on the theoretical grade shown. An abandoned culvert was encountered about 20 ft from the start; a note made at the time suggests the possibility of a downward deflection. Test hole k did not encounter the material in which the slip is known to occur, which merely proves that the slip is below the bottom of the hole. Hole 71 was driven with hand tools. It was nearing the limiting depth for the equipment when it encountered a shattered zone, very similar to one exposed in the pit in hole 70, extending through about 5 ft immediately above the slip surface. This was accepted as sufficient confirmation, and no attempt was made to reach the actual slip surface. If point 9 is disregarded because of a slight loss of volume due to incipient failure of the culvert, the slip drawn from point 8′ to the farthest measured surface movement intersects the culvert at a point which would account for an observed upward displacement of the left part of the failed section. It then continues up the original east bank of the creek, which would be a natural line of weakness.

Some confirmation was available for profile E from test hole 13, the behavior of drains 2 and 4, and from an exposure of the slip surface by creek cutting. Profiles G and J showed characteristics similar to the other profiles, and were accepted without confirmation.

The writer has had very little success in trying to fit circular arcs to actual slides, and therefore is not satisfied with the conventional methods of making stability computations. Most slip surfaces can be represented satisfactorily by a comparatively few straight lines and the section divided into prisms with plane bases. Then the only assumption necessary is the interfacial pressure between the prisms. The frequency of vertical shear displacements at important changes of slope of the slip surface indicates that the error in assuming this pressure to be horizontal would be comparatively small, particularly after vertical cracking has occurred. A force polygon can be drawn then for each prism, and the horizontal forces summed, as shown in Fig. 16(*d*). This procedure is not strictly correct in that the difference of elevation of the lines of

interfacial pressure has been neglected, but the simplification is believed justified.

The greater part of the slip surface of the McKillop slide lies in a very firm silty clay locally known as the Alameda clay, which underlies the hill just above creek level. This clay has a shearing strength of well over 1,000 lb per sq ft in its undisturbed state, but becomes very plastic when remolded. Shear tests, by both direct shear and unconfined compression on completely remolded material extruded from the slip surface at the toe of the slide, indicated a shearing strength of 0.17 times the reconsolidation pressure. The material overlying the Alameda clay at first appearance seems to be entirely different in character, but an examination shows that its clay content gives it similar shear properties. The value of 0.17 was used, therefore, for the entire slip surface. (It should be noted that the writer carefully avoids any use of the expression—

$$s = c + p \tan \phi \qquad (8)$$

—which he regards as an unfortunate mathematical coincidence. In Eq. 8, s is the shearing strength; c is cohesion; p is the normal pressure; and ϕ is the angle of internal friction. Expressed in this nomenclature the test results would have been $c = 0$ and $\tan \phi = 0.17$.) The unit shearing strength on the slip surface is 0.17 times the vertical pressure per unit area; the total shear for the prism is 0.17 times the total weight of the prism divided by the cosine of the angle of inclination of the slip surface. If this analysis is correct, the conventional conception of cohesion plus friction introduces an appreciable error on the side of safety, which may help to explain why the thin factors of safety in current use have not more often resulted in disaster. The writer was led to his conception of shear by the close agreement between the results of direct shear and unconfined compression tests. It is difficult to reconcile the unconfined compression test with a zero cohesion and a coefficient of friction; whereas a simple shearing strength determined by consolidation pressure (or consolidation history of an undisturbed sample) would seem to fit both tests.

A valuable check on the computation is afforded by the behavior of the culvert. Profile H, Fig. 16, was established in the direction of previously recorded movement, and is somewhat skewed with respect to the culvert. On the other hand it is quite probable that the thrust on the culvert is increased by an arch action from the mass of the slide, indicated on the ground by a series of cracks which disappear about where they cross the line of the profile. The profile crosses the culvert near the upper limit of the failed area, and the computed slide thrust of 92,000 lb per ft compares with a value of 93,500 lb per ft for the failure strength of the culvert. This seems to be well within the accuracy of any current method of determining the shearing strength of soil.

Horizontal Borings.—In fields of construction that have not become standardized the engineer must of necessity adapt his methods to suit available equipment and the skill and experience of local contractors. Whereas the author has developed a technique of wells connected by short tunnels, the writer has had considerable success with a machine for making horizontal borings. The essential part of the machine is a reversible air motor with a

hollow crankshaft which delivers water to a cutting bit through a string of hollow rods. When working in clayey material, it is capable of surprising accuracy, but is almost impossible to control in gravel. Progress is rapid, and in 1940 a 4-in. perforated pipe, in place, cost about $1.00 per ft for drains averaging 100 ft long. The cost increases somewhat for longer drains, and increases rather rapidly with the diameter of the pipe installed.

McKillop Slide.—The history of the McKillop slide illustrates several interesting processes of slide development. A competent observer reported topographic indications of considerable prehistoric movement of the northern part of the slide, between the culvert and the street. Cross sections taken prior to the construction of the street show a substantial gully at this point, which was filled by street grading. By 1935 the fill had been extended, presumably by loose dumping, far enough to permit the construction of three houses on the east side of the street. This overloading of the slope, possibly aggravated by some creek cutting, was sufficient to cause collapse during the wet winter of 1935–1936. Later in 1936, the culvert shown in Fig. 16(*a*) was constructed in firm ground along the east bank of the creek, and fill was placed to the height of the east bank.

At about this same time a small slide occurred in another filled gully on the east side of McKillop Road just south of the present limit of the main slide. This appears to be a superficial movement more or less independent of the main slide.

The loss of support due to the northern 1936 slide apparently caused a local concentration of stress sufficient to rupture the Alameda clay immediately south of the 1936 slide. Slow cracking of the houses on the west side of the street, progressing from north to south, indicated that this concentration of stress and consequent rupture traveled southward until it reached the small southern slide. These movements did not reach alarming proportions until the spring of 1940. During the summer of 1940 several drains were installed, and both of the 1936 slides were refilled in an attempt to buttress the slide mass. The culvert was located on developed property, and, therefore, it was not possible to place additional fill in that area. The corrective work was not successful; movement has continued to the present time, with the destruction or removal of all improvements in the area, including the partial failure of the culvert.

Drainage work included several trench drains in McKillop Road and a number of borings made from near creek level. A considerable volume of water was removed; attempts at drainage were abandoned when it was definitely determined that the major part of the slip surface was below creek level. The construction of a counterweight fill at the toe would require the condemnation of developed property on the east side of the creek, and does not appear economically justified. The culvert was considerably larger than required to carry the creek, and has been repaired by installing a steel plate liner backed with asphaltic concrete. There are indications that the slide is now (1946) heaving on the west side of the culvert and forming a new toe which may ride over the culvert instead of thrusting against it. In that case the present flexible culvert will probably not deform enough to cause failure.

Simmons Street Slide.—The Simmons Street slide (Fig. 17) developed in the winter of 1939–1940, and for two winters threatened to move across MacArthur Boulevard and block the main branch of U. S. route No. 50. There is considerable evidence that the slide was a renewal of an ancient movement of practically the same mass. A crack along the south edge of the slide and an upheaval near the southwest corner of Simmons Street and MacArthur Boulevard seemed to be duplicating a gully and knoll described by persons who had been familiar with the area before it was graded. If this former movement did occur it must have been very old, as all traces of a scarp at the head of the slide had disappeared.

During the summer of 1940 a number of drainage borings were made in the lower part of the slide, as shown by the dashed lines in Fig. 17. This work did not prove effective, and movement was resumed in January, 1941. This second movement was sufficient to outline the head of the slide definitely and to permit the location of the water channels shown, which were intercepted by a combination of borings and drains laid by ordinary trenching methods.

Two test pits were dug on Wyman Street and a line of test holes put down to establish the cross section of the slide. The deeper of the two pits was then drained by boring from a point on Simmons Street about 175 ft away. The boring was cased with a 4-in. pipe inside of a 6-in. pipe to provide a slip joint in case of further movement. The boring reached the center of the pit at a point about ½ ft above the planned elevation. It was planned to construct a shaft-and-tunnel drain across the slide, similar to the one described by the author at Burnham Street and 24th Street, but the one bid received was considered excessive. As a substitute twenty-five borings were made along the line of the proposed drain, working from a series of three stagings in the pit. In the critical places the borings were about 1 ft apart vertically, although staggered somewhat in plan. The cost of the work was approximately one fourth of the amount of the rejected bid, and the cutoff seems to have been complete. Some difficulty was encountered in sluicing the wash through the outlet boring. It would have been better to have deferred the installation of the inside 4-in. pipe until after the work in the pit had been completed had it been known that the cutoff would not be constructed as planned.

Additional test holes along the toe of the slide showed that the 1940 borings were not deep enough, and the outlet of the group in Simmons Street had been destroyed by the 1941 movement. A pit was opened over an existing culvert east of MacArthur Boulevard opposite Simmons Street and a new group of borings was made at a lower level. As the water in the north side of the slide was beyond boring range from the culvert it was necessary to bore from a pit over the culvert to another at the west curb line of MacArthur Boulevard and make the drainage borings from the latter. Since the drain connecting the two pits was required to carry surface water from the gutter, it was cased with a 10-in. pipe. Except as indicated, all other borings were cased with 4-in. perforated pipe.

Transit lines were established along all streets in the slide area in February, 1942, and remeasured at intervals until September, 1945, with no measurable movements detected other than those caused by local swelling of the clay soil.

This slide was stabilized before the method of displaced volumes was developed. It is somewhat irregular both in cross section and direction of movement, and exhibited a definite spreading action as it moved downhill. As both irregularity and lateral expansion introduce serious errors the method probably would not have been successful.

Barrows-Holman Slide.—This slide, which is shown in Fig. 18, is typical of several which have occurred in a rather limited area of Oakland. The tract was developed by the owners between 1922 and 1924. Apparently the fill on the north side of Holman Road was placed with very little compaction and no subdrainage. Minor repairs to sidewalks and drives on Barrows Road had been required for years, and considerable settlement had occurred along the north side of Holman Road; but major slide action was not recognized until the early summer of 1942. At that time the toe upheaval along Barrows Road was

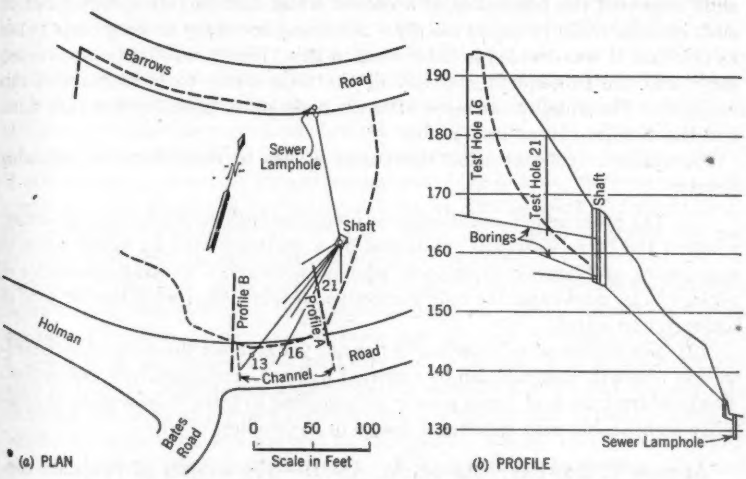

FIG. 18.—PLAN AND PROFILE, BARROWS-HOLMAN SLIDE, OAKLAND, CALIF.

fairly well defined although no serious damage had resulted, and the head of the slide on Holman Road was partly outlined by a series of sidewalk and driveway cracks not wider than 1 in. The adjacent settlement delayed, somewhat, the determination of the exact limits of the slide but the shape was well enough defined to point to a small area on Holman Road where the cracks extended into the street. As the original cross sections showed a fill of about 7 ft on the north side of the street it was obvious that a spring or seep had been covered and that the percolation of the dammed water through the years was responsible for the slide. A series of test holes along the street located the channel almost exactly as anticipated, even to its width. Several 8-in. wells were then drilled in the channel and plans were made for drainage. The greatest known depth of the channel was 28 ft, which would have made a trench drain long and expensive. Two profiles were established in the upper part of the slide, and, although the recorded movements were only a few hundredths of a foot, and therefore

scarcely larger than the inaccuracies of the survey, the result seemed reasonable. Test hole 21 (see Fig. 18) was then put down and the slip surface was found within a foot of the computed elevation.

As soon as financing arrangements could be completed, a shaft was excavated near one side of the slide to an elevation well below the slip, and drained by boring from Barrows Road. Borings were then made from the shaft to drain the channel and pick up such additional water as could be intercepted by a few random borings. The boring to hole 16, a distance of slightly more than 100 ft, actually intersected the well, and the drain pipe was clearly visible in the bottom of the 8-in. well. The boring to hole 13 (about 120 ft) was never seen from the surface, but welding fumes were quite strong at the well while the casing was being installed in the boring.

It was realized that the widening toward the west of the lower part of the slide indicated the possibility of a deeper water feed in this vicinity; but no such channel could be found readily. As it was necessary to keep costs as low as possible, it was decided to defer work in this vicinity until it became necessary; and the subsequent stability of the slide seems to have justified this decision. The slide was arrested after a movement of probably less than 6 in., and the damage caused was minor.

Conclusion.—In conclusion the writer wishes to emphasize the following points:

(1) The problem of landslides is one involving both geology and engineering, whether the investigation is conducted by a geologist with an appreciation of engineering problems or an engineer who has acquired a working knowledge of geology. In most cases the only corrective measure required is the removal of underground water.

(2) The science of soil mechanics has not yet reached the state of standardization where its methods can be accepted without careful analysis and review. The combined work of many men is yet required to bring it to a state of reliability comparable with structural design or hydraulics.

ALFRED V. BOWHAY,[16] Assoc. M. ASCE.—The subject of landslide correction is one that merits a complete review such as Mr. Forbes presents. It is of particular interest to those engaged in municipal engineering as well as in highway engineering.

The municipal engineer is vitally concerned because varied types of municipal improvements involve the removal of support through excavation and the deposit of materials in constructing embankments, both of which (through the action of moisture) are potential slide situations. With a better understanding of the action of the forces of nature, effective measures can be taken to prevent, or to minimize, the destruction of valuable public and private works. It is not within the scope of the civil engineer's practice in municipal engineering to apply any corrective measures other than ordinary drainage. The engineer is competent to study borings and strata so that drains may be placed at the proper locations and depths, thus insuring drainage of excess water. He is also competent to apply surface measures such as consolidation by rolling and

[16] Civ. Engr., Public Works Planning, Bureau of Eng., San Francisco, Calif.

the application of asphalt or cement coatings to divert surface drainage to the regular storm drainage system. In this manner the sliding material may be relieved of seasonal rainfall, and will have an opportunity to drain and dry out, so that it may again reach a state of stability.

Beyond this practice the civil engineer cannot reasonably go—especially in municipalities where only a few slides occur from year to year. In San Francisco, Calif., there have been some eight or ten major slides in a period of thirty years. This record is too limited to establish a standard norm of behavior. To obtain adequate knowledge of the causes and remedies, it is necessary to procure the services of a competent engineering geologist, experienced in the particular procedures peculiar to landslide correction. Such a geologist should have had experience on from fifty to one hundred landslides.

There is a technical aspect of the procedures of the geologist that Mr. Forbes mentions—namely, the tests, in the Crolona Heights slide, of plastic limit, liquid limit, and moisture equivalent. These tests indicate the type of soil or clay, the amount of surplus moisture, and, more particularly, the moisture retention qualities. Because of these factors, some ground loses its moisture by drainage so gradually that three or four years are required for it to dry out to a condition of stability. This slow progress toward stability, and the continued sliding after drains are installed, discourages engineers from trying to stop slides. However, a geologist, with wide experience, through knowledge of comparative conditions, can advise the correct type, number, and location of drains to suit the conditions that these tests indicate. Thus, dewatering or drying out can be reduced to the minimum time economically justified.

The correction of slides involves procedures of great interest to engineers because of the complexity of the problems involved. Often the land is worthless before the slide. There is little value in a cut slope, for example; and, after a slide occurs, the value of the land involved is reduced to a negative sum in most instances. Highway or street frontage must be cleared, and it is essential to repair the area to prevent a recurrence. The question naturally arises as to whether such work will warrant an expenditure greater than that necessary to clear up the debris. In this respect, "the wish is father to the thought," and the general thought is "perhaps it will not slide again." In nearly every instance, cities proceed on this basis. They clean up the debris, put in a minimum of subdrains, and repave or replace the improvement if possible.

The nominal cost of a geologist's services is well worth the public confidence it inspires. Public administrators cannot justify the expenditures frequently called for, except with the best advice obtainable. Even private individuals, homeowners, or those in charge of institutions threatened by slides cannot readily question the technical advice of an engineering geologist, as they quite often question proposals by engineers, made without the benefit of geological study and advice.

The term "maintaining a slide" appears to be on the facetious side, but to maintain a slide has been found to be a necessary and often valuable procedure. In the Laidley Street slide, one of the first major correction jobs of the City of San Francisco, after the drains were installed, the surface was smoothed and rolled with a heavy tractor (used because of a grade of about 20%) and then

given a coating of about 0.5 gal of heavy road oil per square yard. This surfacing acted as an umbrella, and it shed the water to the foot of the slide where it was conveyed to the storm sewer. Naturally in a few years the surface deteriorated, and insufficiently compacted pockets developed; but, by regular annual inspections and study, the conditions were noted and remedied. It was even observed that there were points where additional drains should be installed.

A part of the maintenance work is to keep a discharge record of the drainage system. This record is important in connection with observations of rainfall. Reference stakes that show the progressive horizontal and vertical movement must also be maintained and observed. The study of these data gives valuable aid in improving design by such measures as added drains and improved surfacing, as well as in showing the degree of improvement produced by the corrective work.

It seems advisable to direct attention to the possibility of prescribing general treatment, which Mr. Forbes indicates cannot be done (see heading, "Correction Should Be Based Upon a Thorough Investigation"). Since 1926 the City of San Francisco has used the general treatment of drainage by the construction of ditches with the familiar perforated metal pipe. Later on this drainage was accomplished by chimneys. These chimneys or vertical drains are usually extended downward to a nearly horizontal drain, where the usual metal pipe and rock backfill is installed. This type of drainage was installed in the Parker Avenue slide in San Francisco as reported by Mr. Forbes. The design of the Parker Avenue slide drainage system was prepared by, and under the immediate direction of, the writer. This system was the first of its type, subsequent to which the 3.5-ft by 6-ft drain tunnel was replaced by a very small tunnel (minimum 15 in. by 15 in.) connecting the bottom of the shaft. The latter work was done on the O'Shaughnessy Boulevard slide (see Table 1 and supporting text) also in San Francisco. A perforated metal drain with crushed rock backfill is usually installed in this small temporary tunnel. Lately the shafts have been increased in size to 4 ft by 5 ft, so that they could be timbered and still admit a small clamshell bucket. The cost of this type of shaft is less than that of the 36-in. circular shaft, the excavation for which is all handwork and requires a metal 36-in. shell for lagging. The 36-in. shell sometimes cannot be recovered during the placing of the center drain and rock backfill, generally constructed to within a few feet of the surface.

A great advantage of this general procedure is that a suitable contract can be drawn so that competitive bids may be taken. Quantities can be determined satisfactorily in advance, necessitating a minimum of change in the actual work. This change is always well within the 10% allowance for extras, the limit required by city ordinance. Of course, this contract preparation must be preceded by borings (by contract) and sample studies and tests. From such data, profiles and sections of the strata can be made for study so that, as Mr. Forbes states, corrective works can be designed to meet these determined elements of the problem.

The nine classifications presented in the "Synopsis" are interesting, although they appear to overlap slightly. No doubt there is ample geological reason for differentiation. However, of particular interest is "(1) a shear slide in

which hydrostatic uplift on an unbalanced slope resulted in mass movement of the unconsolidated slope material." This class of slide is further subdivided under the heading, "Landslides"): "Shear slides are frequently associated with the unbalanced slopes that remain after material has been removed from natural slopes." Although Mr. Forbes does not apply this type to the Parker Avenue slide, there were many persons who did. The idea that the particular slope in question was unbalanced, or that there was an unbalanced condition, seems to vitiate the theory of safe slopes, which is still popular in the practice of highway engineering. Under the theory of safe slopes, certain materials will stand at a slope of 1 on 1, others on a slope of 1 on 1.5, and the most unstable excavated materials on a slope of 1 on 2. On Parker Avenue these slopes stood at a slope of 1 on 0.5 for nearly fifteen years. There was some seepage which was provided for, showing a wet ground condition. However, it could be concluded that the slope was safe, particularly on the Lone Mountain side of Parker Avenue, which had a concrete and brick pavement, 35 ft wide. Across Parker Avenue, in a sidehill situation, was the low slope of the cut which was removed or "daylighted" during the subdivision work. This construction was claimed to have unbalanced the material across the street and up the hill. If this were true, then the material could not have been classified as safe for a slope of 1 on 0.5 fifteen years previously. Actually, unbalancing was not a primary factor in this situation, but it was a minor factor in resisting hydrostatic uplift.

In the Parker Avenue slide, water was the primary factor, as the millions of gallons drained from the slide annually will attest (Table 2). The material was stable but highly absorptive, and had a high retention value. There was also the familiar slipping plane of plastic material, which had no resistance to sliding when wet. The great mass of saturated material had an unusually heavy weight, the resultant of which was parallel to the slope of the sliding plane. The weight of the counteracting dry material, which was similar to that of a dam, held this resultant force of the wet material stable. As the saturation extended down the slope, and the slipping plane became further lubricated, the resistance of the dry material to sliding became so low that, like a poorly designed dam or retaining wall, it was thrust aside. The plan of the slide, as well as the photographs, shows this lateral movement. The apparent uplift resulted because the slipping plane turned upward and the material was also thrust upward along this plane. The plan also shows the trend to the northwest of the gulley which formed the bed of the slipping plane.

Unbalancing, therefore, entered into this slide problem only in the sense that the weight of counteracting material, acting as a dam, may have been reduced. The heavy weight of the wet material, and the moisture-lubricated slipping plane of plastic character were the prime causes of movement, which could have occurred whether the excavated material was or was not removed. Slide problems will be more clearly understood if this distinction is kept in mind. Although engineers may speak of slopes in balance and discuss them in such a manner, actually in engineering problems of this kind they are referring primarily to the forces that are in balance.

One of the more important factors in the solution of slide problems is the force that resists sliding. As usual, this force depends on the weight of the

resisting material and the coefficient of friction, which is naturally very low when the sliding surface lies along or within a seam of wet plastic material.

Landslides not only damage highways, streets, and public works, they also damage homes. Some fortunate homeowners can remove their houses to a more stable location. The remaining foundation on private property rapidly deteriorates and becomes a public nuisance and eyesore, a kind of testimonial of the inability of the community to cope with the situation. The less fortunate homeowners, whose houses are so badly wracked and damaged by the slide action, generally appeal to the local governing agency for help or assistance. This help the local agencies, supervisors, or councilmen feel obligated to give. The repairs or replacements are too often makeshift in character because temporary measures are popular in slide correction. Thus, most of the slide areas become not only vacant land but also eyesores. This is a poor testimonial to the engineer and his ability to sell his measures toward a more complete remedy.

More education and enlightenment are needed on this subject. Engineers and engineering geologists must collaborate to convince their communities that these eyesores can be corrected, and that the cost of the remedies is not out of proportion to the benefits. Then one may look forward to less disfiguring areas in the rapidly growing modern cities and along the modern highways of the United States.

D. P. BARNES,[17] M. ASCE.—A wide variety of landslides, together with an explanation of the success achieved by various remedial measures, is discussed in this interesting and practical paper.

The tendency of water to precipitate an earth movement can be explained in different ways. As in so many analytical matters, the choice of a suitable illustration with which to begin the analysis may mean the difference between a simple concept easily applicable to practical cases, or a complex concept with little useful application.

An illustration that appears to have some merit in providing a simple concept of the forces exerted by seepage water is that presented in Fig. 19. Con-

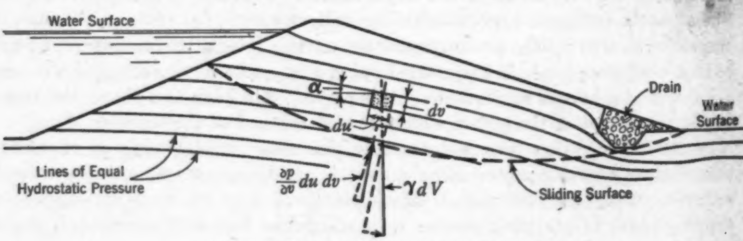

FIG. 19.—SEEPAGE FORCES IN AN EARTH DAM

sider the equilibrium of a soil prism of convenient length, du, and width, dv (thickness unity), with sides parallel and perpendicular, respectively, to lines of equal pressure. The soil in the prism is restrained on all sides by the contacts between soil particles and is acted upon by the hydrostatic pressures and

[17] Engr. Asst. to Asst. Chf. Engr.—Civ., Branch of Design and Constr., U. S. Bureau of Reclamation, Denver, Colo.

its own weight. The water in the prism is acted upon by hydrostatic pressures, by the resistance of the soil particles to change in hydrostatic pressure, and by its own weight.

Isolating the prism, with its soil and water content intact (see Fig. 20), and applying the general equations of static equilibrium, the forces transmitted from the water to the soil are readily determined. For static equilibrium (that is, assuming that no masses are being accelerated), the sum of the components in any direction of all the forces acting on the body must be zero.

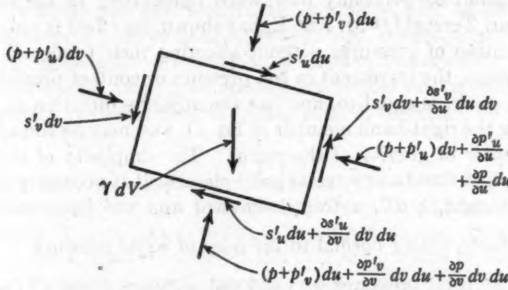

FIG. 20.—ELEMENTARY SOIL PRISM

Let p be the hydrostatic pressure; p' be contact pressure between soil particles; s' be the contact shearing stress between soil particles; V equal the volume of the soil prism; and γ equal the wet unit weight of soil. Adding the components in the u-direction, therefore, yields:

$$\frac{\partial p'_u}{\partial u} du\, dv + \frac{\partial s'_u}{\partial v} dv\, du + \frac{\partial p}{\partial u} du\, dv + \gamma\, du\, dv \sin\alpha = 0 \quad \text{.....(9a)}$$

or, since $\frac{\partial p}{\partial u} = 0$,

$$\frac{\partial p'_u}{\partial u} dV + \frac{\partial s'_u}{\partial v} dV = -\gamma \sin\alpha\, dV \quad \text{..............(9b)}$$

Similarly, considering the components in the v-direction:

$$\frac{\partial p'_v}{\partial v} dv\, du + \frac{\partial s'_v}{\partial u} du\, dv + \frac{\partial p}{\partial v} dv\, du + \gamma\, dv\, du \cos\alpha = 0 \quad \text{.....(10a)}$$

or

$$\frac{\partial p'_v}{\partial v} dV + \frac{\partial s'_v}{\partial u} dV = -\frac{\partial p}{\partial v} dV - \gamma \cos\alpha\, dV \quad \text{..........(10b)}$$

The right-hand members of Eqs. 9b and 10b represent the forces acting on the prism due to gravity and to changes in the hydrostatic pressure. Adding the equations vectorially yields:

$$\left(\frac{\partial p'_u}{\partial u} dV + \frac{\partial s'_u}{\partial v} dV\right) \oplus \left(\frac{\partial p'_v}{\partial v} dV + \frac{\partial s'_v}{\partial u} dV\right)$$

$$= -\gamma \sin\alpha\, dV \oplus \left(-\frac{\partial p}{\partial v} dV - \gamma \cos\alpha\, dV\right) \quad \text{..........(11)}$$

The right-hand and left-hand members, however, need be concurrent only if $\frac{\partial s'_u}{\partial v} = 0$, and $\frac{\partial s'_v}{\partial u} = 0$, which is unlikely. (The sign $\oplus$ in Eq. 11 indicates a vector sum.)

In making a graphical analysis, it is convenient nevertheless to neglect $\frac{\partial s'_u}{\partial v}$ and $\frac{\partial s'_v}{\partial u}$. The error of this procedure is of the same character as that introduced by assuming, in the absence of percolating water, that the weight of the soil is transmitted vertically downward indefinitely in the same line of action. As Karl Terzaghi,[18] M. ASCE, has shown, its effect is only to cause a slight redistribution of pressures without affecting their total. For practical purposes, therefore, the increment in soil pressure or contact pressures through the soil prism, *du dv*, is equal to, and has the opposite direction to, the vector sum comprising the right-hand member of Eq. 11, and may be considered to act through the center of gravity of the prism. The simplicity of this approach arises from the fact that in any rectangular element it is necessary to deal with only the wet weight, $\gamma\, dV$, acting downward and the hydrostatic pressure difference, $\frac{\partial p}{\partial v}\, du\, dv$, acting normal to the lines of equal pressure.

To obtain the total pressures between soil particles along a typical sliding surface in an embankment, therefore, it is necessary only: (*a*) To divide the area intercepted by the sliding arc into convenient finite rectangular elements, (*b*) to determine the forces exerted by the hydrostatic pressure difference $\left(\text{corresponding to } \frac{\partial p}{\partial v}\, dV\right)$ from the equal pressure lines and the forces of gravity from the wet weights, and (*c*) to add their several effects vectorially. In Fig. 19, the forces $\frac{\partial p}{\partial v}\, du\, dv = \frac{\partial p}{\partial v}\, dV$ and $\gamma\, dV$ are shown projected to the sliding surface and there resolved into their tangential and normal components.

It would seem that the mere presence of water, except in so far as it may affect the cohesion or coefficient of friction within the soil mass, is not a direct indication of an increased susceptibility to sliding. For example, on the upstream slope of an earth dam through which water is percolating toward the downstream drain, the action of the water is to shift the resultant of all the forces acting on a prism of soil slightly downstream from vertical, and, thus, to reduce the components tending to produce sliding in the upstream face. The downstream face, however, toward which the water is flowing, has an increased tendency to slide as a result of this same shift in the resultant of the forces acting on each soil prism.

The case of submergence without flow can be deduced by an inspection of Fig. 19 if it is imagined that the downstream water surface is raised to the level of the upstream surface, and that the lines of equal hydrostatic pressure are correspondingly rotated to their normal horizontal position as found in any body of static water. The resultant forces on the soil prism become con-

[18] "The Mechanics of Shear Failures on Clay Slopes and the Creep of Retaining Walls," by Karl Terzaghi, *Public Roads*, December, 1929.

current and vertical, and the forces tending to oppose sliding, while reduced, bear the same relation to the frictional resistance to sliding as before.

Most cases with which the engineer or geologist is likely to deal, with the sole exception of artificial embankments constructed for the purpose of impounding water, will, nevertheless, probably resemble the examples cited by Mr. Forbes in that the presence of water will contribute significantly toward the danger of movement. It may well be, also, that, although an approximate analysis of the case of static submergence indicates no increase in susceptibility to sliding, for many practical construction problems such as those encountered in the installation of piers or underwater footings, the secondary factors such as reduction in cohesion or in coefficient of friction and swelling may outweigh abstract conclusions. Any predictions with respect to susceptibility of a completely inundated embankment to sliding should, therefore, be attempted with caution.

HYDE FORBES,[19] M. ASCE.—The discussions have presented material and considerations which will point the way for the application of methods of landslide investigation and correction developed in one region to conditions obtaining in other regions—which is the primary purpose of the preparation of the paper. Professor Legget states that the writer placed emphasis on the development of instability of San Francisco (Calif.) areas due to the presence of serpentine, yet states that the rock formations are not unique. Large areas in San Francisco are underlain with serpentine and are stable, providing sound foundations. The writer had in mind the fact that all rock disintegrates and decomposes under certain conditions, the ultimate product of that decay being largely hydrated material—clay.

Rock containing a high percentage of magnesian minerals has an affinity for water which gives it a tendency to hydrate. This characteristic makes the peridotite of the San Francisco area a ready subject for metamorphism into serpentine, and its surface is subject to comparatively rapid geochemical change when in contact with water. Other common basic igneous rocks such pyroxenite, diabase (Market and Glendale slide), and some gabbros have exhibited metamorphism and extensive decay; sedimentary formations (Crolona Heights, Bernal Avenue cut, and approach to Broadway Tunnel) develop a blanket of clay that becomes unstable with the absorption of moisture. The adaptation of the methods described to areas of unstable clay accumulation is believed possible regardless of the origin of that clay. Test boring and sampling has shown clay to resist penetration and become consolidated to a greater extent with depth below its surface. Clay becomes stabilized by the drainage of overlying or underlying materials, or by the substantial reduction of the time the clay surfaces are exposed to water, together with provisions for drying the clay.

It is of value to know that the horizontal borehole method of installing drainpipe, described by Mr. Buckingham, has been effective in arresting slides in Oakland, Calif. The method is particularly adapted to tap water under "channel" conditions and the ability to locate such channels appears to be the important factor. The writer used that method successfully to tap free water

[19] Cons. Engr. and Geologist, San Francisco, Calif.

in fairly coarse granular materials in a gully under a fill. The base of the fill had become saturated and the fill was sloughing. In a similar situation, in fine dune sand, the perforations of the drainpipe soon became clogged and the diffused ground water continued to accumulate. The limitations of the percolation or drainage area presented by a small diameter pipe where ground water is diffused through the material, and the possibility of clogging when installed through plastic clay, made the method not applicable to the conditions found to exist in the clay involved in movement at most slides examined. The clay could only be stabilized through drying out, as described as a function of the shafts installed (O'Shaughnessy Boulevard slide).

Mr. Bowhay discusses the "maintenance" required in the earlier work done by the City of San Francisco in connection with landslide correction and stabilization. The object of the later work described by the writer was to avoid such maintenance and to provide permanent stabilization, which seems to have been accomplished. The point is well made by Mr. Bowhay that expedient or temporary measures are never satisfactory, and they are subject to criticism and complaint by taxpayers when eyesores or hazards continue to exist. The design of the slide correction works on Parker Avenue followed the recommendations of the consultants who had been investigating and observing conditions for a period of about one year but were not retained during the design and construction operations. Subsequently, the procedure of advisory and supervisory employment outlined by the writer (see heading, "Continuing Investigation During and After Construction") was adopted by the engineering department. In regard to the future improvement of Parker Avenue, it is believed the necessary extensions can be made at far less cost per unit of length than that of the original work. Mr. Feld emphasizes the advantages of test pits over borings in determining subsurface conditions. It is true that there are advantages; and the continued observations of those conditions in shafts excavated as part of the slide correction works described has revealed necessary modification of original plans based on preliminary investigation. This has also resulted in savings in cost below original estimates.

The lack of correlation of drain discharge from various slide areas with the San Francisco rainfall record noted by Professor Legget was, in part, attributed (see heading, "Preventive and Precautionary Measures") to the increase in effective radius of the works with time, as natural subsurface channels are developed to carry water toward them. In certain areas a decrease in the discharge has been noted as the materials are dewatered. Becoming more compact or consolidated, the surfaces tend to shed the water that falls upon them rather than to absorb it. In further answer to Professor Legget's discussion, the writer's reference to the development of certain laws and values through the use of dry silica sand applied to the treatise by William Cain[20] presented in 1916, using the theories of Rankin and Coulomb in relation to the factors of cohesion and internal friction.

Values had been determined experimentally, for these factors, in connection with clean sand. The writer has been impressed by the number of abstract considerations presented since which were adaptations of that treat-

[20] "Earth Pressure, Retaining Walls and Bins," by William Cain, John Wiley & Sons, Inc., New York, N. Y., 1916.

ment involving those two factors. Values for cohesion and internal friction had been assigned arbitrarily within the range of those determined by Mr. Cain, or through experiments made on samples, the approach being in part theoretical, in part experimental, or, frequently, a combination of the two. The criticism has been made that geologists lack the training in mathematics and mechanics necessary to comprehend such treatment fully, but empirical methods of stability analysis as applied to materials in natural occurrence have been questioned by geologists because nature does not act in an empiric manner. The factors of cohesion and friction are not static, being affected by slight changes in moisture content and, principally, by the continued geochemical change occurring within a body of material.

Mr. Barnes recognizes this as he states, "* * * the secondary factors such as reduction in cohesion or in coefficient of friction and swelling may outweigh abstract conclusions." The colloidal silt and clay particles present or developed in accumulations of sand or other natural material tend to lessen internal friction and, being favorable to absorption of moisture, may render it more cohesive or unstable dependent upon the amount and the mineral character of such material and its absorptive capacity. Water percolating through sand separates the grains, thus reducing friction; and its presence tends to facilitate a change in form from crystalline or fragmental to the amorphous or hydrated form. Mr. Feld enumerates, as one of the internal adjustments causing landslide displacement, "(*c*) a modification of the soil constituents causing a decrease in physical resistance characteristics." Such modification is due to geochemical change and the point the writer wished to make was that the change is continuous.

The admonition for caution in the use of mathematical solution for stability problems, commented upon by Professor Legget, resulted from the writer's experience. Called upon to investigate landslide and other conditions of instability and present findings in court in connection with claims for damages, the writer has been confronted with mathematical computations, asserted to be supported by texts or other publications and to prove the effect of certain acts. In one case a slide occurred because of geological conditions affected by a long period of unusual rainfall. The court took judicial notice that the same conditions generated numerous slides in the same region during the same period. Quoting from the decision of the judge:

> "The expert testimony of Mr. Forbes, together with his factual observations of the locality in and around the slide, afford an adequate and scientific explanation of the cause of the slide, with which the court is in accord and to which it gives credit."

In another case involving a claim for damages in a condemnation suit the decision of another judge stated:

> "I am not at all in accord with defendant's witnesses. I do not believe the big slide * * * was due to excavations of the plaintiff. I believe it was due to natural causes, including the steep slope of the ground, the character of the soils, the rains, and the drainage. * * * the description [by the plaintiff's witness] of the geological conditions of the areas under examination, and reasons for the slips and slides there found, seemed to me to be essentially sound."

Mr. Buckingham points out that landslides are the natural "processes by which topographic forms are sculptured," and the writer has found the cause to lie more often in geologic reasoning based on investigation, which was the basis of the decisions cited, than in abstract consideration of the effect of near-by work. One of the San Francisco slides was treated theoretically, values of unknowns being determined experimentally on samples of the material taken from the slide, and a mathematical solution of the factors and evaluation of the acts generating the slide was published in a bulletin of a public agency. The writer was later employed to investigate the slide and recommend methods of correction. That investigation revealed the slide to have been generated, principally, through ground-water accumulation and uplift, which were not considered in the published treatment. The writer appreciates the value of abstract treatment of stabilization problems, as well as the limitations; he studies the problems and frequently uses them as a tool in analysis and, much less frequently, in making graphic presentations to illustrate the principles involved and the reasoning followed in the design of works for which he recommends the expenditure of money. Also, in order to obtain some idea of the safety factor the works provide, the writer adopts the abstract treatment, with the revision of values assigned to unknown factors as he "believes" they may become changed through the installation of works. He does not use it as a substitute for adequate geological investigation, however. Mr. Buckingham's comment in this regard finds the writer in full agreement. The writer's comment has been previously presented.[21] The uncertainty in applying the results of laboratory determinations of values to field conditions lies in the fact that it is never true that a body of natural material will exhibit uniformity of physical properties consistent with tested samples; nor will those properties remain constant for any considerable time.

Mr. Lambe presents an interesting treatment in relation to the effect of submergence which, in some respects, is confirmed by Mr. Barnes' analysis. In that connection, it may be of interest to note that a subaqueous landslide is a common occurrence. The foundation for the south pier of the Golden Gate Bridge was originally planned as a caisson to be sunk and landed at a predetermined depth below rock surface. Excavation was carried on within a prescribed area into which the caisson was to fit and the caisson was built. When the matter was referred to the writer by the contractor's engineer, it was estimated that about twice as much material had been excavated from the subaqueous site as could be accounted for by the volume of material within the boundaries of the excavated area. Divers were sent down and found that landslides had occurred from all sides. The caisson was abandoned, towed out to sea, and sunk, and a new foundation was designed to fit the conditions resulting from the sliding walls of the excavation. The problem of possible underwater slide shearing structures was presented in connection with the intake towers at the end of the new (1945) adits for the San Andreas Reservoir (Crystal Springs Lakes) of the San Francisco Water Department. Many alluvial fans and detrital accumulations on the floor of the reservoir were found to have suffered landslides with saturation on submergence, and these old slides

[21] *Transactions*, ASCE, Vol. 110, 1945, pp. 340–341.

were revealed when the reservoir water level was lowered. The slide surfaces were examined and the slopes found to be as flat as 1 on 2½ to 1 on 3. Similar material surrounding the towers was graded to those slopes, therefore, before the water level was raised again.

Slide analysis on the basis of displaced volumes described by Mr. Buckingham has its value as well as its sources of error. The moving mass most generally breaks up to a number of units horizontally and seldom is the movement uniform in rate from top to bottom. A large slide along Camino del Mar, the scenic drive following the Golden Gate in San Francisco, was investigated in 1946. Certain lower areas of the slide exhibited movement at rates in excess of those taking place in adjoining areas, due to a higher moisture content of the clay, and so that striated scarps were left as banks to each "glacier-like stream" of clay. During the winter 2-in. pipes were set in boreholes, and carried through the displaced fill, underlying sand, and clay into bedrock in some instances, and in others ending in the clay above bedrock. By late summer the pipes reaching into rock had been sheared at rock line and those ending in clay were dragged so their projecting ends pointed up the slope; the clay in which they were landed moved at a faster rate than the overlying sand and fill. The maximum thickness of moving ground was 125 ft, composed of 35 ft of fill, 35 ft of moist sand, 10 ft of saturated sand, and 45 ft of clay. The latter was the plastic product of the decomposition of the bedrock which had accumulated to that thickness in the bottom of a bedrock gully through movement from the sides and down the slope of the gully. Such differences in rates of movement are important in the location, depth, and type of stabilization works selected. The effect of movement on the many observation pipes set in the Parker Avenue boreholes showed that the moving mass was separated vertically in horizons of varying character of material and varying groundwater conditions, each horizon with a distinct character and rate of movement; all horizons had to be drained and stabilized down to bedrock. This has been usual and the stabilization works have been carried into the bedrock and drainage pipes have been set in that rock in most of the installations. That is an added reason why the horizontal borehole treatment does not apply to the slides discussed, although successfully applied to the Oakland slides described by Mr. Buckingham.

Mr. Feld adds greatly to the value of the paper in citing the application of drainage methods to conditions of instability developing within a body of material, although exterior displacement, or landslide, does not result. Mr. Feld agrees with the writer as to the necessity of obtaining a complete picture of subsurface conditions and it is evident that he has a good understanding of geology and geological phenomena; but he finds it difficult to agree with the writer that boring records and samples are of little value if not collected by an experienced geologist. It is probable that the writer did not make himself clear on the point.

Since about 1917 contractors and engineers have submitted for interpretation, driller's logs, in some instances accompanied by samples and frequently attached to specifications. Such material was of no value, except when taken from localities familiar to the writer through previous work or in

connection with structural requirements which presented simple problems, as it was impossible to produce an interpretation having the reliability necessary when a contractor is to risk his money in making a bid, or upon which an engineer must depend in design; and the services sought had to be refused. In years past, the City of San Francisco has let many contracts for boring which produced only driller's logs and bottled samples and for which there was left no record of interpretation. The writer has found, and wishes to convey in his statement, that a geologist experienced in problems presented, which require further subsurface information, after making a careful study of the surface conditions and history of the locality in question and its vicinity, can direct the location of a minimum number of borings or test pits to produce the maximum working data. During the progress of drilling and sampling, he can observe mechanical actions which are informative; he can determine ground water and soil conditions at sufficiently close intervals so that he can project ahead and tell drillers and inspectors what to watch for and note during his absence; and he can make current geological interpretation while matters are fresh in mind. The saving in cost of exploration in such instances has more than covered the cost of services rendered and the results obtained have been used with confidence which proved warranted. Mr. Harman mentions the value of geological investigation and direction of work in accordance with the results of such investigation; but an amplification of his experience with landslide correction and stabilization work on city-owned land conducted as "relief projects" would have explained his views.

Mr. Buckingham presents the reasoning he follows in the analysis of landslides through surface topographic features. As a rule much can be derived from such observation, but the exceptions are important, and occur frequently enough to make subsurface observation a requisite. No evidence was found that sliding had occurred on the slope at St. Mary's Playground before the the fill was placed. The fill compressed the soils through which water previously passed freely down the slope; pressure was developed and the fill slid out of place. At Parker Avenue the uniform sand slope of Lone Mountain gave no evidence of the underlying bedrock gully. Water was found in disintegrated bedrock underlying residual clay in that gully, and in sand beds between clays which had been developed when those sands were surfaces. The flow net, as modified by the escape of water from the disrupted mass during a period of more than a year following the slide, is shown by contour lines in Fig. 21. The variation of water level in the holes to bedrock (circled) from those not registering the deeper water at that time is noted in numerals.

Mr. Lambe designates the writer's consideration of the ground-water hydrology involved in the generation of landslides as being described "in general terms which, to the engineer, do not present a clear picture of the true nature of the effects." This view is undoubtedly warranted, as a consideration of the subject, even in connection with but one of the slides, proved to add too greatly to the length of the paper. The continued observation of the water levels in pipes set in preliminary boreholes has provided very necessary data for the correction and determination of the effectiveness of installed works at several of the slides. The graphic analysis of such observations at the

Parker Avenue slide was quite extensive, largely through the use of contour lines of equal water elevations as movement and drainage continued. Fig. 21 is such an analysis for a specific date. It would have been of interest in Mr. Harman's discussion of the St. Mary's Playground slide had he presented his analysis of the water levels measured in pipes set in many borings around

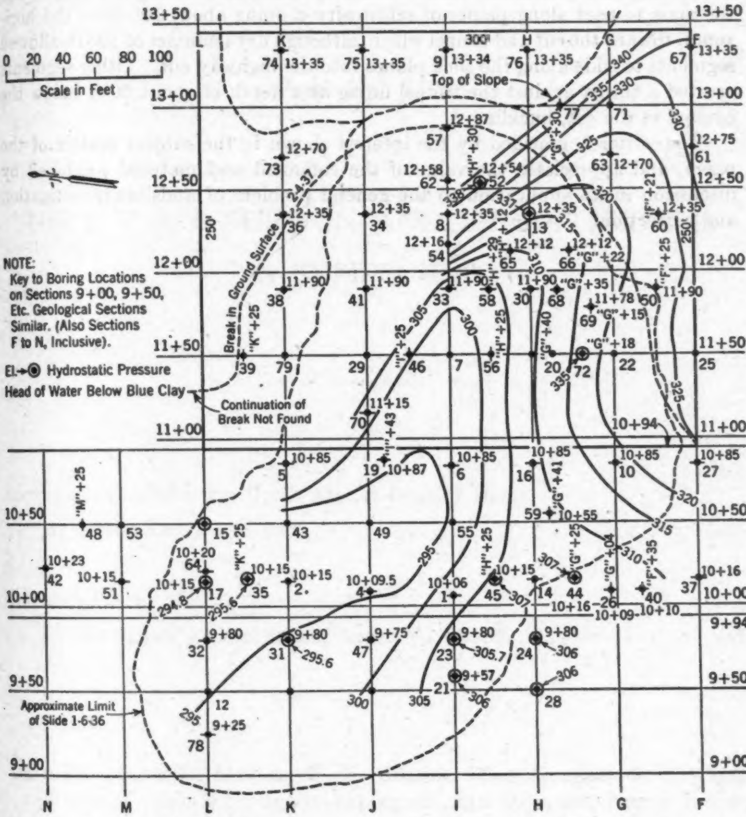

FIG. 21.—FLOW NET AND GENERALIZED CONTOUR OF PERCOLATING GROUND WATER; PARKER AVENUE SLIDE, APRIL 1, 1937

the slide and covering several years. A water table could be defined for the area; but many inconsistencies were found in individual measurements which were not explained until the boring for the correction work was under way.

Mr. Sill describes in detail the geological conditions resulting from the weathering of granitic rock, and the slippage of masses of such rock lying between a steeply dipping fault plane and the excavated face of a spillway. It is of interest to note that movement was arrested by preventing the entry

of surface water. It has been the writer's experience that finely divided fault gouge acts as a lubricant as well as a plane of parting, and that dry masses will part from the main body and slide along the slanting footwall of a fault zone if excavation leaves them unsupported. A similar experience was had with micaceous schist. The State Highway Department blasted a cut in that rock over a Western Pacific Railroad tunnel near Keddie, Calif. The blasting caused the mass to part along planes of schistosity dipping about 70° from the horizontal toward the cut and tunnel which, although dry (summer of 1931), allowed segments to slide along the slick planes into the highway cut. Other segments created a thrust against the tunnel lining at a depth of about 60 ft below the bottom of the cut, buckling it.

The writer is gratified by the interest shown in the subject matter of the paper, and appreciates the value of the comment and material produced by discussion in its application to the general problem of landslide investigation and correction.

NOTE.—Published in December, 1945, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

EXPERIMENTS ON EFFECTIVE UPLIFT AREA IN GRAVITY DAMS

By Serge Leliavsky Bey[1]

Synopsis

In a gravity dam, water filters through the natural pores of the material of the structure and develops an internal pressure of uplift. This paper describes tests made to determine the effective area of pores, to which this internal uplift pressure is applied. To that end, water was driven into the pores of masonry and concrete specimens, which were, at the same time, subjected to directly applied, mechanically developed loads, and tested to destruction on a machine of original design. These results permit the designer to replace conventional assumptions of design by physically measured uplift coefficients.

Introduction

In the design of masonry or concrete dams the uplift due to the penetration of water into the structure is a factor that has never been completely investigated. There are two essentially different schools of thought in connection with this problem. According to the earlier group of theories—which comprised Maurice Lévy's law (communication to the French Academy of Sciences submitted by Maurice Lévy, on August 5, 1895), the Lieckfeldt method,[2] the Link theory,[3,4] and others[5]—the uplift pressure was assumed to penetrate into the material through cracks (see Fig. 1), and the horizontal or hydrostatic pressure of water was assumed to be exerted externally on the face of the dam. These uplift theories were very popular in Europe in the earlier years of the twentieth century and were incorporated in some of the larger projects of the period; but as experience and knowledge accumulated they were gradually abandoned.

The modern principle, accepted by Karl Terzaghi,[6] M. ASCE, P. Fillunger,[7,8] O. Hoffman,[9] and many other research workers in all parts of the world, is that water filters through the natural pores of the material of the dam. For that purpose the structure need not be considered cracked or injured but may be perfectly sound and strong, at the same time being more or less pervious. (Messrs. Terzaghi, Fillunger, and Hoffman are chiefly responsible for the latest developments in the theory of internal uplift in masonry dams. The serious student of this subject is referred to their several published contributions.) That the two effects (effects of pressure in the cracks and in the pores) might be superimposed has been suggested from time to time but the idea does not seem to have gained popularity because in one case there is a purely abstract conception of a hypothetical crack whereas the other concerns a physical phenomenon, capable of being investigated by means of the usual methods of experimental science.

As a corollary to the new conception it appears that the horizontal water pressure is not applied to the face of the material, as was formerly believed to be the case, but is totally or partly transferred into the body of the dam (shown by the arrows in Fig. 1(*b*)).

This change in the ideas concerning the point of application of the hydrostatic pressure necessarily must have affected the methods of stress analysis. It may be shown, however, that the normal stresses on horizontal planes and the shearing stresses are not altered, the normal stresses on vertical planes being the only ones that need to be revised. Although an exhaustive reply to this question might call for model tests, preliminary calculations tend to show that there is no cause for apprehension, at least in so far as the usual type of sections is concerned.

It follows from the foregoing that "uplift" can be defined as a "pressure in the pores" or an "interstitial pressure." The first and obvious problem in this connection is to find the intensity to which such a pressure should be raised, in order to cause the material to be broken.

Curious as this might seem, the published information on this subject is very scarce and rather inconsistent. In other branches of engineering it is standard practice to test specimens to failure in the laboratory, and thus to ascertain the effect of load upon the resistance for use in practical design; but very little evidence of similar character has been supplied concerning the force of uplift and its effect upon concrete or masonry.

The first set of experiments to be cited in this connection is the well-known investigation, as early as 1900, by Prof. August Föppl.[10] The apparatus he used is shown in Fig. 2.

Water under pressure supplied through the intake was driven into the pores of the material, and so caused the concrete to burst. The following are the

pressures, in atmospheres, which were required in order to produce failure of exactly identical specimens: 11.0, 3.8, 12.0, 6.4, 15.0, 29.0, 7.0, 3.0, and 2.0. Obviously, with such irregular results no conclusions could be reached.

The technical consensus tends to attribute the inconsistency of these experiments to secondary influences and accidental circumstances, the effect of which had not been properly dealt with in designing the apparatus.

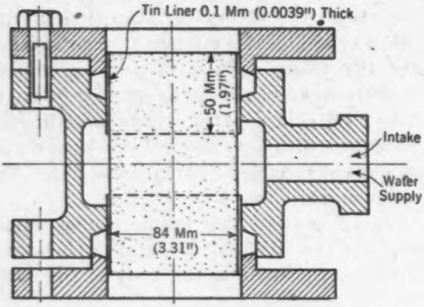

FIG. 2

In addition to Professor Föppl's tests, several others might be cited in which the test pieces were broken (or were intended to be broken) by the direct action of the uplift force: A test at the Bull Run Dam in Oregon; an experimental investigation which formed the subject of an unpublished thesis at the California Institute of Technology at Pasadena; a set of tests made by S. H. Woodard, M. ASCE, and reported by the late D. C. Henny,[11,12] M. ASCE.

Although the details of the mechanical devices used in these experiments were not published it appears that they were based upon the same general principle as the Föppl apparatus; but, in addition to this, the tensile breaking stress of the materials experimented upon was determined, in every case, by means of control specimens, on testing machines of the usual type.

The difference in the results derived in these interesting experiments seems to have been very great: The ratio of the interstitial area affected by the uplift pressure to the total sectional area was found to be 3% in one of these tests but appeared to increase to as much as 183% in another experiment.

One might naturally be reluctant to use these results in either design or theory, because the numerical value of the ratio in question must lie logically in between the coefficient of volumetric porosity, as a minimum, and 100%, as a maximum. It is rather difficult to interpret what actually occurred, particularly as the published information about these tests is indeed very scanty; but, according to Mr. Henny (as interpreted by the writer), the fact that the results in this case were far from consistent was most probably due to two causes: (a) The control briquettes did not furnish the true value of the tensile breaking stress, and (b) the pressure of the water injected into the pores was not uniformly distributed over the entire area of rupture (being undoubtedly less at the center than at the periphery).

These technical causes might have been effective in the two other cases as well, but the main source of the trouble seems to be deeper than that, as explained subsequently herein.

[11] "Problems in Concrete Dam Design," by D. C. Henny, *Engineering News-Record*, Vol. 106, No. 11, March 12, 1931, p. 433.

[12] "Stability of Straight Concrete Gravity Dams," by D. C. Henny, *Transactions*, ASCE, Vol. 99, 1934, p. 1041.

Four other experimental investigations on uplift should be cited—namely, those of Max Rudeloff and Panzerbieter,[13] Fillunger,[14] Terzaghi[15] (1934) and N. Kelen.[16] An example of the testing devices used in these experiments is shown in Fig. 3. These four series of tests differed greatly in value, but they

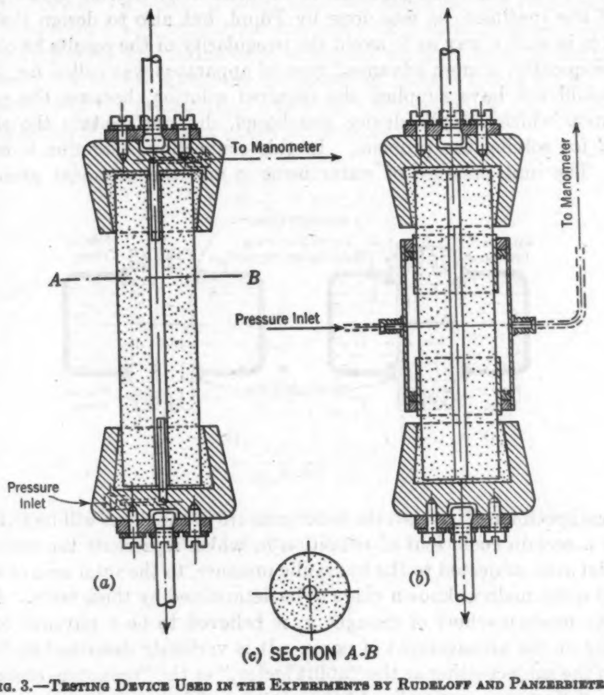

FIG. 3.—TESTING DEVICE USED IN THE EXPERIMENTS BY RUDELOFF AND PANZERBIETER

had one point in common—although the uplift force was present in every case, and the results of the tests were more or less dependent upon it, the failure itself was due to another agency, a mechanically developed load. This led to some ambiguity in interpreting the results obtained, thus rendering their significance difficult to assess, and leading consequently to much controversy as to the true interpretation of the tests.

The existence of uplift (as an interstitial hydraulic force which was capable of causing failure) was still considered in certain circles as not being fully proved; and, even if it existed, opinions were often expressed that the magni-

tude of that force was a matter of chance and could not be dealt with as a measurable physical quantity.

Therefore, it was believed that, in order to determine a convincing conclusion about the uplift pressure, the first and obvious step in solving the problem was to cause the material to be broken by driving water into the pores of the specimen, as was done by Föppl, but also to design the testing apparatus in such a way as to avoid the irregularity of the results he obtained.

Consequently, a more advanced type of apparatus was called for, but this alone would not have supplied the required solution, because the principle itself, upon which Föppl's device was based, did not contain the elements required for solving the problem. In this connection, attention is called to Fig. 4. The unit pressure of water being p and the sectional area of the

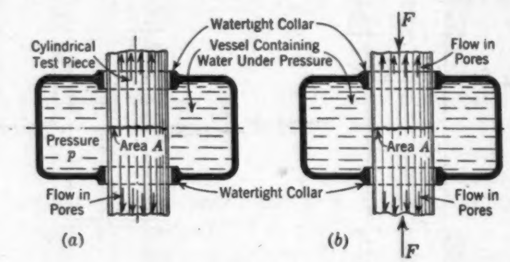

FIG. 4

cylindrical specimen, Fig. 4(a), the total pressure in the pores will be $p\ A$ multiplied by a certain coefficient of reduction n_a which represents the ratio of the interstitial area subjected to the hydraulic pressure, to the total area of the section, and is the main unknown value to be determined by these tests. According to the modern school of thought n_a is believed to be a physical constant depending on the arrangement of pores. It is variously described in different works on the subject either as the "uplift factor," or the "reduction coefficient," or as the "effective porosity." At the moment of failure, when the specimen bursts, the force $n_a\ p\ A$ must be equal to the resistance z of the specimen; that is,

$$n_a\ p\ A = z \qquad (1)$$

Unfortunately, Eq. 1 contains two unknown factors, n_a and z, and it is obvious that it cannot be used for finding either of them. Apart from technical details, therefore, the general layout of Föppl's testing arrangement did not satisfy the conditions of the problem.

In other instances, mentioned previously herein, z was determined by means of control specimens, so that apparently, had the causes of excessive dispersion been removed, these experiments might have supplied at least a partial solution to the problem. It will be shown, however, that, for reasons concerning the range of conditions experimented upon as compared with the probable deviation, consistent results would have been exceedingly difficult to obtain, if this method had been followed.

Proposed Solution of the Problem

The principle of the author's solution of this problem is shown in Fig. 4(*b*). The material is placed under the same conditions as it is in a dam; that is, the specimen is first subjected to the effect of a force F, so that, when the uplift begins to produce its effect, it must not only overcome the resistance of the material, but must also counteract the effect of a certain compressive force, which in a full-sized dam is due to its structural weight. Suppose that, having tested several identical specimens subjected to various forces F_1, F_2, F_3, etc. it is known that the pressures at which they broke were p_1, p_2, p_3, etc. The following series of formulas can then be written:

$$\left.\begin{aligned} n_a\, p_1\, A &= z + F_1 \\ n_a\, p_2\, A &= z + F_2 \\ n_a\, p_3\, A &= z + F_3 \\ &\;\;\cdots\cdots \\ n_a\, p_n\, A &= z + F_n \end{aligned}\right\} \qquad (2)$$

from which

$$\left.\begin{aligned} n_a &= \frac{F_2 - F_1}{p_2 A - p_1 A} \\ n_a &= \frac{F_4 - F_3}{p_4 A - p_3 A} \\ n_a &= \frac{F_n - F_{n-1}}{p_n A - p_{n-1} A} \end{aligned}\right\} \qquad (3)$$

The result is not only one, but several equations, from which n_a can be determined. The more general form of Eqs. 3 is:

$$n_a = \frac{\Delta F}{A\,\Delta p} \qquad (4a)$$

or

$$n_a = \frac{dF}{A\,dp} \qquad (4b)$$

The physical interpretation of Eqs. 4 is as follows: The additional pressure Δp is absorbed in overbalancing the additional force ΔF; therefore, Δp multiplied by the effective area $n_a A$ must be equal to ΔF.

This solution is valid only when a relationship is found to exist between $p\,A$ and F. In the absence of definite information on the subject, the problem of proving the existence of this relationship was at least as important as that of estimating it quantitatively; but, once the relationship had been established empirically, the new solution was independent of the precise nature of the physical causes which determined the value of the coefficient n_a. Had the problem been considered from the standpoint of the results of the earlier tests, the existence of this relationship between $p\,A$ and F might have appeared rather doubtful.

The value of n_a may be conceived either as being correlated with the interstructural arrangement of the pores in the normal condition of the material tested; or, alternatively, this material may be assumed to be already affected

before the actual failure takes place, being at that moment in the state of "agony" observed in certain earlier tests. A third interpretation could also be imagined; in fact, one may visualize the effective area as being affected by the crack itself, or, in a strict sense, by the process of its gradual development, so that the failure of the less resistant or more accessible parts facilitates the penetration of water into the material, until, at the moment when the final fracture occurs, a certain (possibly quite a large) part of the area of rupture is already open to the direct action of the pressure.

So long as a measurable relation is found to exist between $p\,A$ and F, it would not really matter which of these three interpretations was taken to be true; or, should another physical explanation be suggested, the results of the tests would still remain valid and applicable to the statical analysis of the dam section. Nevertheless, when analyzed, the tests themselves supplied a definite indication that the first of the three suggested explanations is the correct one, but this point will be considered subsequently in this paper.

A certain correction must be introduced into the value of n_a obtained as suggested herein, in order to account for the fact that, apart from producing uplift, the water contained in the pores increases the weight of the material. For a more or less triangular profile the diagram of this additional weight, for any horizontal section considered, is nearly triangular; which means that, at any point, this effect may be assumed to be proportional to the uplift pressure. Therefore, it may be taken into account by a corresponding reduction in the value of n_a. The final value of the uplift factor would then be found from:

$$n = n_a - n_v \qquad (5)$$

in which n_v is the volumetric porosity of the material.

This method of calculation seems to be justified for the reason that n_v is very small. It is evident, however, that an alternative path could also be followed—namely, to take n_v into account by a corresponding adjustment of the structural weight of the dam, and then to multiply the interstitial, pressure intensities by the unreduced value of n_a. The first procedure seems to be more usual because it sets off the difference in the relative values of the two coefficients and therefore gives a better idea of the total effect which the filtering of water may produce upon the mechanical stability of the work.

Calculation of Pressure Intensities of Filtering Water

This problem is not specifically discussed in this paper. It is rather more simple and more obvious than that referring to the value of n_a. It has been treated extensively in modern technical literature and may now be considered as belonging to the scope of a textbook. For example, Professor Terzaghi has written on the subject in various papers,[17] as have E. W. Lane,[18] M. ASCE, W. Weaver,[19] Hoffman[20] and many others.

[17] "Beanspruchung von Gewichtstaumauern durch das strömende Sickerwasser," by Karl Terzaghi, *Die Bautechnik*, Vol. 12, July 6, 1934, Heft 29, p. 379.

[18] "Security from Under-Seepage Masonry Dams on Earth Foundations," by E. W. Lane, *Transactions*, ASCE, Vol. 100, 1935, p. 1235.

[19] "Uplift Pressure on Dams," by W. Weaver, *Journal of Mathematics and Physics*, M.I.T., Cambridge, Mass., June, 1932, p. 114.

[20] "Permeazioni D'Aqua e loro Effeti nei Muri di Ritenuta," by O. Hoffman, Milan, 1928.

In the study of streamline flow as in many other cases of physical analysis the investigator is fully dependent on boundary conditions, which forces him to adopt graphical and approximate arithmetical solutions, or to use model tests and electrical-analogy methods in connection with the design of weirs and dams built on granular soils because the structural details of the foundations of such works may often create exceedingly complicated boundary conditions in so far as the seepage of water is concerned. As compared with these involved cases, the triangular profile of a gravity dam resting on rock is usually very simple to analyze mathematically. In fact, Hoffman has shown[21] that in this case the field of pressures tends to be delimited by a plane, which means that the pressure diagram is nearly triangular. Many times before Hoffman defined it, this principle was used more or less intuitively, in designs, theoretical analyses, and specifications.

To convert from the conditions applying to an ideal triangular profile to those of a practical dam section, the effect of the roadway at the top and the interruption of continuity at the base must be taken into account. These are chiefly local effects, however, which are of rather secondary importance as compared with the main tendency toward a linear pressure distribution. There is no great difficulty in finding the numerical values of the corresponding corrections.

Occasionally, departures from the accepted theory have been reported in connection with pressure-pipe observations in actual dams. There are reasons to believe that the cause of the trouble is partly in the accidental differences in the value of Darcy's coefficient; but, as in every case reported the number of observation points was far too small for the application of scientific statistical investigation methods, the personal element seems to have played a large part in the interpretation of these results. One must distinguish, however, between the accidental differences in the texture of the material in the dam itself, and the systematic differences in Darcy's coefficient over the line of contact with the foundations. Departures from the theoretical triangle are accidental in the first case, but might be systematic in the second case. They should then be taken into account by means of the same methods of calculation as were adopted for granular foundations. Galleries, drains, and differences in the mixtures and methods used in casting the toe and heel areas of the dam are some other causes that may account for systematic variations.[22,23,24]

After much preliminary work, the engineers working on granular foundations in India have succeeded in showing that theory, model tests, and pipe observations were all in agreement.[25] There is no apparent reason why the same should not apply to rock foundations, except that, in the latter case, the investigator is faced[26] with the much more difficult problem of computing the value of n_a, which is the specific subject of this paper.

General Principle Underlying the Design of the Experimental Machine

In detailing the testing apparatus for the proposed study it was essential to insure that, when the test piece broke, the pressure p had already penetrated into the thickness of the material and was the same over the entire area of the surface of rupture; or, alternately, if the specimen failed before the penetration was complete, means had to be provided to ascertain, subsequently, the true intensity that the pressure in the pores had actually attained at the moment of failure. To solve this problem, the part of the test piece in which the failure was intended to take place was made hollow, similar to a ring or a pipe with very thick walls, as shown in Fig. 5. (Rudeloff[13] had previously adopted a somewhat similar arrangement for his experiments, but this was not known to the writer until 1938 when the finished drawings of his own testing machine had been completed.)

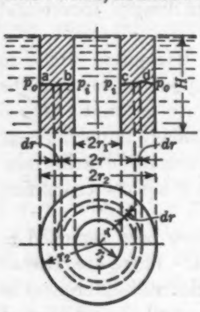

Fig. 5

The sequence of the operations performed in the course of an experiment on the writer's apparatus was as follows: At the beginning of the experiment the test piece was subjected to a certain force F and the water pressure in the container was raised to the intensity p_o, which, hereafter, is denoted as the "outer pressure." At the same time, the empty space inside the test piece was filled with water, connected to a manometer, and closed. The pressure in that space ("inner pressure") was then allowed to rise naturally, until it became constant, or nearly so. In order to prevent this rise from becoming too rapid, or from being abrupted, an air vessel was introduced into the system of pipes connected with the inner space of the specimen.

By that time, if the test piece still remained unbroken, the outer pressure p was increased, and the apparatus was left standing until the inner pressure became constant again. The same procedure was repeated, the pressures being stepped up, until failure finally occurred. Thus, the rise of the inner pressure p_i (which was recorded throughout the duration of the entire test) depended on the quantity of water percolating through the walls of the specimen, and on the velocity of infiltration. It indicated the intensity of the pressure in the pores in immediate contact with the inner periphery of the specimen. A reverse order might have also been adopted—namely, keep the pressure p_o constant and reduce the force F gradually until the specimen broke. This sequence would have been easier but was believed to be inadmissible, because in actual practice the material in the dam begins by being compressed by the weight of the superimposed layers; and then only is it subjected to the filtering effect of the water. It was considered essential, therefore, that the sequence of the various causes of stress should be reproduced in the test in the order it occurs in nature.

Had failure occurred when p_i and p_o were equal, the conclusion would be that, at that moment, the pressure in the pores on the outer and inner surfaces of the ring-shaped specimen were the same. In such cases the resultant pressure was calculated by multiplying the sectional area of the specimen by

$p_i = p_o$ (as was originally assumed in explaining the principle of the solution); yet, more often than otherwise, the specimen broke when p_i was less than p_o. (In fact p_i never equals the full value of p_o. A slight difference always remains; but in many cases its effect on the results is almost imperceptible.) Then the resultant depended on the law controlling the distribution of the pressure intensities over the section:

$$p = \frac{Q}{2\,\pi\,H\,K} \log_e r + C \ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

in which p is the unit pressure at the radius r; Q is the discharge; K is Darcy's filtering coefficient; and H is as indicated in Fig. 5.

Eq. 6 is the standard formula for radial filters, which is given in various textbooks on the subject,[27] and may be transformed into:

$$p = (p_o - p_i)\,\frac{\log_e \dfrac{r}{r_1}}{\log_e \dfrac{r_2}{r_1}} + p_i \ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

The average value of pressure over the cross section is then as follows:

$$p_a = \frac{1}{A}\int_0^A p\,dA = \frac{1}{A}\int_{r_1}^{r_2} 2\,\pi\,r\,p\,dr \ldots\ldots\ldots\ldots (8)$$

Substituting for p its value obtained from Eq. 7, and integrating:

$$p_a = p_i + (p_o - p_i)\left(\frac{r_1^2}{r_2^2 - r_1^2} - \frac{1}{2\log_e \dfrac{r_2}{r_1}}\right) \ldots\ldots\ldots\ldots (9)$$

or

$$p_a = p_i + (p_o - p_i)\Delta \ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

in which

$$\Delta = \frac{r_1^2}{r_2^2 - r_1^2} - \frac{1}{2\log_e \dfrac{r_2}{r_1}} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

In conducting the tests the average pressure p_a calculated from Eq. 10 was substituted for p in all the cases in which, at the moment of failure, the inner and outer pressures were not the same.

The physical meaning of Eq. 10 is perfectly clear—the average pressure intensity is equal to the sum of two terms p_i and $(p_o - p_i)\,\Delta$. The first represents the limit reached if the outer pressure falls and becomes equal to p_i; or, conversely, if the inner pressure rises and attains the value p_o. The second term shows the effect of the difference $p_o - p_i$ and depends on the value of Δ which, in turn, is a function of the ratio $\frac{r_2}{r_1}$ of the outer and inner radii. This

[27] "Hydraulik," by Philipp Forchheimer, B. G. Teubner, Leipzig und Berlin, 1914, p. 433.

function is shown graphically in Fig. 6. Eq. 10 applies also to the case in which $p_i > p_o$ except that the flow is reversed, and, therefore, instead of being convex the curve of pressures must be concave.

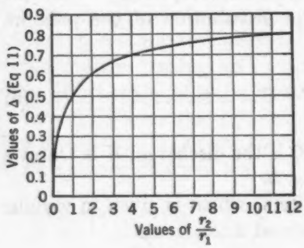

Fig. 6

Referring again to the arrangement actually adopted in the tests (that is, $p_o > p_i$), attention is called to the fact that, thus far, no proof has been offered that n_a is constant. Since this was one of the questions that the experiments were intended to answer, the investigation was conducted in such a manner that the results would have remained significant regardless of whether n_a was found constant or variable. With this object in view the results of each series of tests were represented graphically on a chart, the values of F being plotted as ordinates against $p_a A$ as abscissas.

A series of points was thus obtained, which one could expect to define either as a straight line, or a curve. When the points define a straight line, n_a is shown to be constant (and equal to the tangent of the angle between this straight line and the horizontal). When they define a curve, the variable slope of the curve represents the value of n_a corresponding to various values of $p_a A$ and F. Should the observed points be irregularly dispersed over the entire diagram, defining neither curve nor straight line, this would indicate either that the apparatus was improperly designed or that the uplift was not controlled by any regular law.

In such computations, the greater the range of variation of the variables, the more convincing is the result. In perfecting the details of the testing apparatus, therefore, it was believed convenient to use a device which allowed for reversing the direction of the force F. Thus it was possible to obtain positive as well as negative values of that force, which did not affect the substance of the conclusions, but permitted an increase in the range with the same testing equipment.

The Test Specimen

One of the reasons for adopting a ring-shaped type of test specimen has been given. The ring shape also solves the problem of air drainage, as the air contained in the pores in the critical part of the specimen can escape freely into the inner space.

The diameters of the specimens adopted in earlier experiments on uplift were:

	Diameter (cm)
Föppl	8.4
Rudeloff and Panzerbieter	9.0
Terzaghi	8.0
Woodard	5.0

Although sometimes referred to as "concrete," the materials used in these experiments were actually "mortar," being made of cement and sand without

the addition of the coarser aggregate. Since the new experiments were intended to explore a wider range of conditions, it was considered essential to introduce broken stone or gravel into the mixtures tested.

To derive consistent results from samples of such a nonhomogeneous substance, the dimensions of the specimens must be much greater than the irregularities that cause the nonhomogeneity of the material. For that reason, the section of the test piece in the new experiments was made slightly greater than 150 sq cm, the outer diameter being 15 cm when cast, and somewhat less than that when tested, owing to the removal of the "skin"—an operation which was always performed before placing the specimen in the apparatus.

As no marked difference was discovered, later, between the dispersion of the individual tests in the groups prepared, respectively, with and without coarse aggregate, there is sufficient reason for believing that the adopted dimensions of the specimen were adequate.

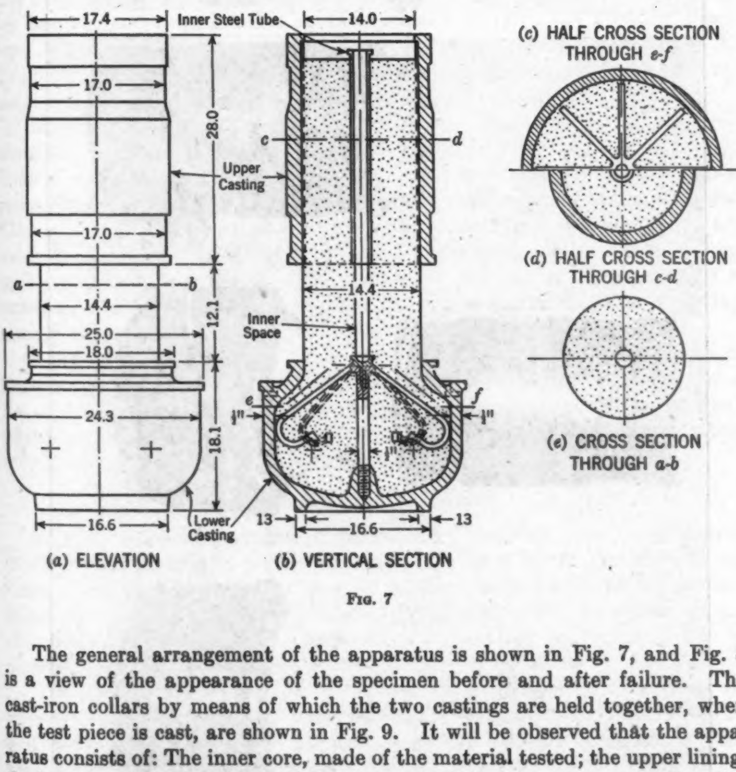

FIG. 7

The general arrangement of the apparatus is shown in Fig. 7, and Fig. 8 is a view of the appearance of the specimen before and after failure. The cast-iron collars by means of which the two castings are held together, when the test piece is cast, are shown in Fig. 9. It will be observed that the apparatus consists of: The inner core, made of the material tested; the upper lining; the lower casting; the pipe in the upper part of the inner space; and the reinforcing bars in the lower part of the core.

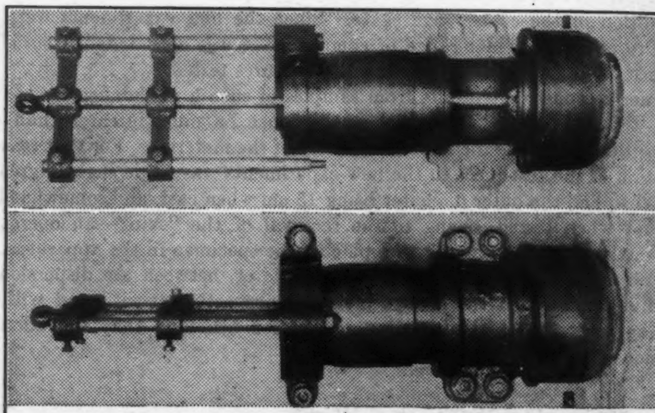

FIG. 9

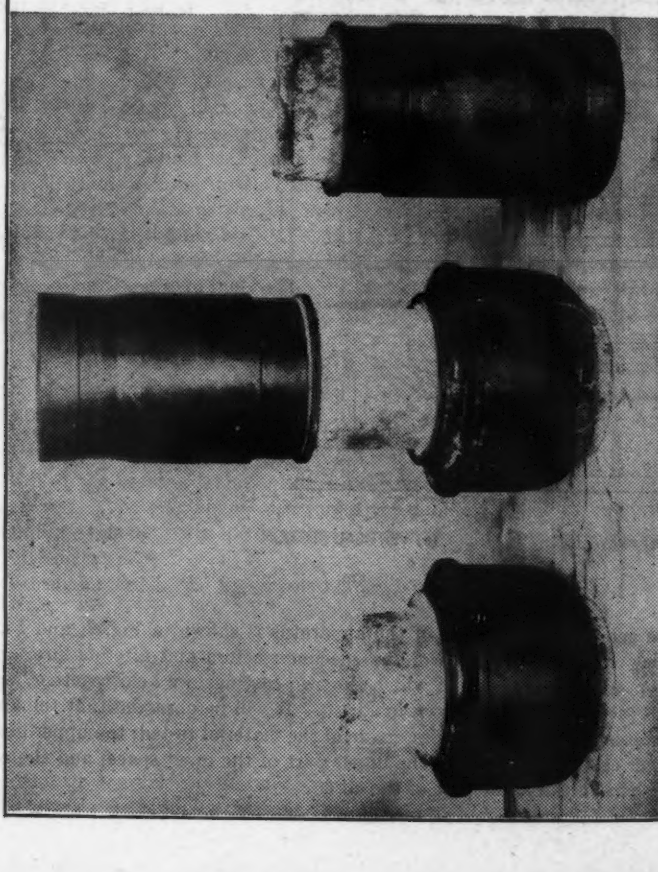

FIG. 8

The first point that calls for comment is the unsymmetrical layout of the specimen. Instead of having both its ends projecting beyond the specimen container, as was done in Föppl's experiments and Rudeloff's experiments, the test piece is entirely enclosed on its lower side, so that only one watertight collar is required instead of two. This arrangement is preferable for technical reasons, both in regard to simplicity of design and facility in conducting tests.

The function of the upper casting is twofold: (1) To provide a watertight and smooth surface for the leather collar to slide over; and (2) to transmit to the material tested the force F—compression or tension as the case may be.

It is essential that this force should not be applied directly to the concrete by means of any object placed on its top surface, because such an object would obstruct the exit from the pores through which the water is filtering during the experiment. Should this occur, the conditions would not be the same as in an actual dam. Therefore, the design adopted was as follows: The force F is transmitted by a cup and a brass collar to the upper rim of the top casting, and retransmitted to the specimen through the shearing effect from the inner deformed surface of the lining to the concrete adhering to it. The lower casting (which resembles in shape a common kitchen kettle) has no other function than to maintain the specimen in position.

Both castings were made heavy and strong, and all surfaces that control the position of the specimen relative to the container were machined carefully, thereby avoiding the secondary effects that caused the failure of Föppl's experiments. The remaining parts of the test specimen are of less importance. The pipe in the upper part of the inner space (diameter, 2 cm) is required for fixing the connections to the flexible pipe leading to the air vessel and to the manometer that measures p_i. The reinforcing bars in the lower part of the tested material are introduced in order to prevent the failure from occurring along a curved surface, subject to critical inclined stresses.

A pair of pincers, made of $\frac{3}{4}$-in. round iron, was used to lift and transport the specimens. They were arranged in such a way as to engage with the upper rim of the lower casting, so that no tension stresses, even of the smallest intensity, were set up in the tested material at any moment before the test proper was actually started.

The Testing Machine

The testing machine consists of the four parts: (*a*) Test vessel, or container, in which the specimen is placed for testing; (*b*) lever system, required to develop the compressive or tensile force F; (*c*) accumulator with inverted plunger, frame for carrying the loads, counterweight, manometer for measuring p_o, etc.; and (*d*) air vessel, with manometer for measuring p_i, and a system of flexible pipes designed to connect with the inner space of the specimen.

The lever system (item (*b*)) comprises the main lever with bearings, tie pieces and rocker, the secondary lever with adjusting screws and counterweight, and the cup-and-collar device arranged to engage with the upper lining of the specimen when the test is in progress.

As seen from Figs. 10 and 11, all these parts are erected on a main frame built of riveted channels and gussets. For the tests, this frame was fixed on

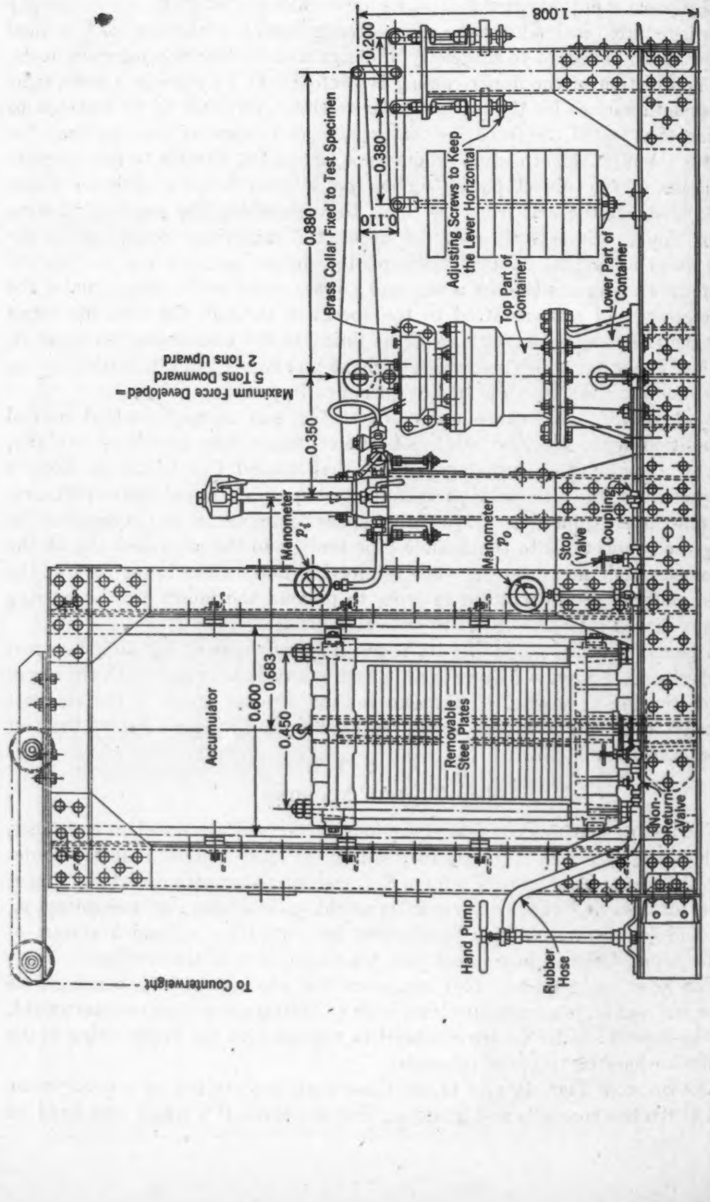

FIG. 10.—GENERAL ARRANGEMENT OF TESTING APPARATUS

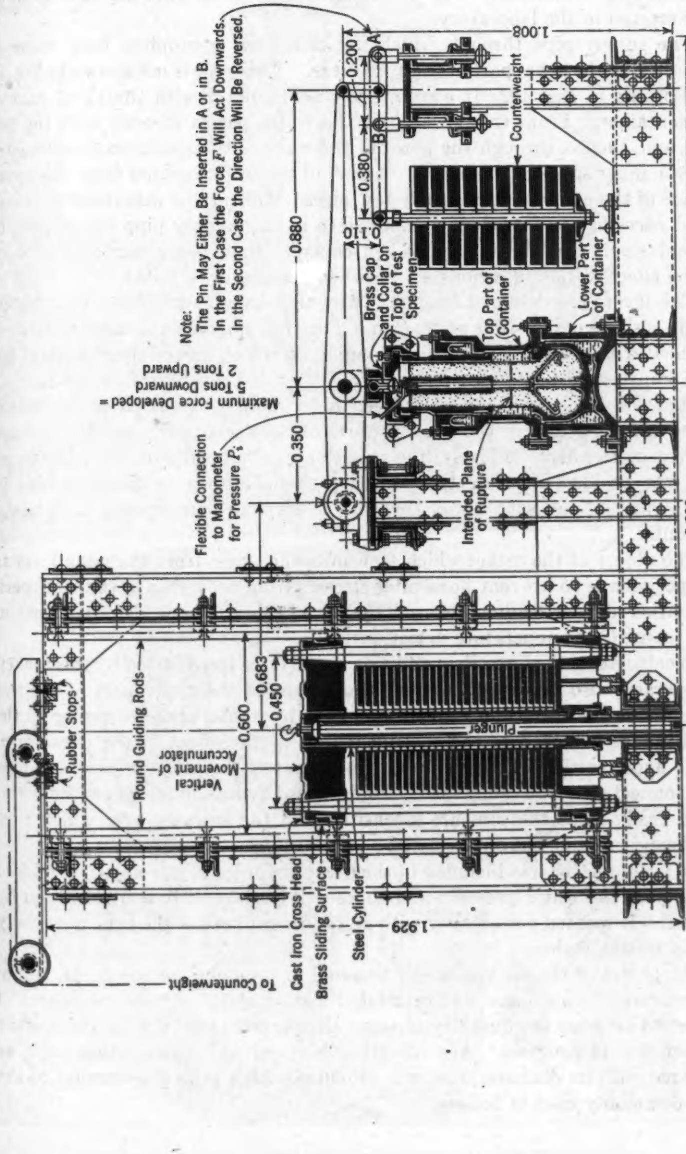

FIG. 11.—VERTICAL SECTION THROUGH AXIS OF TESTING APPARATUS

an independent block of concrete, about ten tons in weight, which was constructed separately from all other foundations of the building, so as to avoid the effect of vibrations. Fig. 12 contains two views showing the machine fully erected in the laboratory.

The supply pipe through which the container is supplied with water is connected at the lower part of the apparatus. This pipe is not shown in Fig. 11 but appears in Fig. 10. It connects the accumulator with the lower part of the container. From this lower part the water passes directly into the top part, and, thence, through the pores in the walls of the specimen, it percolates into the inner space of the latter. A part of the water escapes from the upper surface of the concrete or masonry test piece. During the experiments, it was found necessary to introduce a small sieve in this supply pipe connection, to prevent small particles of the broken concrete from being carried backward by the effect of the pulsations set up when the specimen failed.

The levers are designed in such a way that they can be used to produce, at will, either compression or tension. For that purpose the smaller lever is provided with two bearing pins; depending on which one of them is used, the force transmitted to the test piece is either directed downward or upward.

Had the position of the axles been fixed rigidly, the slope of the levers, due to the deflection of the various parts of the apparatus, would have been so great as to affect, seriously, the precision of the results of the experiment. This was avoided by using the adjusting screws shown on the right side of Figs. 10 and 11—in such a way that the levers were permanently maintained horizontal.

The object of the rocker which transmits the stress from the main lever to the specimen is to prevent horizontal stresses from occurring in the test specimen either during loading (caused by the effect of elastic deformations) or later (caused by temperature variations).

In calculating the force F, in addition to the force transmitted by this rocker, the operator also takes into account the weight of the upper part of the test piece (above the surface of rupture), and the hydraulic pressure acting on the metal linings attached to the specimen; that is, the effect of the pressure p_o on the under surface of the top casting and that of the pressure p_i on the pipe bent connected to the inner space. Both these hydraulic forces can be determined easily since the pressure intensities and the surfaces over which they are effective are all known precisely.

An accumulator was included in the design in order to develop the required intensity of the water pressure and to keep it permanently controlled during the test. It was fed periodically with an ordinary pump of the type commonly used in testing boilers.

The object of the air vessel was to avoid an irregular, or too rapid, rise of the pressure. Its volume was calculated accordingly. It was considered of interest to measure the quantity of water that entered into the air vessel while the test was in progress. Accordingly the vessel was made rather high, as compared with its diameter, and was provided with a glass gage similar to the gages commonly used in boilers.

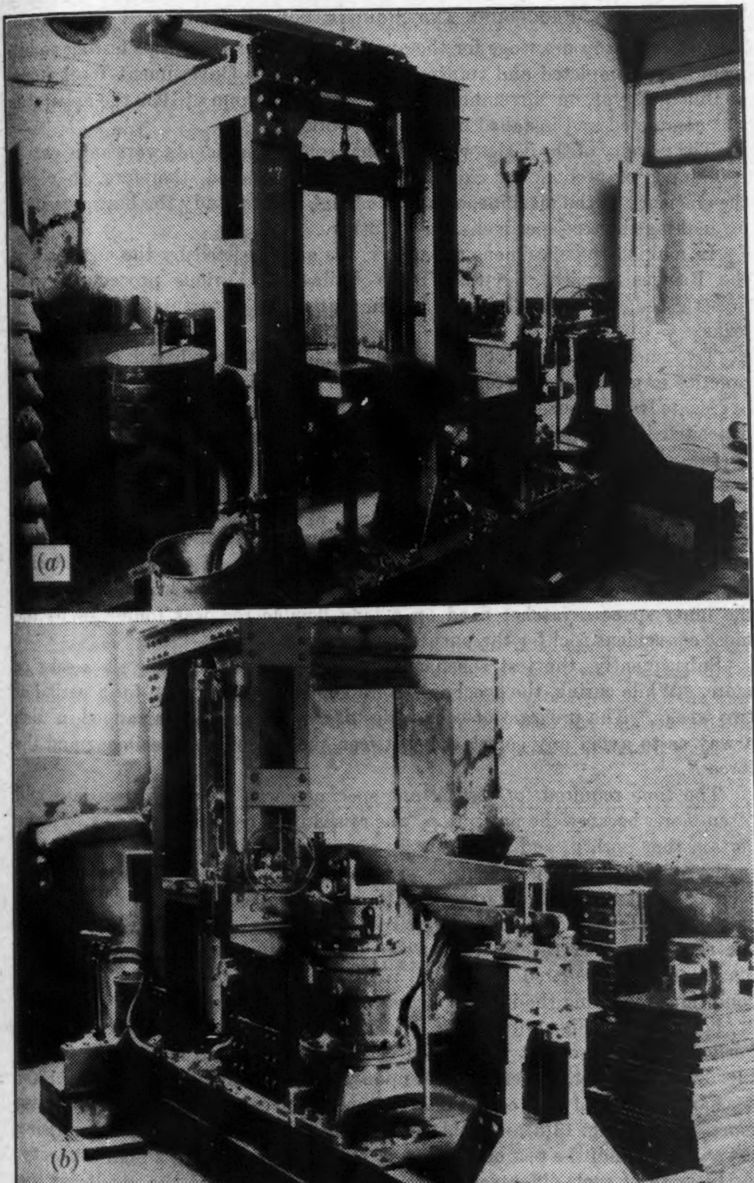

FIG. 12.—VIEWS OF THE LABORATORY WITH TESTING MACHINE FULLY ERECTED

Procedure and Significance of Tests

Detailed shop drawings for the apparatus and for the entire testing equipment were completed and transmitted to the Cairo Government Workshops, at Bulaq, Egypt, on November 2, 1937. In the autumn of 1939 the apparatus was completed and installed in the same workshops.

The novelty of the design was such that some adjustments were anticipated. A number of preliminary experiments were conducted, therefore, to verify the efficiency of the machine, on the one hand, and to study the best procedure for making the test specimens, on the other.

In making the specimens the writer was ably assisted by the engineers of the Bridges Service, Egyptian State Railways. Various procedures were investigated, the object being to obtain uniformity of texture and absence of leaks.

Two methods were finally adopted. The first was based on standard practice in making concrete. In the second method, the particles of the large aggregate were pressed into the layers of mortar after the latter had been deposited in the mold, precisely as in building a masonry dam. The entire operation was completed at such a speed, and with such efficiency, as to form one single, uninterrupted, and continuous process.

The specimens were left standing on a shelf until the following day, when the upper collar and the steel core were dismantled. At the same time the "skin" was removed from the exposed parts of the tested material. For the outer surface this was done by means of a steel brush, whereas in the inner space a ratchet fixed on a long flexible rod was found to be the most convenient tool for the purpose.

Subsequently, the test specimens were allowed to cure for six weeks or more. While curing, the specimens were kept thoroughly wet, for a period of two weeks. The program of each series of experiments was arranged in such a way as to avoid any correlation between the age of the specimens and the force F.

The time required for testing one specimen was at least three days and often more, because the pressure p_o was raised only very slowly, so as to make certain that both p_o and p_i were truly representative of the pressures existing in the pores in immediate contact with the outer and inner peripheries of the tested material. In this connection attention is called to Fig. 13 which shows three characteristic instances selected from among the diagrams representing the rate of the increase in pressure in the individual experiments. Similar diagrams were prepared for all the tests. They are typical in representing conditions regarding the interdependence between p_o and p_i.

For example, Fig. 13(a) shows a case in which the material appeared to be fairly permeable, so that p_i followed very rapidly after an increase in p_o. In Fig. 13(b), however, the effect of p_o upon p_i was less rapid, whereas Fig. 13(c) is characteristic of the conditions that are the extreme opposite to those represented in Fig. 13(a). In this last experiment, the pressure p_i began rising toward the end of the test only, when p_o had already attained a high intensity.

In spite of such differences in the values of p_o and p_i, the results of the individual experiments were quite consistent with each other. It follows,

therefore, that Eq. 10, which defines the relative effect of p_o and p_i upon p_a, is not only correct theoretically, but is also applicable to the case under review. As will be shown subsequently, the results attained by Rudeloff supply another proof in support of this conclusion.

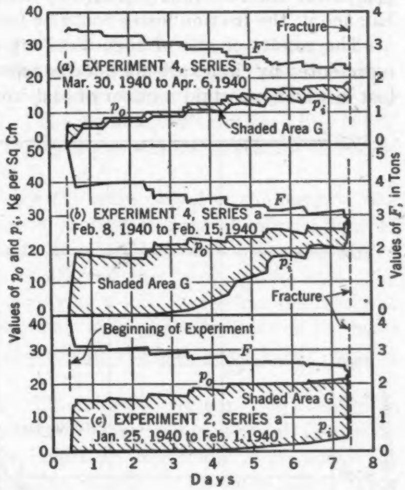

Fig. 13.—Rate of Increase in Pressure

Attention is also called, in this connection, to the diagrams shown in Fig. 14. The two experiments which they represent were conducted with the special object of verifying Eq. 10, and of ascertaining the effect of variations in the program of loading on the results of the test. These experiments were made generally similar, therefore, but the programs of loading—that is, the rates of increase of the pressure p_o adopted in the two cases—were essentially different. In spite of that, these experiments gave practically the same result. This may be of some importance, as it shows that the program adopted in filling the reservoir does not affect the uplift in the dam.

Another point, which was also rather important in the tests, was to ascertain the mechanical friction losses in the bearings of the lever systems and in other parts of the apparatus, in order to find the effect of friction on the force F. On several occasions during the experiment the machine was loaded with a special test specimen, which was generally similar to the standard specimen

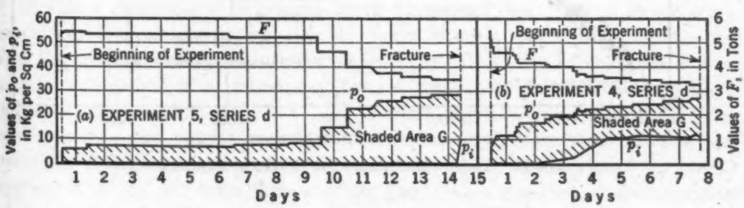

Fig. 14

but was filed across (before being placed in the test vessel) in about the same spot in which failure usually occurred in other specimens. No inner space was provided in this specimen. Consequently, the pressure p became instantly effective over the full section filed, as soon as the accumulator had been loaded with the corresponding number of plates.

It follows, therefore, that in this special experiment water had direct access to every point of the area that had been filed through. Thus, it was possible to compute the unreduced effect of the water pressure precisely. By comparing the resultant pressure so determined to the lever load required to balance it, the friction losses could be found easily.

The results of one of such tests are shown in Fig. 15. The experiments represented by circles are intended to reproduce conditions similar to a standard test in which a certain number of cast-iron weights are placed on the lever and

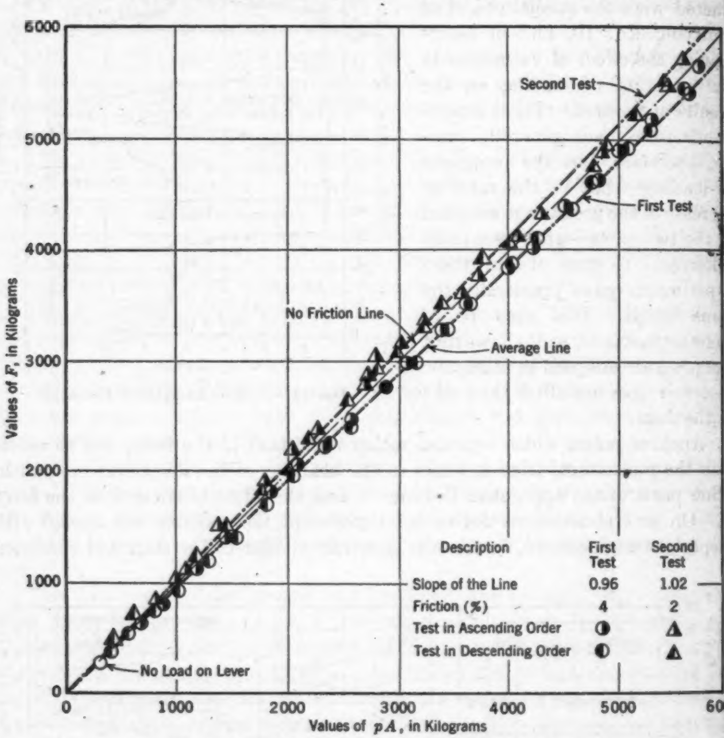

FIG. 15.—TEST TO DETERMINE THE EFFECT OF FRICTION

the pressure p_o is gradually increased until the micrometer shows that the top of the specimen begins moving upward. In this case the friction forces are directed in the same way as in a standard test; that is, they all tend to increase the force F. It is only logical, therefore, that the corresponding points are below the "no-friction line," the recorded pressures $p\,A$ being always greater than the calculated force F. This experiment was repeated many times and for various loads, first in the rising and then in the falling order, the entire set of tests being completed in 48 hr.

The tangent of the angle between the mean line drawn through these points and the vertical is calculated by the formula,

$$\tan \theta = \frac{\Sigma(x\,y)}{\Sigma y^2} \qquad (12)$$

which is derived from the "least-squares" principle.[28] The symbols y and x appearing in this equation represent the individual values of F, and the corresponding recorded pressures $p\,A$, which are used respectively as ordinates and abscissas in plotting curves in Fig. 15. The slope of the calculated line is 4% less than 1 on 1. Accordingly, a correction of 4% was introduced in all standard tests when calculating the value of F.

Although this might have sufficed for the main object of the tests, it was nevertheless considered of interest, as a matter of general information, to conduct another friction test, similar to the first but with the order of the operations reversed; that is, instead of loading the lever system and then gradually raising the water pressure (applying a load to the accumulator) as was done during the first test, the pressure was kept constant while the lever load was gradually increased, until the top of the test piece began moving downward.

It is clear that, in this case, the friction forces must act in a direction opposite to F. This was actually confirmed by the results, since all the points representing this test (triangles in the diagram) were found to be above the zero-friction line; the slope of the mean line, calculated for these points in the same manner as for the first friction test, was 2% steeper than 1 on 1.

The magnitude of the friction forces is different in this case, as compared with the first test, because the leather collar in the upper part of the container, which is shaped in section as an inverted **U**, is capable of developing different resistances depending on whether the legs of the **U** tend to become opened or closed. This means that the friction must depend on whether the test specimen moves upward or downward, being greater in the first case than in the second.

It was a satisfaction to observe that, in general, the friction forces were reasonably low, as compared with the main forces applied to the specimen; thus the friction correction introduced into the calculation of the force F was more in the nature of a refinement, than a substantial factor that may have influenced the conclusions. It is also of some importance to realize that the consistency of the results of the friction tests supplies another proof of the exactness of the calculation of the force F, because the deviations of the points appearing in Fig. 15, from their average line, give a measure of the precision of the results of this calculation. For example, the standard deviation for forty-two points is found to be 41 kg, which is only about 1% of the average value of F. This is an independent confirmation of both the principle and the details of the method applied in calculating this force.

Apart from, and parallel with, the main experiments, a second series of tests were conducted in order to determine the porosity of the tested material. This porosity is required for finding the correction term n_v in Eq. 5.

[28] "Calcul de l'inclinaison des minarets," by S. Leliavsky, *Report on the Reconstruction of the Mosque Mohammed Aly Pasha*, Ministry of Wakfs, Cairo, 1931–1933, p. 95.

All these tests were made in the laboratory of the Bridges Service of the Egyptian State Railways. The specimens were taken from the test pieces used in the uplift experiments, after their failure. In all the cases, the porosity tests were repeated daily with the same specimen, for several months. According to the standard program this period was intended to be subdivided into four sections, as follows: (*a*) Specimen kept in water; (*b*) specimen kept in the room; (*c*) specimen exposed to the effect of wind and sun; and (*d*) specimen placed in the heater. Each operation was continued until the weight of the sample became constant. The results of two cycles, on seven samples, in series d, e, f, and g, are shown in Table 1.

TABLE 1.—RESULTS OF POROSITY TESTS

Sample and series	Critical pressure (kg per sq cm)	Time from failure to first test (hr)	Porosity (%) After Successive Stages of the Test						Total duration of test (days)
			First Cycle			Second Cycle			
			Room temperature	Exposure to sun	Placed in heater	Immersion in water	Room temperature	Placed in heater	
	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)
A, d	27	4	8.2	10.7	15.6	1.3	14.1	....	112
B, d	32	2	6.6	8.7	....	1.5	8.2	14.3	105
C, d	8	2	7.9	8.5	....	0.6	8.5	14.5	100
D, d	16	40	9.6	11.3	18.7	....	....	....	99
E, e	12	11	3.1	3.7	7.0	. .	....	....	35
F, f	30	2	8.3	6.1	10.3	....	....	...	114
G, g	15	2	3.5	5.7	12.0	....	....	....	67

In certain cases, it was believed of interest to reimmerse the dried samples. After a period of ten to twenty days in the tank, they absorbed almost the same quantity of water as when subjected to the exceedingly high pressure in the container; there was only 1% to 2% difference in the moisture content corresponding to either case. This result is instructive as it shows that the capacity of absorption is independent of the pressure applied.

The conclusion to be drawn from Table 1 tends to diminish the importance of the porosity on the stress analysis of dam sections—at least in so far as Fillunger's ideas on the subject are concerned. Fillunger believed[7,8] that the uplift factor was equal to the difference between the porosity of pure cement paste (when set) and the average porosity of the composite material (including cement, sand, and either gravel or stone). These two constants were supposed to represent respectively the coefficients n_a and n_v in Eq. 5. This conclusion was derived theoretically, assuming that the surface of fracture was an ideal plane which passed through the structural joint without intersecting any of the particles of either the fine or the coarse aggregates. In the light of more recent interpretation (which appears to be chiefly due to Hoffman[29]), the surface of rupture, being a surface of least resistance, is itself dependent on the structure of pores. In other words, the percentage area of the voids intersected by this irregular surface is greater than the volumetric porosity

[29] "Permeazioni D'Aqua e loro Effeti nei Muri di Ritenuta," by O. Hoffman, Milan, 1928, p. 28.

of the material. This upsets the Fillunger assumptions, because they are based upon the hypothesis of Delesse[30] according to which the superficial and volumetric porosities are the same (as is actually the case for a plane section). (In 1930, Fillunger restated his theory in a paper read before the Second World Power Conference.[31] It is substantially the same theory as in his earlier publications, but instead of the common symbols of Cartesian algebra he introduces the vectorial notation, which makes the discussion rather more general, although this notation is less familiar to the average engineer.)

The moisture content under normal conditions appears to be rather high in the writer's tests (see Table 1), leaving a very small margin for additional absorption. This means that, when samples of the material destined for use in a dam are being tested in order to find their specific gravity, they already contain such a large percentage of water that their weight is almost the same as when fully saturated. In this connection attention is called to the porosity coefficients appearing in Col. 4, Table 1. It will be observed that these are the values that must be included in the second term of the uplift formula (Eq. 5), as representing the factor n_v. They are found to vary from 3.7% to 11.3%, with an average of about 7%.

These values are very low, corresponding to from only 2% to 4% of the total weight of the material. It appears, therefore, that a 7% effective volumetric porosity can be accepted as a sufficiently close and safe approximation for all cases. Of course, in a large structure the porosity would tend to be slightly greater than in a small block made of the same material; but then the efficiency of evaporation would be higher in the second case, so that a certain compensation must occur. Since the effect of this coefficient on the results of the stress analysis is indeed very small, there is every reason for accepting $n_v = 0.07$ as a sufficiently accurate basis for the calculation of stability. On the other hand, where the construction of a new dam is contemplated, the coefficient n_v can easily be determined experimentally before the profile is designed.

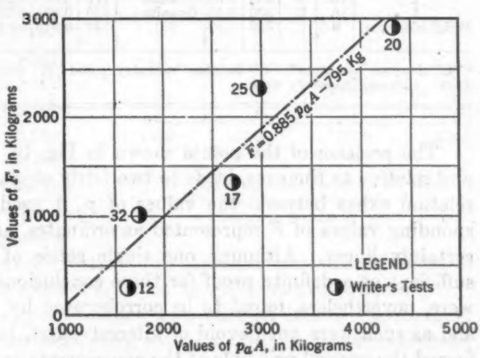

FIG. 16.—SERIES a; CAST DECEMBER 2, 1939, AND TESTED JANUARY 17 TO FEBRUARY 28, 1940 (SEE TABLE 2)

RESULTS

In describing the results of the tests in this section, the writer has followed the chronological order in which the conclusions were revealed. This was found advisable, because the object of and the particular problems to be

[30] "Procédé Mécanique pour Déterminer la Composition des Roches," by M. Delesse, *Annales des Mines*, 4 Série, Tome XIII, 1848, pp. 379–388.

solved by some of the later experiments originated from the analysis of the earlier tests.

The results of the first series of tests (referred to as series a) are shown in Fig. 16. The ingredients used in making these test pieces were: Broken Assuan granite and Assuan sand—both taken from the same quarries which were previously used in building and heightening Assuan Dam on the Nile River in Egypt. They were mixed with Portland cement from the Turah Factory, the proportion of cement to sand to stone (by volume of dry material) being 1.0:1.6:1.1. Descriptive data and comparison of results of twelve series of tests are presented in Table 2.

TABLE 2.—Results of Tests on Twelve Series of Specimens

Series (see Figs. 16 to 24)	Number of tests	Method of preparation[a]	Cement (kg per cu m)	Water-cement ratio (by weight)	Type of coarse aggregate	Average age at test (days)	Uplift Coefficient		At Failure		Probable deviation of a point (tons)	Range of F-values (tons)	Ratio, $\frac{\text{Col. 11}}{\text{Col. 12}}$
							n_a	Probable error	Resistance (tons)	Average stress (kg per sq cm)

[a] "C" denotes "concrete"; "S" denotes "masonry"; and "R" denotes "mortar." [b] Concrete cast in two days. [c] Dressed masonry work.

The position of the points shown in Fig. 16, both in respect to each other and relative to the axes, leads to two fairly obvious conclusions: (*a*) A definite relation exists between the values of $p_a A$ used as abscissas and the corresponding values of F represented as ordinates, and (*b*) this relation is almost certainly linear. Although one single series of tests would not have been sufficient as a definite proof for these conclusions, the tests of that one series were, nevertheless, found to be corroborated by the results of all other tests, and as such were not devoid of interest—first, because these conclusions confirmed the general principle of the experiments and proved the efficiency of the testing apparatus; and, second, because they showed that the coefficient n_a was constant. It was also apparent from Fig. 16 that the slope of the line representing the coefficient n_a was very steep.

In finding the slope in question (which was the main problem to be solved by these experiments) it was believed advisable, in order to exclude the personal equation, to adopt the same method for all the series tested; and with this object in view the following simple formula embodying the "least-squares"

principle was used:

$$n_a = \frac{N\,\Sigma(x\,y) - \Sigma x\,\Sigma y}{N\,\Sigma x^2 - (\Sigma x)^2} \qquad (13)$$

in which x and y are the coordinates of the points and N is their total number. Also,

$$z = \frac{\Sigma x^2\,\Sigma y - \Sigma(x\,y)\,\Sigma x}{N\,\Sigma x^2 - (\Sigma x)^2} \qquad (14)$$

The values of the constants defining the average line were calculated by means of Eqs. 12 and 13, applied to each of the series tested. For series a (Fig. 16) the coefficient n_a was found to be equal to 0.885 (see Table 2). This is considerably more than is usually assumed in designing dam profiles (excluding exceptional cases, of course), but it tends to approach the limit suggested by Professor Terzaghi. On the other hand, such a high numerical value completely disproves the Fillunger theory, because the volumetric porosity of the materials tested was only about 0.15.

One other point that Fig. 16 seems to demonstrate is the effect (on the results of the tests) of the ratio of the areas occupied, respectively, by the binding material and the particles of the aggregate appearing on the surface of rupture. In fact, when the average line is taken as a basis of comparison, the points with higher ratios move to the left. Had this been a general rule, it might have been interpreted in two ways—the higher percentage of the stone surface may have meant either a larger uplift factor n_a or a smaller resistance z. In both cases, the primary cause would have lain in the different microstructural characteristics of solid material as compared with a surface of contact between two different substances.

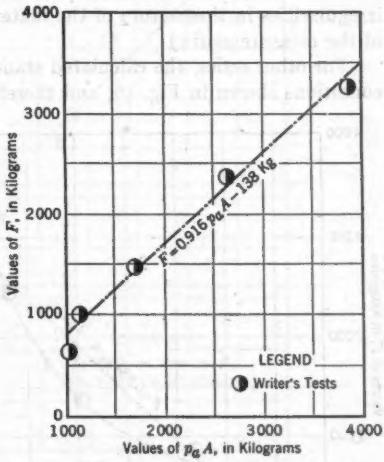

FIG. 17.—SERIES b; CAST JANUARY 17, 1940, AND TESTED MARCH 9 TO APRIL 9, 1940 (SEE TABLE 2)

In order to explore this subject further, two parallel sets of experiments (see series f and g, Table 2) were conducted, with and without coarse aggregate, respectively.

The proportion of cement in the first series of specimens was rather high. It was considered advisable, therefore, to use a relatively small proportion of cement in the second series (1.0:2.7:3.3), the ingredients being the same as in series a. The results are shown in Fig. 17.

The characteristics of the line in Fig. 17 confirm the results of series a; that is, the relation which the data represent is obviously linear and the slope of the line is again very steep. In spite of the difference in the proportion

of cement, the factor n_a calculated for series b, the same as for series a, is found to be equal to 0.916, which is only 3% greater than series a (see Table 2).

Apart from that, Fig. 17 is also interesting in that it reveals a case in which the individual points are very close to the calculated line. Should the "probable" deviation (namely, 0.6754 times the standard deviation) be taken as a measure of the dispersion of the points, regardless of its physical significance (which, with such a small number of entries, is naturally very limited), the following values may be of interest:

Series	Probable deviation (tons)
a	0.215
b	0.070

(The term "deviation" is used in preference to "error," for in this case the cause of the differences between the observed and theoretical values lies in the irregularities in the texture of the material tested, and not in the inaccuracies of the measurements.)

For other series, the calculated standard deviation tended to approach the conditions shown in Fig. 16, and therefore Fig. 17 must be considered exceptional. No physical reason is given to explain the exception, the cause being most probably a matter of chance.

In series c, Fig. 18, the conditions of the test were the same as series a and b except that the aggregate proportion was 1.0:1.1:2.2. The results are similar to those demonstrated by Figs. 16 and 17 except that these data might also be interpreted as representing a curve, AB. This was the only case in any series in which such a definite curve could have been drawn through the points obtained; but, even here, the curve was absurd because the slope of end B would have been much steeper than 1 on 1 (which was obviously impossible since n_a could not have been greater than 100%).

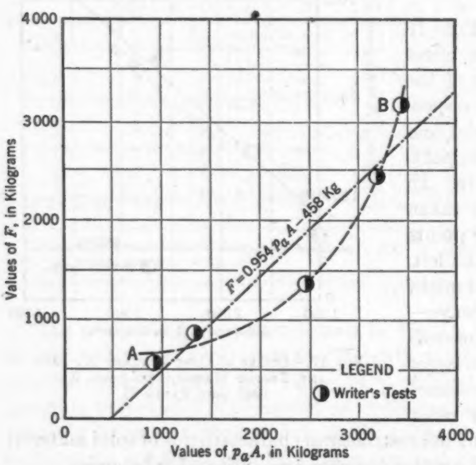

FIG. 18.—SERIES c, CAST MARCH 4, 1940, AND TESTED MAY 22 TO JULY 1, 1940 (SEE TABLE 2)

It follows that in series c, as in all other series, the variation was linear and $n\ a = 0.954$ was computed in the same manner as in the earlier series (see Table 2).

In order to avoid conditions such as those that produced Fig. 18, and also to study the effect of extending the data into negative values of F, the number

of specimens in all subsequent series was increased. For instance, series d, Fig. 19, comprised as many as twelve experiments. The larger number of plotted points in Fig. 19 offers a more strict proof of the main conclusions derived from the earlier tests—namely, that there is a systematic relationship between the product $p_a A$ and F, that the relationship is linear, and that the slope of the calculated line is rather steep.

It must be observed, however, that, although this general result was supported by the twelve experiments represented in Fig. 19, the calculation of the average line was based on six records only, because the "weight" of the other six points (shown by dotted circles in Fig. 19) was believed to be less; in other words, the data for these experiments were considered to be less

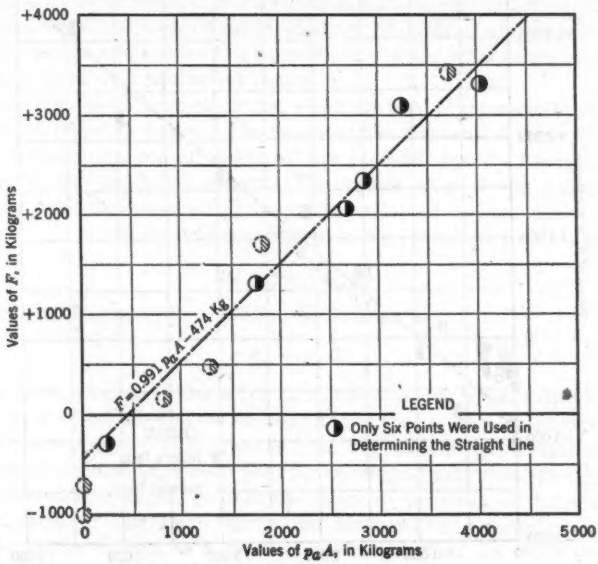

FIG. 19.—SERIES d; CAST APRIL 14 AND 15, 1940, AND TESTED JULY 9 TO SEPTEMBER 23, 1940 (SEE TABLE 2)

certain than those for the other experiments. In regard to the two points in Fig. 19, at $p_a A = 0$ (mechanical tensile tests with no hydraulic pressure, conducted with identical specimens, and using the same machine), it was found that the time factor affected the conditions of failure of the material to a far greater extent than many engineers are inclined to accept. The importance of this factor was discovered almost accidentally during the test run for series d. During one period the machine was left with the specimen still in position, with a constant load. After a lapse of about 15 min the specimen failed suddenly. This conclusion concerning the time factor refers chiefly to short periods. If the duration of the test exceeds two or three days, the effect of the rate of loading appears to vanish, or is almost imperceptible.

The next test under similar conditions was conducted more slowly and consequently the breaking tensile limit was found to be lower. Thereafter it was realized that, in order to obtain consistent results, the duration of a purely mechanical tension test must be the same as that of a standard uplift experiment—about three days. This rule was adopted for all subsequent series and the results were found to be quite reliable.

Four other tests in the same series were also considered as being less precise than the remainder, because the specimens broke at night. (Subsequently,

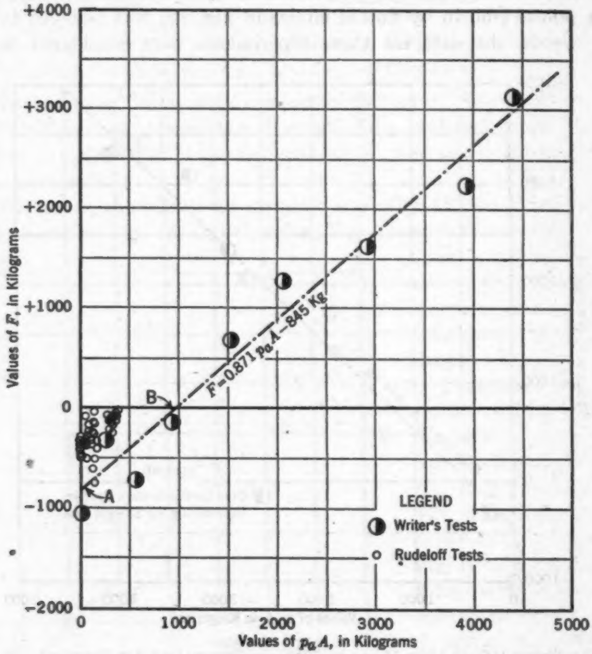

FIG. 20.—SERIES e; CAST AUGUST 7 AND 10, 1940, AND TESTED SEPTEMBER 28 AND NOVEMBER 4, 1940 (SEE TABLE 2)

orders were issued to remove two loads from the accumulator, before closing the room for the night, and to replace them again in the morning. Failures at night were thus avoided.) The four corresponding points were calculated from the last values of p_i recorded in the log book during the day, and were shown by dotted circles in the diagram; but, of course, they were not included in the calculation of the line. Nevertheless, they fell close to the latter.

At this stage of the investigation, in comparing the results determined, the most striking point appeared to lie in the fact that the coefficients n_e calculated for various groups were found to be almost the same. It was decided therefore to alter the ingredients in the new series in such a way as to

ascertain whether the coefficient in question was affected by the nature (if not by the quantities) of the materials used in making the specimens. With this object in view a coarser sand (obtained by washing the sand that had been used before) was used in making the fifth series.

The results of these tests are illustrated in Fig. 20. Although the coefficient n_e is found to be still high (0.871), it is nevertheless slightly lower than the average calculated for the first four groups, which amounts to 0.937 (see Table 2). Thus, by removing the finest particles of the sand it appeared that the uplift was reduced by about 7%, as compared with the average for other series.

To illustrate the importance of the range of conditions under which uplift experiments are to be made, it was decided to plot, on any one of the diagrams representing the writer's experiments, the tests of Rudeloff and Panzerbieter.[18] While Fig. 20 was selected for this purpose, any of the other series might have been used instead with equivalent results.

The coordinates of the small circles, which are used to represent the Rudeloff tests, are computed as follows: The values of the mechanical forces F (which, in these experiments, are all negative) are read off directly from the tables appearing in the published report. The values of $p_a A$ are calculated in accordance with the particular arrangement adopted in each series of these experiments. For the arrangement shown in Fig. 3(*a*), the formula used is

$$p_a = p_i\,(1 - \Delta) \qquad \text{(15a)}$$

and, for the arrangement in Fig. 3(*b*), the formula is

$$p_a = p_o\,\Delta \qquad \text{(15b)}$$

Substituting in Eqs. 15 the breaking values of p_o and p_i published by Rudeloff, the required values of p_a are found in a form that represents his experiments in the writer's graphs. It is obvious from Fig. 20 that the forty-four points so obtained could not have been used for developing empirical formulas or for finding physical constants, because the range of variation of the coordinates was too narrow. The small circles are arranged in a meaningless group, which cannot be defined as a curve or a straight line. In other words, the effect of accidental circumstances that caused the dispersion of points was too large as compared with the range of variation of the main factors; and the entire set of Rudeloff's records was equivalent, in the weight of the information it conveyed, to only one point in Fig. 20.

In the investigation reported herein the conclusions are based on the difference between the individual tests, and not on their average value; and, therefore, in spite of all precautions that had been taken in designing the writer's apparatus and planning his experiments, greatest care and utmost diligence had to be exercised subsequently in making the specimens, and in handling them, in order to reduce the dispersion of the points. Only the most competent, experienced men, fully realizing the importance of regularity in their work, should be employed in such experiments, to insure consistent results. In fact, it was observed that, whenever changes in laboratory assistants occurred, the dispersion of the points immediately became greater, and

two or three series had to be discarded for this reason. The maximum ratio of probable deviation to range of force that can be allowed reasonably in such tests is 1:10. Beyond this ratio the results should be considered as untrustworthy.

Another point, calling for comment in regard to Rudeloff's tests, as they are represented in Fig. 20, is that the ratio of the outer to the inner diameters of the test pieces used in this investigation (the test pieces in question were made hollow as in the writer's tests) was 6.43. When this value is used in Eqs. 15 it will be found that, for Fig. 3(*a*), $p_a = 0.25\ p_i$; and, for Fig. 3(*b*), $p_a = 0.75\ p_o$.

Thus, with equal pressures, the effect in the second case (Fig. 3(*b*)) was three times as much as in the first arrangement (Fig. 3(*a*)), in spite of which the points (which included both arrangements) fell close to each other in Fig. 20. In other words, in order to equalize the conditions that caused failure, the inner pressure had to be raised to an intensity three times as high as that of the outer pressure. In this respect the agreement between test and formula is found to be fully satisfactory.

This goes a long way to show that the formula assesses correctly the relative effect of the two pressures p_o and p_i; and the principle upon which it is based, therefore, is not only correct theoretically, but is also consistent with actual facts.

Another illustration of the importance of a wide range of conditions is afforded by the experiments of Woodard,[12] and by the experiment conducted at Bull Run Dam. The physical interpretation of these experiments was intended to be based on the difference between the conditions that cause the failure of the specimen in the testing machine of the common type (that is, without uplift pressure) and effect of uplift pressure acting alone (without any additional mechanically developed stress). In Fig. 20, these two cases correspond to points A and B, in which the average line intersects, respectively, the vertical and horizontal axes. A glance at Fig. 20 will show that the section of the line defined by these two points is relatively very short. As they are too close to each other, minor errors in determining the position of these two points experimentally must largely affect the slope of the line drawn through them, the calculated value of n_a being uncertain and possibly misleading. Had the same precautions been taken in preparing the test pieces and in conducting the test proper as in the writer's experiments, the ratio of the probable deviation to the range of forces would still have been high. For instance, under conditions similar to those of Fig. 20, this ratio would have been 1:5 (as compared with 1:25 in the writer's test). There is little wonder, therefore, that the results of the earlier uplift tests did not supply the solution to the problem. More precision might have been attained by repeating the test several hundred times, and then taking the averages of the results so obtained; but even so, with two points only, it would have been impossible to obtain a clear picture of the true relation between the variables, and many factors affecting the experiment (such as the predominant effect of time in the mechanical-tension test) might have remained undetected, thus aggravating the inaccuracy of the final calculation.

Fig. 21 includes two series of tests, referred to as groups f and g, respectively. In representing them on the same chart the object was to facilitate comparison because, in this case, the problem was concerned with the difference (if any) in the results obtained with two mixtures. To ascertain the effect of the large particles, these two series were made identical in regard to the composition, except as to one point—the presence in one mixture, and the complete absence in the other, of the coarser aggregate (gravel).

The ingredients were proportioned in such a way as to provide for nearly the same quantity of cement per cubic meter of finished material in both cases.

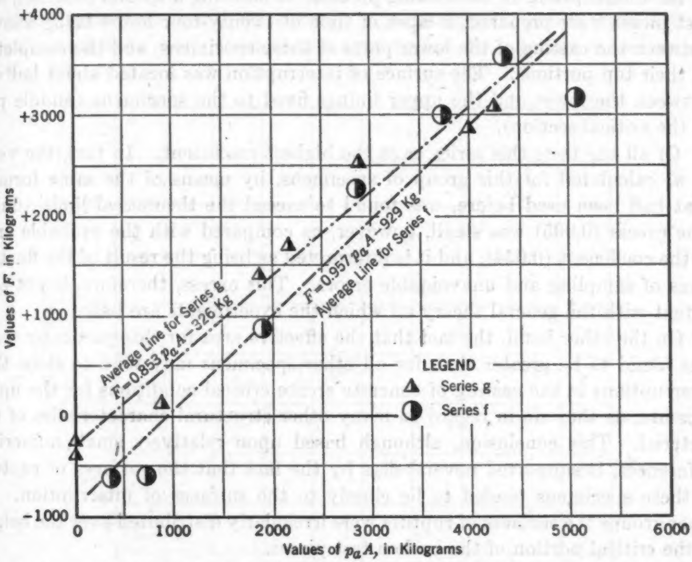

FIG. 21.—SERIES f (CAST OCTOBER 13, 1940, AND TESTED DECEMBER 17, 1940, TO JANUARY 20, 1941) AND SERIES g (CAST OCTOBER 16, 1940, AND TESTED JANUARY 26 TO FEBRUARY 18, 1941) (SEE TABLE 2)

In interpreting Fig. 21 attention is called to what was stated in connection with the first group (Fig. 16), on the possible action of the coarser aggregate, which was supposed to be affecting either the uplift factor (in which case the slope of the two lines in Fig. 21 should have been different) or the resistance of the material against tension. In the latter case the lines would have been parallel, but at some distance from one another.

The results of the tests, as represented in Fig. 21, appear to show that these two effects exist simultaneously, but that they are combined in such a way that they often escape attention because, in a sense, they balance each other. The addition of the aggregate appears to increase the factor of uplift (as one might naturally have expected) but, at the same time, the resistance of the material against tension is also increased, which causes the two groups of the experimental points to be superimposed upon each other.

On the other hand, the differences in the uplift coefficients are found to be so small as to be largely influenced by accidental causes, so that the true conclusion to be derived from Fig. 21 is that the effect of the aggregate is rather of secondary importance.

Another seven specimens were later prepared from fine gravel instead of the coarse gravel that had been used in mixing group f. They were referred to as series h. As the results of these tests were very close to the average conditions, they do not call for any particular remark.

The next series tested (series i) was intended to reveal the effect (if any) of the interruptions in the casting process. Following a special program, nine test pieces were prepared, a lapse of time of twenty-four hours being allowed between the casting of the lower parts of these specimens, and the completion of their top portions. The surface of interruption was located about halfway between the lower and the upper linings fixed to the specimens (middle part of the critical section).

Of all the tests this series gave the highest coefficient. In fact, the value of n_a calculated for this group of specimens, by means of the same formula that had been used before, was found to exceed the theoretical limit—unity. The excess (0.005) was small, however, as compared with the probable error of the coefficient (0.034), and it is interpreted as being the result of the fluctuations of sampling and unavoidable errors. This excess, therefore, is not consistent with the general theory on which the experiments are based.

On the other hand, the fact that the effective area for this particular series was found to be greater than for all other specimens may tend to show that interruptions in the casting of concrete create critical conditions for the uplift pressure, as they do in regard to many other structural characteristics of the material. This conclusion, although based upon relatively small numerical differences, is supported nevertheless by the fact that the surfaces of rupture in these specimens tended to lie closely to the surfaces of interruption. In other groups the surfaces of rupture were irregularly distributed over the height of the critical portion of the broken test pieces.

The eight specimens belonging to series j were intended to supply more information about the effect of the size of the sand particles. With this object in view a sand coarser than that in series e was selected in making them. The reduction in the value of the uplift coefficient that had been observed in series e, and had apparently been due to the removal of the smaller grains in that series, did not seem to have been increased or maintained when the medium particles were also removed and large particles alone were present. The value of such conclusions is very much reduced, however, by the fact that the numerical differences, upon which they are based, are of the same order of magnitude as the probable error.

All the groups thus far described were prepared according to one of the two standard methods ("concrete" or "masonry") discussed under the heading, "Procedure and Significance of Tests" (see also Table 2, Col. 2). On the other hand, the system adopted in making the test pieces of group k differed substantially from all that had been done before. An objective attempt was

made, in this case, to duplicate the methods commonly used in building masonry dams.

The critical sections of these test pieces were built in alternate courses, consisting of three to four pieces of granite laid on approximately horizontal beds. Consequently, the size of the individual stones was larger than in all earlier series, and each stone was dressed roughly so as to reduce the thickness of the joints and to minimize the quantity of mortar per unit volume of the finished material. To make the stones fit more accurately, the critical sections of the test pieces were built before placing the cast-iron collars in position.

Although the value of the coefficient of uplift deduced from these experiments was again very near to the average ($n_a = 0.888$), the points representing the individual tests were closer to the average line than in the earlier series (see Fig. 22).

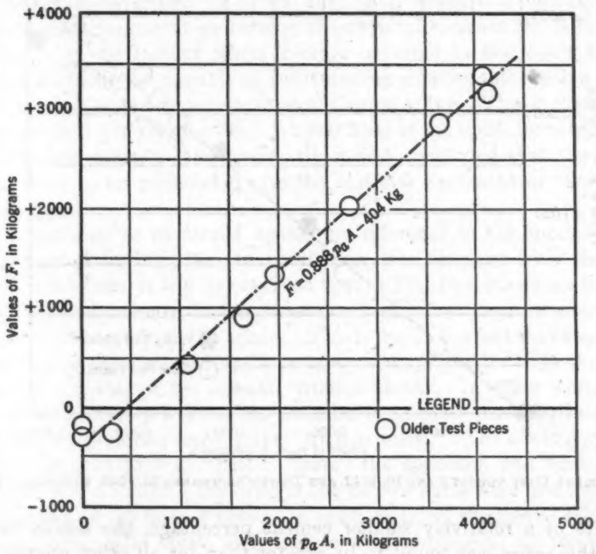

FIG. 22.—SERIES k; CAST FEBRUARY 2 AND 3, 1942, AND TESTED JULY 15 TO AUGUST 25, 1942 (SEE TABLE 2)

Consequently, with this particular method of construction the results of the experiments were more regular and, being less affected by accidental circumstances, conformed more strictly to the theoretical conditions of an ideal case. The reason for the better results obtained with this series might be twofold:

(a) The horizontal beds may have presented more uniform conditions for the filtering of water and for the development of the uplift pressure; and

(b) The dressing of the stones (such as it was) and the greater regularity in the joints may have resulted in more uniform tensile resistances.

In concluding the program of experiments described in this paper, a set of tests was run with a greater number of specimens. The range of ages of these

specimens was increased in such a way as to accentuate the effect of the time factor, should such effect be actually present. Accordingly, a series of sixteen test pieces was cast from August 8 to August 10, 1942; four of them were tested from September 28 to October 28, 1942; and the remaining twelve were tested from December 15, 1942, to February 12, 1943.

As demonstrated by Fig. 23, no difference whatever can be detected between the earlier and later experiments, and the entire series is fully satisfactory in so far as regularity of results is concerned. The coefficient n_a is equal to 0.858 and the probable error of this factor is 0.024.

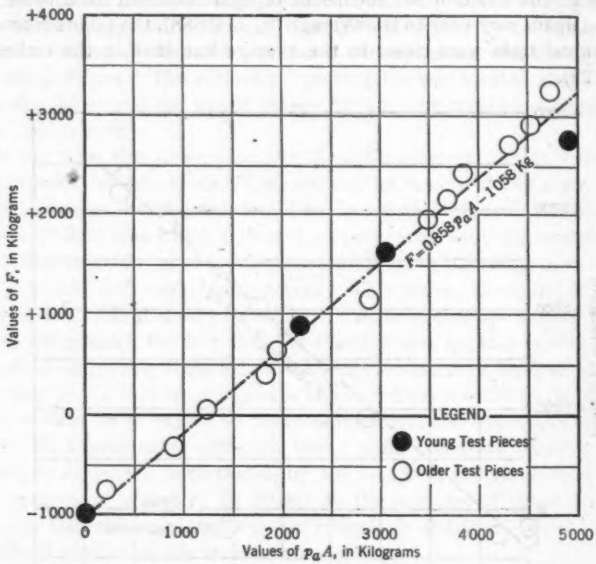

FIG. 23.—SERIES l; CAST AUGUST 8 AND 10, 1942, AND TESTED SEPTEMBER 28, 1942, TO FEBRUARY 12, 1943

In spite of a relatively smaller cement percentage, the tensile breaking limit for this series was found to be greater than for all other groups. This was most probably due to the more intensive ramming and to a lower water-cement ratio. Also, the workmen had acquired a greater ability in preparing the test pieces, so that a generally better class of material was obtained.

In addition to the data in Table 2 that have already been discussed, this table also contains information such as the water-cement ratios, which are calculated in the usual way (by weight).

In regard to the values in Col. 11, Table 2 (probable deviations of a point), and Col. 8, Table 2 (probable errors of the coefficient n_a), it should be realized that these terms are used conventionally. Little physical significance can be attributed to statistical parameters based upon so small a number of points as that which is contained in each series taken individually (with the possible exception of series l which comprises sixteen tests). These values must be

interpreted as representing results of certain well-known arithmetical operations. As such they are of some interest as a means for comparing the dispersion of the points in the different series, provided the word "probable" is not taken too literally.

Another point to be mentioned in connection with Table 2 concerns the tensile resistances of the material. The average breaking intensity of the tensile unit stress for all the series tested was found to be about 4.6 kg per sq cm, whereas for the experiments in which only mechanical tension was used it was about 3 kg per sq cm. Should individual series be considered, the two values will be found to be very close. For instance, in series 1 the tensile resistance calculated from the average line was 6.6 kg per sq cm, whereas under mechanical tension alone it was found to be 6.5 kg per sq cm.

The fact that the resistance of the material determined under mechanical tension was actually similar to, or less than, that which was indicated by the uplift tests explained much concerning the physical cause of the failure of the test pieces. At the instant when fracture occurred in the uplift tests, the material was still found capable of withstanding considerable tension (at least as much as when tested under mechanical tension only). This is evidence that the specimen had not yet cracked. At that instant the uplift force had already reached its full value, and consequently it was concluded that the channels through which water penetrated into the material were natural "pores"—not failure cracks.

The point may be explained further by reference to the special "friction tests" presented in Fig. 15. In comparing this diagram with the several curves of uplift tests, it will be observed that in Fig. 15 the average line passes through the origin of coordinates, whereas in all other cases it intersects the axes at some distance from the origin. This is due to the fact that the abscissas of the points of the standard uplift tests are always greater than those of the corresponding points of the special "friction tests." In other words, it was always found necessary to raise the pressure to a higher intensity in the uplift tests than with the same force in the "friction tests." The obvious reason for this condition was that in "friction tests" the specimen was filed crosswise beforehand, so that during the experiment its two parts were held together by the application of the force F only. In uplift tests, on the other hand, the two parts formed one solid block, and, therefore, in addition to the force F, there was also the resistance of the material to be overcome by the uplift pressure. Had a crack existed in the "uplift test" the results must have been the same as in the "friction test."

Thus, although the principle of these experiments was compatible with both the old and the new schools of thought, the numerical results tended to show that the modern group of theories supplied the true explanation of the phenomenon (in so far, at least, as the tests themselves were concerned).

Elsewhere, in this paper, the writer has shown that the differences in the values of the uplift factors obtained for various series were surprisingly small. The possibility was also explored that the entire body of tests might not be analyzed as a single composite group of records. This approach would have appeared unorthodox if it had been advanced in the earlier part of the investiga-

tion; but it suggested itself later, as a natural conclusion derived from the numerical results of the tests. (The differences between the individual values of n_a calculated for each series are of the same order of magnitude as the corresponding "probable" errors. This means that these differences may be attributed to accidental circumstances.)

It should be realized, however, that the value of z in the different series (the ultimate resistance of the specimens against tension) is not, and cannot

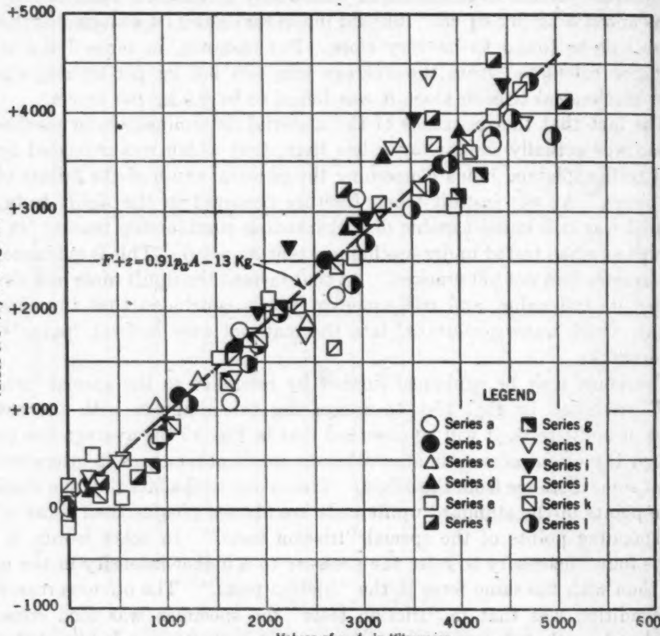

FIG. 24.—COMBINATION OF NINETY-FIVE EXPERIMENTS

be, the same (*a*) for all the various proportions of cement used, (*b*) for the differences in the periods of curing, and (*c*) for differences in the water-cement ratios. Consequently, had the tests relating to different series been superposed upon each other as they occurred, the differences in z would have exaggerated the dispersion of the points and obscured the issue. Therefore, they were removed prior to combining the tests in a single group, and values of $F + z$ were plotted as ordinates instead of F.

The diagram so obtained (Fig. 24) may also be conceived as being derived from Figs. 16 to 23, by using different origins of the vertical scale for different groups in such a way that all the calculated lines intersect at the origin.

The parameters of the new average line calculated for all the ninety-five points taken together, by means of the same formulas as before (Eqs. 13 and

14), are: $z = 0.013$ ton and $n_a = 0.91$. The constant z is so small that, to all intents and purposes, the average line may be assumed to pass through the new origin of coordinates (see Fig. 24). This tends to prove that the principle upon which the adjustment of the ordinates is based is generally reasonable.

The standard deviation for the new combined diagram is 0.305 ton, which is almost the same as the average of the values computed for the individual series (see the line of weighted means in Table 2).

On the other hand, the advantage of the composite diagram, as compared with Figs. 16 to 23, is that, with almost the same standard deviation, it contains a much larger number of observations. From the viewpoint of the statistician a record comprising ninety-five entries may be regarded as very meager, but it represents, nevertheless, a substantial improvement on the individual series which contain only five observations. Thus, it is possible to apply some statistical methods of investigation to the composite group, which can never be applied to the smaller individual groups, considered separately.

The correlation method was adopted for the statistical analysis of the composite data, with the following results:

Description	Correlation	Regression
Coefficient	$r = 0.974$	$b = 0.91$
Probable error	$\Delta r = 0.0035$	$\Delta b = 0.014$
Approximate ratios	$\frac{\Delta r}{r} = 1:300$	$\frac{\Delta b}{b} = 1:70$

These coefficients appear to be very satisfactory. With the number of experiments available, therefore, the curve in Fig. 24 can be accepted as final, and the value $n_a = 0.91$ can be considered as a fairly reliable average, the corresponding probable error being only about 1.5%. The same values of b are found by the least-squares method. In a preliminary investigation, with seven groups only, the same computation gave $n_a = 0.92$. These seven groups have also been combined without excluding z (that is, using the values of F and $p_a A$ as in the individual diagrams) and almost the same results were obtained.

Fig. 24 has also served as a general basis for detecting the presence of systematic errors, if any. Two main sources of such errors may be anticipated: (*a*) The effect of time; and (*b*) the effect of the difference $p_o - p_i$.

(*a*) *Time.*—Great care was exercised in arranging the test program so as to avoid any apparent or concealed association between the age of the specimens and the main mechanical characteristics of every individual test. Additional evidence was gathered confirming the fact that the time factor had no influence on the test results. The first step in the check analysis was to compute the deviations from the average line, for every test, by the formula:

$$\Delta y = y - n_a x + z \qquad (16)$$

in which x and y are the coordinates of the point; and n_a and z are the constants of the average line.

The correlation and regression coefficients between these ninety-five deviations and the age of each of the ninety-five specimens tested were then computed. The result ($r = 0.059$ and $b = 0.00025$ ton per day) is obviously negative. The coefficients are so small as to warrant the conclusion that the tests were not influenced by the time factor.

(b) *Difference* $p_o - p_i$.—The effect of the difference $p_o - p_i$ is to create compressive stresses in the material at right angles to the geometrical axis of the specimen and to the main tensile stress that causes its failure. Since the critical breaking value of the tensile stress in question may be influenced by the compressive stress at right angles to it, an effort was made to ascertain whether the results of the experiments were actually affected by the magnitude of the difference $p_o - p_i$.

Messrs. Fillunger and Terzaghi have demonstrated beyond any reasonable doubt that the effect of an interstitial hydraulic pressure upon the resistance of a porous solid is negligible, so long as this pressure is equally distributed over the walls of the pores. Since the existing evidence confirming this statement is conclusive, it follows, in so far as the present tests are concerned, that the ultimate resistance of the test piece is not affected, in all the cases in which $p_o = p_i$. However, the cases in which p_i is smaller than p_o remain to be investigated. When this happens the ring-shaped part of the specimen is subjected to stresses similar to those in a pipe of a boiler. Since these stresses are compressive, z could be smaller for higher values of $p_o - p_i$.

The solution of this problem had been attempted previously by Rudeloff who undertook a special set of tests in which an India rubber envelope was placed around the specimen, thereby preventing water from penetrating into the pores. Since in his experiments the pressure was applied on only one face of the wall of the test piece (see Fig. 3) the effect of the ring stresses, in the sense referred to herein, could have been more pronounced than in the tests reported by the writer. In any case, the ring stresses were present and were the same as in the main tests, but there was no water in the pores and, consequently, no interstitial pressure. Hence, the entire effect, had it been found to exist, would have been attributable to the ring stresses alone.

Such special experiments were conducted by Rudeloff for every type of material and testing device used in these experiments; but the present concern is with the apparatus shown in Fig. 3(*b*) because it is mechanically similar to the device used by the writer. Similar to the writer's apparatus, the main stress causing failure in the Rudeloff apparatus is tension, but the secondary ring stress is compression.

The average results obtained by Rudeloff are represented graphically in Fig. 25. The average line is calculated by the least-squares method; its slope (regression coefficient) is found to be 0.034 (or 0.002 ton per atmosphere) which is too small to be detected. Clearly, the effect of compressive ring stresses on the ultimate resistance against tension is negligible.

In the writer's experiments, had the effect of the difference $p_o - p_i$ on z been present, it would have resulted in points with larger values of $p_o - p_i$ tending to move upward, the average line being taken as the basis for com-

parison. Then, the deviations Δy computed by Eq. 16 must have been related to, and affected by, the differences $p_e - p_i$. This possibility was explored analytically, the results being: Correlation coefficient $r = 0.068$; and regression coefficient $b = 0.0016$. (In order to represent the regression coefficient as an absolute number, the deviations Δy were divided by the sectional areas of the specimens.)

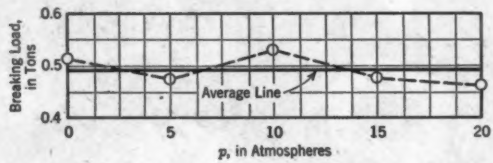

FIG. 25.—RESULTS OF RUDELOFF'S EXPERIMENTS (NO INTERSTITIAL PRESSURE)

Rudeloff's results are thus confirmed. The correlation and regression coefficients are found to be so low that the existence of an interdependence between $p_e - p_i$ and the resistance of the material z is definitely disproved. Although the physical interpretation of this conclusion does not directly concern the subject of the present inquiry, it may be suggested as a most plausible explanation that in Mohr's graphical criterion the lines are curved, as assumed by certain authors, and not straight. This would substantially reduce the effect of the transverse compressive stresses on the resistance against the main tension stresses, particularly in the negative zone, close to the vertical axis of Mohr's diagram.

To complete the description of the writer's tests the following observations should be recorded:

(a) The deviations of the ninety-five points from the average line agreed in a general manner with the bell-shaped Gaussian frequency curve.

(b) Darcy's coefficient calculated for the various test pieces varied within rather wide limits and did not indicate any correlation with the uplift factor or with any other physical constant. An approximate value of this coefficient can be obtained from the equation:

$$K = \frac{\log_e r}{2\,\pi\,H}\,\frac{\int_0^T Q\,dt}{\int_0^T (p_e - p_i)\,dt} \quad \ldots\ldots\ldots\ldots\ldots\ldots (17)$$

in which $\int_0^T Q\,dt$ is the total quantity of water percolating through the specimen during the test and $\int_0^T (p_e - p_i)\,dt$ is found from a diagram in which p_e and p_i are plotted against time (see shaded area G in Figs. 13 and 14).

(c) In most cases the failure occurred abruptly, without any warning, but certain specimens suddenly became very leaky an appreciable time before failure occurred. The state of the material during this period (which varied from 2 min to 30 min) could be described as "agony." Although capable of withstanding a large amount of tension, the walls of the specimen allowed water

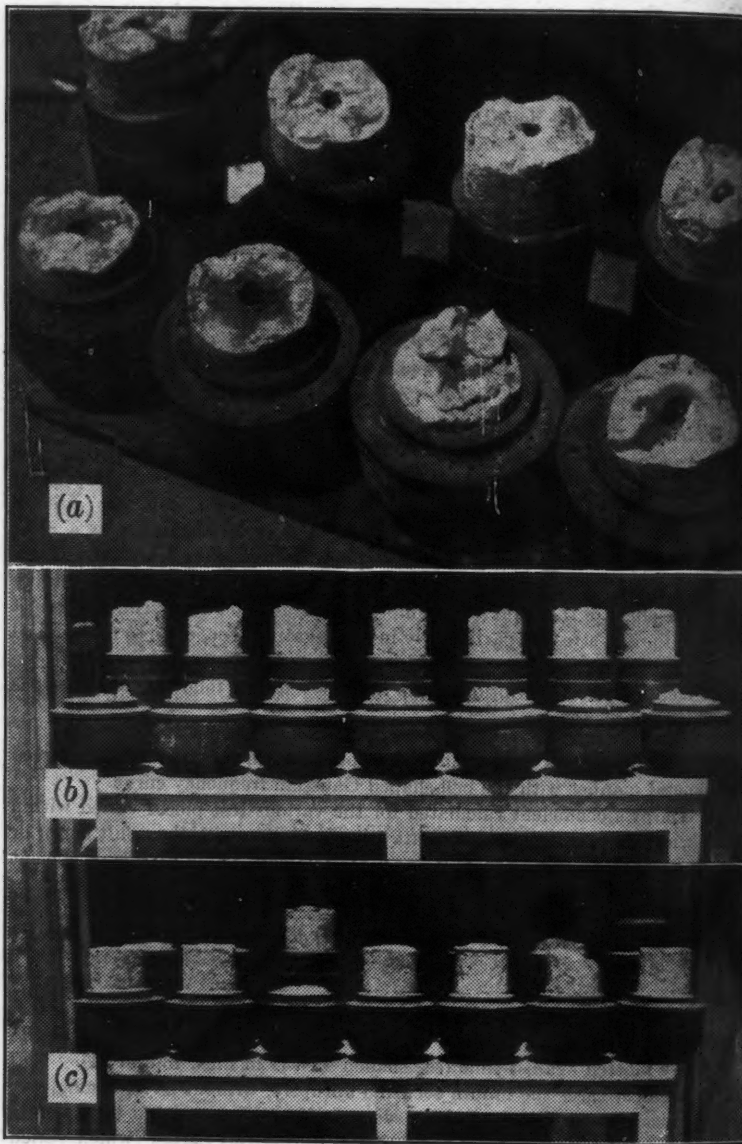

Fig. 26.—Views of Test Specimens After Failure

to pass freely through them, and the deformations became sometimes excessive. A somewhat similar phenomenon had been observed earlier by Kelen.[16]

Some views of the test pieces after failure are reproduced in Fig. 26.

Conclusions

Although the investigation began with the analysis of individual diagrams, some of which contained five points only, it was later found possible to construct a combined chart having ninety-five points to support the empirical relations which it represented. The conclusions thus derived may be summarized as follows:

(1) Uplift was shown to exist, sufficient to cause failure, by tension, of perfectly solid and sound material. This was true despite the fact that, at the moment this failure occurred, the block was subjected to a mechanically developed compression of variable intensity which tended to oppose the effect of uplift. Sometimes this pressure intensity was as much as 18 kg per sq cm, which is equivalent to a height of superimposed masonry of about eighty meters.

(2) It may be even more important to know that the uplift force was proved to be a measurable quantity, subject to certain laws and capable of analysis by laboratory experimentation—perhaps even more directly measurable than some of the forces that are usually believed to be known, such as the impact effect. This conclusion deserves emphasis since there are many who draw pessimistic comparisons between the alleged "uncertainty" of the uplift effect in dams, as opposed to the precision of the stress analysis in steel framework.

(3) The average value of the "effective superficial porosity" n_a, which was the main unknown to be determined by these experiments, was found to be 0.91, with a probable error equal to 0.014.

(4) Within narrow limits (about three times the standard error) this coefficient appears to be dependent upon certain physical characteristics of the ingredients used in making the material. Such influences must be considered as secondary, however, because the value of the coefficient changes only very slightly, and the causes of such very small changes might be accidental. For practical purposes the coefficient n_a can be assumed to be almost constant.

(5) In general, n_a is much greater than the porosity of the material tested (regardless of the assumption under which the latter may be determined), which completely disproves the ideas of Fillunger, and strongly supports the theory of Terzaghi. According to the latter theory, large values of the coefficient n_a are explained by the fact that the microstructure of a porous solid (see Fig. 27) is an agglomeration of a large number of small blocks, with points of contact so minute as to belong to a still higher order of minuteness. In three series of observations Terzaghi determined values of n_a, respectively, as 0.97, 0.97, and 0.998. The surface of rupture (line AB, Fig. 27) is an irregular surface of "least resistance" which passes almost entirely through the micro-

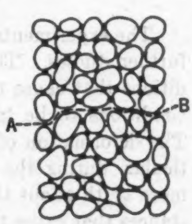

Fig. 27

voids. This seems to supply a possible explanation of the very large difference between n_a and the porosity, observed in the writer's tests.

(6) Although the logic underlying the writer's experiments is compatible with any reasonably evolved theory concerning the characteristics of the uplift pressure, the results derived contain evidence that favors the modern school of thought on this subject.

(7) The factor n_a is found to bear no relation to Darcy's coefficient of filtering, which means that, other things being equal, leakage and sweating cannot serve as evidence that uplift forces are present. It follows that the division of dams into "leaky" and "dry" categories is illusory in so far as uplift is concerned.

(8) On the other hand, if a dam which is known to have been "dry" should suddenly show signs of becoming "leaky," this might be a very strong warning that an "agony period" is impending. Leakage must be prevented or reduced as much as possible in any case, because it may be the cause of the gradual deterioration of the material.

(9) The coefficient n_a is independent of the stress to which the material is subjected (linear relationship between $p_a A$ and F). It is also independent of several other factors which, apparently, might have affected it, such as the cement and water percentages, the temperature, the rate of rise of the pressure, and the consecutive order of loadings and pressures applied.

(10) The increase in the weight of material due to the penetration of water into the pores is less than might have been expected because, in the natural state of the material, the pores are already partly filled with water. The water that may be added, over and above the normal moisture content, represents an average of about 7% of the volume of the materials tested. Therefore, this is the value which, according to the modern views on the subject, must be subtracted from n_a in order to obtain the final, net value of the uplift factor.

(11) It follows that the uplift factor, by Eq. 5, is $0.91 - 0.07 = 0.84$. The writer recommends 85% as a fairly accurate average round figure.

Suggestions for Further Research

The experiments described in this paper should serve as a starting point for further studies. The writer's interpretation of the tests is based upon the conditions that cause the rupture of the specimen, which indeed are the critical conditions to be taken into account in evaluating the safety of a project. The deformation of the test piece could be recorded throughout and, in particular, during the final period before rupture. Such records might reveal more truth about the mechanics of failure and help in explaining the circumstances that cause the "agony" conditions.

To study deformations would require certain alterations in the mechanical details of the apparatus. Had time and money been available, it was the writer's intention to proceed with these additional tests, but under the conditions extant during World War II this was impossible, and some appreciable time will elapse before such results can be obtained and analyzed.

Acknowledgments

The officials of the Egyptian Government have encouraged the experiments described in this paper and have helped in the investigation. In particular the writer is indebted to H. E. Hurst, Director General of the Physical Department, Ministry of Public Works, for valuable assistance and advice, and to the past and present staff in the writer's office, for help with the experiments and computations.

He wishes also to record his admiration for the excellent work done by the Cairo Government Workshops in making the testing machine, according to his drawings, and the expert assistance of the engineers of the Bridges Service, Egyptian State Railways, who helped in preparing the test specimens.

DAMS ON POROUS MEDIA

By Mohamed Ahmed Selim,[32] Assoc. M. ASCE

Synopsis

When a dam or weir is constructed on a porous foundation, some of the water will percolate underneath it toward the downstream side. The purpose of this paper is to present experimental data on the uplift forces, acting on a dam built on porous media, and on the accompanying loss of head. The electric-analogy method of analysis was chosen because of its simplicity, economy, and reliability. Different conditions of substrata and various combinations of simple horizontal floors and cutoff walls are considered.

Introduction

Two empirical methods have been used in designing dams on porous foundations—the first that proposed by W. G. Bligh[33] and the second that proposed by E. W. Lane,[18] M. ASCE.

The Bligh Theory.—Mr. Bligh[33] treated the course of seepage beneath a dam on the assumption that the water follows a path along the line of contact of the dam foundation (including the cutoff walls) with the foundation material. This contact between dam and foundation is sometimes called the line of creep, and the method may be called the line-of-creep method. The head is assumed to drop along a straight line from the headwater to the tailwater (if there is any) in proportion to the distance along the line-of-creep. According to the Darcy law for a fluid of unit dynamic viscosity,

$$Q = K \frac{h A}{L} \qquad (18)$$

in which Q is discharge in cubic feet per second; h is head in feet; A is gross cross-sectional area in square feet; K is a dimensional coefficient; and L is length of path in feet. From continuity, $Q = A V$; hence,

$$L = K \frac{h}{V} \qquad (19)$$

For a given size distribution of material, there appears to be a definite maximum velocity, V_m, at which water can emerge below the dam without carrying away the foundation material, thus causing failure of the structure. Combining this value of V_m with K, which also depends on the material, to form a new constant, $c = \frac{K}{V_m}$, Eq. 19 becomes

$$L_m = c\, h \qquad (20)$$

[32] Lecturer "A," Irrig. Dept., Faculty of Eng., Fouad First Univ., Giza, Egypt; formerly Instructor in Mech. Eng., Univ. of California, Berkeley, Calif.

[33] "The Practical Design of Irrigation Works," by W. G. Bligh, D. Van Nostrand Co., New York, N. Y., 1910.

in which L_m is minimum safe length of travel path (length of creep), and c is a constant depending on the foundation material. Mr. Bligh assumed that horizontal length of contact was just as effective as a vertical length. In other words, for a dam with horizontal floor of length b and an upstream cutoff wall of depth d_1:

$$L_m = b + 2\,d_1 = c\,h \qquad (21a)$$

For a dam with horizontal floor of length b, and upstream and downstream cutoff walls of depths d_1 and d_2:

$$L_m = b + 2\,d_1 + 2\,d_2 = c\,h \qquad (21b)$$

The Lane Theory.—The Bligh theory was accepted widely because of its simplicity until, in 1934, Professor Lane introduced his empirical "weighted-creep" theory. In this theory it is assumed that the line of flow will follow the line of contact between a dam and its foundation; but the vertical contact is considered more effective than the horizontal contact, and the coefficient c is different from that given by Mr. Bligh. After a study of the designs of a large number of dams in the United States and of the failure of some others, Professor Lane recommended that a unit horizontal length of contact be considered to be one third as effective as a unit length of vertical contact.

For a dam with horizontal floor of length b and upstream cutoff wall of depth d_1:

$$L_m = \frac{b}{3} + 2\,d_1 = c_1\,h \qquad (22a)$$

For a dam with a horizontal floor of length b and upstream and downstream cutoff walls of depths d_1 and d_2:

$$L_m = \frac{b}{3} + 2\,d_1 + 2\,d_2 = c_1\,h \qquad (22b)$$

From Eqs. 22,

$$\frac{\text{Loss of head per unit length of vertical}}{\text{Loss of head per unit length of horizontal}} = 6 \qquad (23)$$

Throughout this paper, this ratio has been called the "efficiency of the vertical."

R. B. Khosla has developed quite an ingenious method of solving problems in this field. For comparison, some of his results are mentioned in this paper; but, because of limited space, the reader is referred to the original source[34] for more complete information.

Theory of the Flow of Water Through Homogeneous Porous Media

Flow may be either laminar or turbulent depending for the most part upon the resistance offered by the material through which the liquid is flowing. The resistance of a porous medium composed largely of grains smaller than gravel is sufficient to prevent turbulent flow if natural channels are prevented

[34] "Design of Weirs on Permeable Foundations," by R. B. Khosla, N. K. Bose, and E. Taylor, *Publication No. 12*, Central Board of Irrig., Simla, India, September, 1936.

from enlarging. Hence, for ordinary practical purposes, only laminar flow need be considered.

For two-dimensional flow, the general differential formula for the steady flow of water through homogeneous materials has the form of a LaPlace equation:

$$\frac{\partial^2 p}{\partial x^2} + \frac{\partial^2 p}{\partial y^2} = 0 \qquad (24)$$

Eq. 24 is obtained by substituting the Darcy law of flow—

$$u = k\frac{dp}{dx} \quad \text{and} \quad v = k\frac{dp}{dy} \qquad (25)$$

—into the equation of continuity

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \qquad (26)$$

in which p is the pressure, k is a permeability coefficient which includes the effect of viscosity, and u and v are the two components of the discharge per unit gross area in the directions x and y, respectively. Eq. 26 is dependent on the following conditions: (1) The voids are completely filled with water; (2) the porous medium is uniform in all directions; (3) the quantity of flow entering any small element of volume is equal to the quantity flowing out of this element of volume during any given time; and (4) both water and material are incompressible.

Eq. 24 represents two families of curves, intersecting at right angles, which are usually referred to as the flow lines and equipotential lines (or lines of equal head loss). Four methods are in common use for the solution of Eq. 24; namely—(*a*) the mathematical method, (*b*) the graphical method, (*c*) the method of model experiments, and (*d*) the electric-analogy method. The writer's paper is confined to the electric-analogy method. For treatment of the other methods, beyond the scope of the present paper, the reader is referred to the work of W. Weaver;[19] A. Casagrande,[35] M. ASCE; E. W. Lane and F. B. Campbell, Members, ASCE, and W. H. Price;[36] R. Rhoades and M. N. Sinacori,[37] Assoc. M. ASCE; M. G. Ionides;[38] and B. F. Reltov.[39]

Electric-Analogy Method

The method introduced by N. N. Pavlovsky[40] in 1920 is more advantageous than other methods because: (1) It is simple, economical, and rapid; (2) it

gives results that correspond to the exact theoretical solution, even in complicated examples where the theoretical solution is very difficult or even unreliable; and (3) it can be used in certain instances to investigate cases of nonhomogenous media. Development of this method was possible because of the analogy between the Ohm law for flow of electricity and the Darcy law for the flow of water in granular material. Thus, if the components of the current are i_x and i_y, in the x-direction and y-direction, respectively, the equation of continuity is

$$\frac{\partial i_x}{\partial x} + \frac{\partial i_y}{\partial y} = 0 \qquad (27)$$

but, according to the Ohm law,

$$i_x = C\,\frac{\partial E}{\partial x} \quad \text{and} \quad i_y = C\,\frac{\partial E}{\partial y} \qquad (28)$$

in which C is a coefficient and $\partial E/\partial x$ and $\partial E/\partial y$ are the components of voltage gradient in the x-direction and the y-direction, respectively. Hence, substitution of Eq. 28 into Eq. 27 gives the following LaPlace equation:

$$\frac{\partial^2 E}{\partial x^2} + \frac{\partial^2 E}{\partial y^2} = 0 \qquad (29)$$

The similarity of Eqs. 24 and 29 is the basic principle by which the electric-analogy method is applied. Thus, if an electrolyte is placed in a shallow tank in which a set of boundary conditions are introduced which are analogous to a certain hydraulic system, the flow lines of electricity and the equipotential lines can be plotted. The details of this procedure have been described previously by L. F. Harza,[41] engineers of the Bureau of Reclamation,[42] and many others. A complete description of the general methods used need not be repeated. Certain improvements in the technique of the experimental equipment have been developed, however, and are described in the section to follow.

Experimental Equipment and Technique

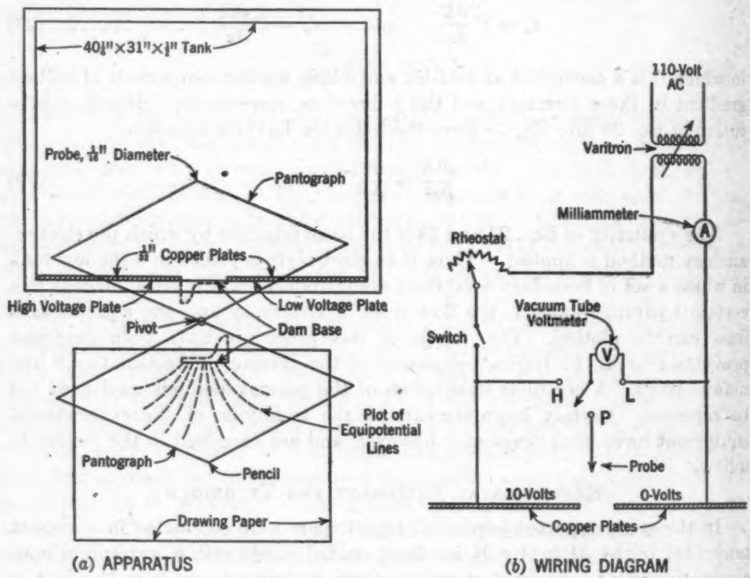
In the study reported herein, all experiments were conducted in a wooden tank ($40\frac{1}{2}$ in. by 31 in. by $2\frac{1}{2}$ in. deep) coated inside with a waterproof nonconductive paint. In most electric-analogy experiments made in the past, a Wheatstone bridge and earphones have been used to detect the equipotential lines. When these experiments were conducted for a considerable time, however, the experimenter often experienced difficulty in recognizing the null points. Instead of using the Wheatstone bridge and earphones in the present experiments a vacuum-tube voltmeter was used. This instrument was equipped with six accurately calibrated scales covering various ranges to a maximum of 16 v. It was also equipped with a 10,000-ohm resistance and could be used to measure the voltage at any point in the tank without using an appreciable amount of current. During an experiment the various equi-

[41] "Uplift and Seepage Under Dams on Sand," by L. F. Harza, *Transactions*, ASCE, Vol. 100, 1935, pp. 1352–1385.

[42] "Model Studies of Penstocks and Outlet Works," *Bulletin No. 2*, U. S. Bureau of Reclamation, Denver, Colo., 1938, pp. 107–118.

potential lines were detected by means of a probe attached to a pantograph. For example, if the 90% line was to be plotted, the voltmeter was maintained at 10 v, and the probe was moved along that potential curve to various closely spaced points corresponding to a voltmeter reading of 9 v.

Fig. 28(*a*) shows the arrangement of the pantograph, equipped with probe and pencil, and the experimental tank. As an illustration, the setup for mapping the equipotential lines under a dam with only a horizontal floor is shown. In this example, the sides of the tank upstream and downstream from the base of the dam were covered with copper plates. Therefore, current flows through the electrolyte from one plate to the other in a manner analogous to that of the flow of water from the upstream bed to the downstream bed.



(*a*) APPARATUS (*b*) WIRING DIAGRAM

FIG. 28.—EXPERIMENTAL SETUP FOR PLOTTING EQUIPOTENTIAL LINES FOR A DAM WITH A HORIZONTAL FLOOR AND NO CUTOFF WALLS

In mapping the flow lines for the dam shown in Fig. 28(*a*), the position of the copper plates and that of the nonconductive surfaces was reversed—that is, the base of the dam was constructed of copper plate and the entire perimeter of the tank was covered with copper, with the exception of that part of the sides which represented the upstream bed and downstream bed of the stream. The equipotential lines which are mapped with this latter arrangement then represent the flow lines of the system.

Fig. 28(*b*) shows the general wiring diagram of the apparatus. Alternating current (120 v, 60 cycles) was used in the experiments to avoid polarizing effects of the electrodes. Using a variable-potential transformer, a potential of only

10 v could be maintained on the circuit. The supply of current was regulated by a rheostat and measured by a 200 milliammeter. The control switch shown in Fig. 28(*b*) was set on "L" (low) when "zeroing" the voltmeter, set on "H" (high) when the over-all voltage between high and low was selected, and set on "P" (probe) while mapping the equipotential lines. The over-all voltage for determining the potential distribution was measured by placing the probe very near the high voltage plate. This latter step was necessary to eliminate oxidizing effects on the plate.

The base length of all model dams was maintained at 6 in. The model floor and cutoff walls were constructed of $\frac{1}{32}$-in. copper plates when the flow lines were mapped and of $\frac{1}{32}$-in. bakelite plates when the potential lines were mapped. The electrolyte, $\frac{3}{4}$ in. deep, was a solution of copper sulfate in distilled water acidulated with sulfuric acid (50 g of copper sulfate and 25 cc of sulfuric acid per 5 gal of water). In plotting the flow lines, the large current required by the relatively large copper area necessitated a dilution of the solution to half the foregoing concentration.

Probable Sources of Error

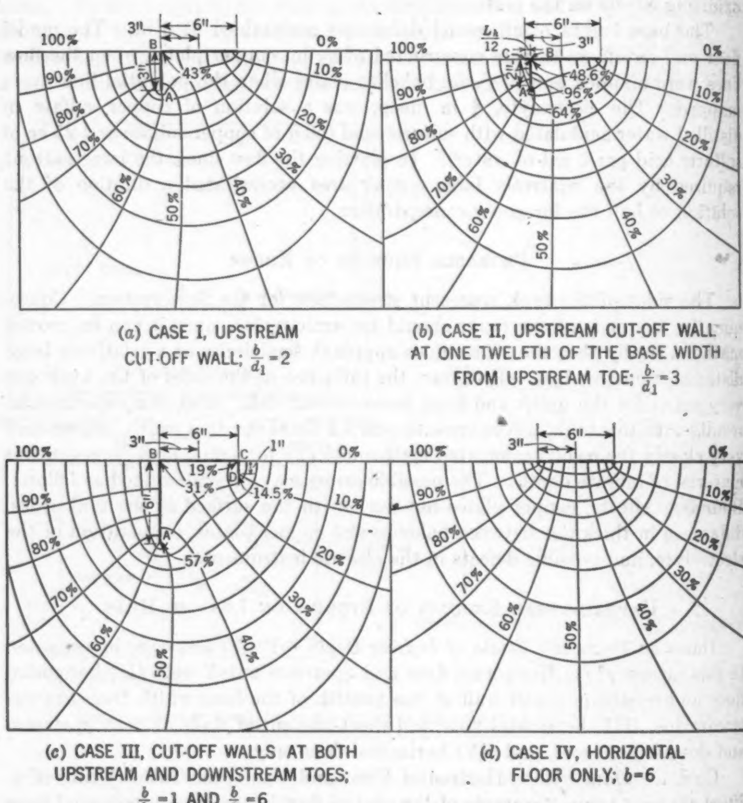
The sides of the tank represent streamlines for the flow system. Consequently, the ends of the tanks should be semicircular, since it can be proved mathematically that the streamlines approach semicircles at a relatively large distance from the dam. However, the influence of the sides of the tank was very small for the uplift and head losses considered. Also, the experimental results with this tank, whose breadth was 5.2 times the dam width, approached very closely the results calculated mathematically for a dam on a homogeneous material of infinite depth. The possible errors may be summarized as follows: Boundary effects, copper plates not flush with the surface at the tank sides, difference in thickness between bakelite and copper plates, evaporation of the electrolyte, and possible defects in the electric instruments.

Experimental Results of Studies on Loss of Head

Dams on Permeable Strata of Infinite Depth.—Four cases were investigated in this category: (I) Horizontal floor and upstream cutoff wall, (II) horizontal floor and upstream cutoff wall at one twelfth of the base width from the upstream toe, (III) horizontal floor and sheet-pile cutoff walls at both upstream and downstream toes, and (IV) horizontal floor only.

Case I. Dam with a Horizontal Floor and Upstream Cutoff Wall.—Fig. 29(*a*) shows a typical example of the plot of flow lines and equipotential lines for the set of experiments in which the depth of cutoff wall d_1 was varied to give values of the ratio, b/d_1, between 1 and 6. These data are summarized in Table 3. The reading at point A, Col. 2 (see Fig. 29(*a*)), represents the percentage of head remaining to be lost after subtracting the percentage lost along the upstream face of the sheet piling. Similarly, the reading at point B (Cols. 3 and 4) represents the percentage of head remaining to be lost by the horizontal floor. Subtraction of the reading at point B from 100 gives the percentage of head that is lost because of the cutoff wall (that is, lost in the

length 2 d_1). Losses of head per unit length of path, expressed as percentages of h, are given in Cols. 5 and 6, subscripts v denoting the depth of cutoff wall, or vertical path and subscript b denoting the horizontal path. In other words, h_v (Col. 5) $= \dfrac{100 - \text{Col. 3}}{d_1}$; and h_b (Col. 6) $= \dfrac{\text{Col. 3}}{b}$. In Cols. 7 and 8, Table 3, the efficiency of the vertical is computed as the ratio $\dfrac{\text{Col. 5}}{\text{Col. 6}}$.



(a) CASE I, UPSTREAM CUT-OFF WALL; $\frac{b}{d_1} = 2$

(b) CASE II, UPSTREAM CUT-OFF WALL AT ONE TWELFTH OF THE BASE WIDTH FROM UPSTREAM TOE; $\frac{b}{d_1} = 3$

(c) CASE III, CUT-OFF WALLS AT BOTH UPSTREAM AND DOWNSTREAM TOES; $\frac{b}{d_1} = 1$ AND $\frac{b}{d_2} = 6$

(d) CASE IV, HORIZONTAL FLOOR ONLY; $b = 6$

FIG. 29.—FLOW LINES AND EQUIPOTENTIAL LINES, DAM WITH HORIZONTAL FLOOR ON PERMEABLE MATERIAL OF INFINITE DEPTH

Case II. Dam with Horizontal Floor and Upstream Cutoff Wall at One Twelfth of the Base Width from the Upstream Toe.—A typical example of a plot of the flow line and equipotential lines is shown in Fig. 29(b), and the data are summarized in Table 4. Similarly to Table 3, the reading in Col. 2, Table 4, is that part of the head which remains to be lost by the cutoff wall

and the remainder of the horizontal floor. The loss of head along the upstream part of the horizontal floor ($b/12$ in this case) is 100—Col. 2.

From Table 4(b) it is obvious that the efficiency of the vertical cutoff wall is decreased by moving the wall slightly toward the downstream toe. From an economical point of view, the cutoff wall should be as close as possible to the upstream toe of the dam.

[a] Expressed as percentages of h. [b] Compare with Col. 3, Table 3. [c] Efficiency of the vertical, h_v/h_h; compare these values with Col. 7, Table 3.

The general effect of the downstream cutoff wall on the readings at points A and B for a particular b/d_1-ratio can be found quickly by comparing the top line where $b/d_2 = \infty$ with the other b/d_2-ratios. In an effort to summarize these data for the designer, Col. 11, Table 5, was computed to give the efficiency

of the cutoff wall under various values of b/d_2 and b/d_1. These values show the fallacy of using excessive lengths of downstream cutoff wall, because in such cases the horizontal length of the floor has relatively little effect as part of the so-called path of percolation.

[a] Expressed as percentages of h. [b] Efficiency h_v/h_h of the upstream and downstream cutoff walls. [c] Efficiency h_v/h_h of the total path; that is, both cutoff walls and the horizontal floor. E. W. Lane, M. ASCE, ceported this value as 6 in all cases.

Case IV. Dam with Horizontal Floor Only.—The plot of the flow lines and equipotential lines for this case is shown in Fig. 29(d). Data from this plot are discussed subsequently in the section on uplift diagrams.

Dams on Permeable Stratum of Finite Depth H.—Only three cases were investigated in this category, Case II being omitted. Experiments were conducted on two depths (H) of permeable stratum—namely, with $H = 2\,b$ and $H = b$.

Case I. Dam with Horizontal Floor and Upstream Cutoff Wall.—A typical example of a plot of the flow lines and equipotential lines is shown in

Fig. 30(a). Comparing Cols. 3 and 4, Table 6, with Cols. 2 and 3, Table 3, it is evident that a finite depth of permeable layer has only a small effect on the head-loss readings. The effect of the finite depth of porous material in reducing the efficiency of the vertical lengths as compared with that for an

infinite depth of material is demonstrated by comparing Col. 7, Table 6, with Col. 7, Table 3.

Case III. Dam with Horizontal Floor and Sheet-Pile Cutoff Walls at Both Upstream and Downstream Toes.—For this arrangement of floor and cutoff walls, only the case in which $H = 2b$ was investigated. A typical plot is shown in Fig. 30(b), and the data are summarized in Table 7.

Case IV. Dam with Horizontal Floor Only.—The data from these plots are discussed subsequently in the section on uplift diagrams.

Permeable Strata Under the Dam Composed of Two Materials with Different Permeabilities and the Depth of the Upper Layer is Finite

A dam with horizontal floor only was investigated for this condition. Because of the difficulty of adapting the upper plates to the various positions of the glass false bottom, only the equipotential lines were drawn (see Fig. 31). At the boundary between isotropic soils of different permeability, the equipotential lines are deflected in such a manner that the angles α and β and the permeabilities as defined by Eq. 18 or 25 are related as follows (see Fig. 31):

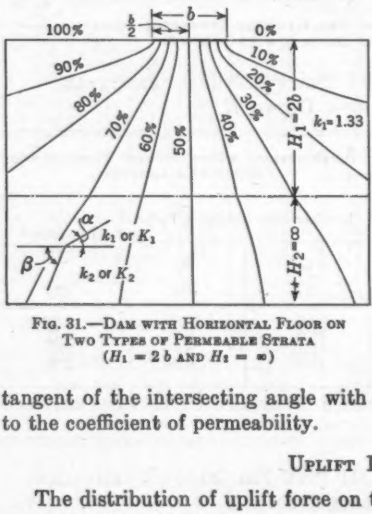

Fig. 31.—Dam with Horizontal Floor on Two Types of Permeable Strata ($H_1 = 2b$ and $H_2 = \infty$)

$$\frac{\tan \beta}{\tan \alpha} = \frac{k_1}{k_2} = \frac{K_1}{K_2} \qquad (30)$$

Eq. 30 states merely that the deflection of the equipotential lines occurs in such a manner that the tangent of the intersecting angle with the boundary is inversely proportional to the coefficient of permeability.

Uplift Diagrams

The distribution of uplift force on the base of a dam may be conveniently represented in the form of a diagram. In the present investigation, uplift diagrams were prepared from the various graphs of equipotential lines by plotting, as ordinates, the values of head at the intersection of the potential lines with the base of the dam. The maximum ordinate of 100% h will be that at the upstream toe and the minimum ordinate at 0% h will be at the downstream toe. The following definitions are useful in discussing uplift diagrams: A_F is the area of diagram expressed in terms of the base width b and the head h (representing the total uplift force); $\bar{X}$ is the distance at the center of gravity of the uplift diagram from the downstream toe of the dam; and M is the moment of uplift force about the downstream toe of the dam. "Bligh's uplift diagram" is a triangle with the maximum ordinate at the upstream toe and the zero ordinate at the downstream toe. This diagram is for

a dam with a horizontal floor only and zero depth at the downstream toe. "Theoretical uplift (horizontal floor only)" is the uplift calculated by the formula:[19]

$$P = \frac{h}{\pi} \cos^{-1} \left(\frac{2x}{b} \right) \qquad (31)$$

in which the origin is at the midpoint of the floor and P is the value of the force in percentage of the total head, h, acting on the dam.

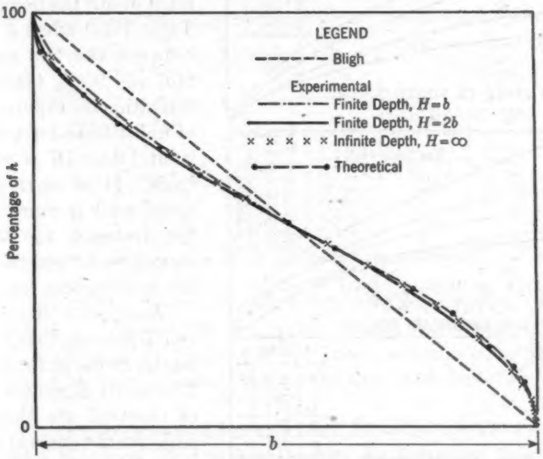

FIG. 32.—UPLIFT DIAGRAM, DAM WITH HORIZONTAL FLOOR ONLY

Dam with Horizontal Floor Only.—Fig. 32 shows the uplift diagram according to Mr. Bligh, the Weaver theoretical formula, and the author's experiments for a dam with a horizontal floor only. A comparison of uplift forces and the resulting moments for the various conditions of thickness of permeable strata are given in Table 8. The coincidence between the theoretical (that is, mathematical) and experimental results is evident. The effect of finite depth of permeable layer is very small and the results still approach the theoretical values. In connection with Table 8, as well as in the data to follow, the values of moment are given only for comparative purposes, because the type of dam to which this information would be applied nearly always has such a wide base that overturning is no problem.

TABLE 8.—COMPARISON OF RESULTS, DAM WITH HORIZONTAL FLOOR ONLY

H	A_F	$\bar{X}$	M
	(a) THEORETICAL		
∞	$0.5\,b\,h$	$0.625\,b$	$0.3125\,b^2 h$
	(b) EXPERIMENTAL		
∞	$0.504\,b\,h$	$0.626\,b$	$0.313\,b^2 h$
b	$0.496\,b\,h$	$0.629\,b$	$0.312\,b^2 h$
$2\,b$	$0.492\,b\,h$	$0.630\,b$	$0.310\,b^2 h$

Dam with Horizontal Floor and Upstream Cutoff Walls (*Permeable Strata of Infinite Thickness*).—Uplift diagrams for the cutoff wall at the upstream toe are shown in Fig. 33(b) and in Fig. 33(c) when the sheet piling is one twelfth of the base width from the upstream toe. Data from these diagrams are summarized in Table 9, which also shows the effect of the upstream cutoff wall in reducing the uplift force and its moment about the downstream toe. Table 10(a) offers a comparison between the two cases (Tables 9(a) and 9(b)), taking into consideration the experimental value of uplift force for a dam on horizontal floor ($H = \infty$) only as a basis. It is obvious that the cutoff wall is more effective at the upstream toe than if it is moved back from the toe toward the downstream toe.

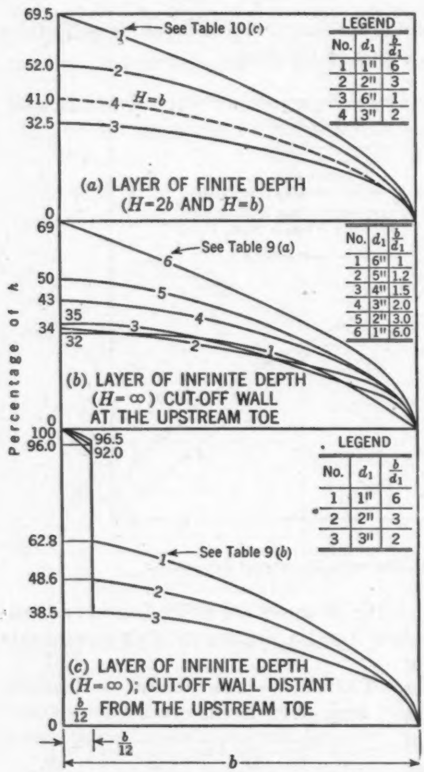

FIG. 33.—UPLIFT DIAGRAMS, DAM ON A PERVIOUS FOUNDATION, WITH HORIZONTAL FLOOR AND UPSTREAM CUTOFF WALL (b = 6 IN.)

Dam with Horizontal Floor and Upstream Cutoff Wall (*Permeable Strata at Finite Depth*).—The uplift diagrams and values of moment are shown in Fig. 33(a) for the cases of finite thickness, $H = b$ and $H = 2\,b$. The effect of the upstream cutoff wall on the uplift force for various thicknesses of the substratum can be noted in Table 10 by comparing Col. 2 ($H = \infty$) with Cols. 6 and 7 and Col. 4 ($H = \infty$) with Cols. 8 and 9. The basis of comparison is the uplift force obtained experimentally for a dam with horizontal floor only, on a very deep permeable layer.

Dam with Horizontal Floor with Upstream and Downstream Cutoff Walls (*Permeable Strata of Infinite Depth*).—The uplift diagrams for various lengths of the downstream cutoff wall for a length of upstream cutoff wall (d_1) equal to the base width (b) are shown in Fig. 34(a). A summary of data for several arrangements of upstream and downstream cutoff walls is shown in Table 11. Clearly, the effectiveness of the upstream cutoff wall, in reducing both the uplift force and its moment about the downstream toe, is offset by the use of a downstream cutoff wall. This effect is heightened by increasing the depth of the downstream cutoff wall. Consequently, a cutoff wall at the upstream

toe only is better for design as far as the uplift force on the dam and the moment about the downstream toe are concerned. The downstream cutoff wall may be valuable, however, in reducing the exit gradient to such a value that material will not be disturbed by the outflow from under the dam.

* Percentage reduction in uplift forces and moments about the downstream toe.

The uplift diagrams from these experiments are shown in Fig. 34(b). A comparison of these results with those for similar arrangements of floor and cutoff walls for an infinite thickness of permeable stratum is given in Table 12. The same conclusions appear to apply for the case of finite depth of permeable layer (Table 12) as for that of infinite depth (Table 11).

Effect of Layers of Different Permeability on the Uplift Diagram of a Dam with Horizontal Floor Only.—These experiments were made to show the effect on the uplift force and the resulting moment about the downstream toe when adjacent layers with different permeabilities are present. The depth of the upper stratum was changed from $H = b$ to $H = 2\,b$; and the ratio of permeabilities, k_1/k_2, had values of 1.33 and 1.5. The uplift diagram for one such experimental condition is shown in Fig. 35 along with the comparable curve by Mr. Bligh and the theoretical curve by Mr. Weaver. The difference between the theoretical and experimental curves appears to be negligible. Data from the various diagrams for dams with horizontal floors only are summarized in Table 13. The change in uplift force and moments did not exceed $\pm 2\%$ for $k_1/k_2 = 1.33$ or $\pm 3\%$ for $k_1/k_2 = 1.50$. However, because of the limited number of experiments, a general conclusion cannot be reached.

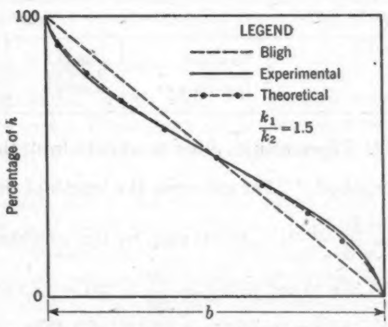

FIG. 35.—UPLIFT DIAGRAM, DAM ON A FINITE PERVIOUS LAYER ($H_1 = b$ and $k_1 = 1.50$) OVERLYING AN INFINITELY DEEP PERVIOUS LAYER ($H_2 = \infty$ AND $k_2 = 1.0$)

APPLICATION OF EXPERIMENTAL RESULTS TO PRACTICAL EXAMPLE

Example 1.—A weir 10 ft high, with a horizontal floor ($b = 60$ ft) and with a cutoff wall ($d_1 = 20$ ft) at the upstream toe rests on an impervious foundation as shown in Fig. 36. The ratio b/d_1, therefore, has a value of 3; and, according to the data in Table 3(a), the loss of head due to the sheet piling is 50.5% of the head, h, and the loss of head due to the horizontal floor is 49.5% of h.

From Table 3(*b*), the ratio of the loss of head per unit of vertical length to the loss of head per unit of horizontal length is 3.06. If γ is the weight per cubic ft of water, the uplift force on this dam (see Table 9) is $0.336\,b\,h\,\gamma = 201.6$ lb and the moment of this force about the downstream toe is $0.189\,b^2\,h\,\gamma = 6{,}804\,\gamma$ ft-lb.

TABLE 13.—COMPARISON OF RESULTS, DAM WITH HORIZONTAL FLOOR AND WITHOUT CUTOFF WALLS, ON STRATA OF VARIOUS DEPTHS

$\frac{k_1}{k_2(=1)}$	Condition of substratum	Uplift Force		Moment about Downstream Toe	
		A_F	Change (%)	M	Change (%)
(1)	(2)	(3)	(4)	(5)	(6)
(a) $H = \infty$					
1.0	Uniform	$0.5\ b\,h$	0	$0.313\,b^2\,h$	0
(b) $H = b$					
1.33	Stratified	$0.492\,b\,h$	−1.6	$0.310\,b^2\,h$	−0.96
1.50	Stratified	$0.491\,b\,h$	−1.8	$0.319\,b^2\,h$	+1.92
∞	Impermeable	$0.496\,b\,h$	−0.8	$0.312\,b^2\,h$	−0.32
(c) $H = 2\,b$					
1.33	Stratified	$0.496\,b\,h$	−0.8	$0.316\,b^2\,h$	+0.96
1.50	Stratified	$0.486\,b\,h$	−2.8	$0.322\,b^2\,h$	+2.78
∞	Impermeable	$0.492\,b\,h$	−1.6	$0.310\,b^2\,h$	−0.96

These results differ markedly from those determined by the weighted-creep method.[18] For example, the length of the path of percolation is $L_w = \frac{b}{3} + 2\,d_1 = \frac{60}{3} + 40 = 60$ ft; and, by the weighted-creep method, the loss at head due to the sheet piling is $\frac{20}{60}\,h\,100 = 66.66\%$ of h; but the loss of head due to the horizontal floor is 33.4% of h (Fig. 36(*b*)); and the uplift force on the dam

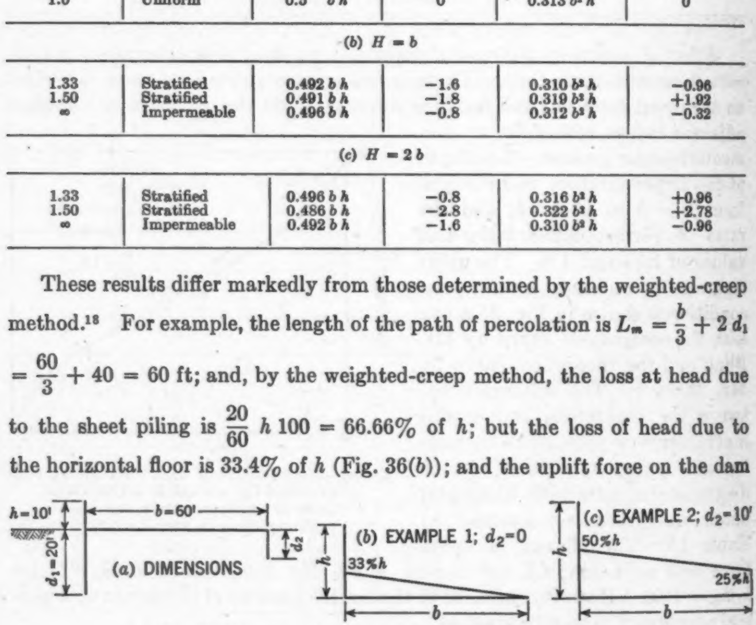

FIG. 36.—PRACTICAL APPLICATION OF EXPERIMENTAL RESULTS

is $0.167\,b\,h\,\gamma = 100.2\,\gamma$ lb. Finally, the moment of this force about the downstream toe is $0.111\,b^2\,h\,\gamma = 3{,}996\,\gamma$ ft-lb.

Example 2.—For a weir with both upstream and downstream cutoff walls, assume the same weir as in Example 1, except that a 10-ft downstream cutoff wall is added ($d_2 = 10$ ft). According to Table 5(*a*), for the case of $b/d_1 = 3$ and $b/d_2 = 6$:

Path	Loss (percentage of h)
d_1	45.5
d_2	30.0
b	24.5

These data give a ratio of head loss per unit vertical length to head loss per unit horizontal length of 5.57 for the upstream cutoff wall and 7.34 for the downstream cutoff wall (see Table 5(b)). The uplift force from Table 11 is $0.425\, b\, h\, \gamma = 255\, \gamma$ lb; and the moment of this force is $0.251\, b^2\, h\, \gamma = 8{,}835\, \gamma$ ft-lb.

In comparison, the weighted-creep analysis yields a length of the path of percolation equal to $L_m = 2\, d_1 + \frac{b}{3} + 2\, d_2 = 40 + 20 + 20 = 80$ ft and the losses of head are:

Path	Loss (percentage of h)
d_1	50
d_2	25
b	25

The ratio of loss of head per unit of vertical path to the loss per unit of horizontal floor is assumed to have a value of 6. The pressure distribution is assumed to be that shown in Fig. 36(c); and the uplift force then is $0.375\, b\, h\, \gamma = 225\, \gamma$ lb and the moment of this force about the downstream toe is $0.208\, b^2\, h\gamma = 7{,}488\, \gamma$ ft-lb.

Summary and Conclusions

A new experimental technique is presented in this paper. A vacuum-tube voltmeter is used instead of earphones and a Wheatstone bridge to detect the lines of equal voltage, and a pantograph is used for the direct plotting of the points.

The advantage of an upstream cutoff wall in reducing the uplift force is demonstrated. A downstream cutoff wall tends to increase the uplift force and hence to offset the value of the upstream cutoff wall. The downstream cutoff wall may be necessary, however, to prevent the formation of channels beneath the dam. It is recommended that only a relatively short downstream cutoff wall be used in connection with a relatively deep upstream wall.

When the thickness of the stratum of porous material under a dam is greater than the base width, the uplift force and moment are essentially the same as when the porous media is of infinite depth.

Acknowledgment

The data on which this paper is based are included in an academic thesis by the writer, entitled "Underflow and Uplift Pressure for Dams and Weirs on Porous Media by Electric Analogy." It was presented to the University of California at Berkeley in May, 1941, in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Irrigation Engineering. Copies of the thesis are filed at the University of California and at Engineering Societies Library in New York, N. Y.

DISCUSSION

W. H. Holmes,[43] Assoc. M. ASCE.—Designers of dams should find the paper by Mr. Leliavsky extremely interesting and important because it indicates that the effective area on which uplift acts may be larger than is usually assumed. Any solution of a problem that gives results different from the conventional should be critically examined.

From simple mechanics, neglecting friction in the apparatus, the sum of the vertical forces is equal to zero, or

$$\Sigma V = 0 \qquad (32)$$

In this case, at any section of the test cylinder, forces acting to resist uplift are weight, W, of that part of the cylinder above the section; externally applied force, F, on top of the cylinder; and the tensile strength, z, of the test cylinder. The forces tending to rupture the cylinder are the average liquid pressure, p_a, acting on the area, $n\,A$ (in which A is the total area of the test cylinder and n is the effective area on which the pressure is applied).

For the condition just prior to the instant of rupture, Eq. 32 becomes:

$$W + F + z - p_a\, n\, A = 0 \qquad (33a)$$

Neglecting the weight of the cylinder, Eq. 33*a* reduces to:

$$F = n\, p_a\, A - z \qquad (33b)$$

Stress, f, in terms of load on a unit area and unit tensile strength, c, of the material may be obtained by dividing Eq. 33*b* by the cross-sectional area, A, as:

$$f = n\, p_a - c \qquad (33c)$$

For demonstration, series 1 will be examined since, as Mr. Leliavsky states (in introducing Fig. 23), "* * * the workmen had acquired a greater ability in preparing the test pieces." The results of series 1 (Fig. 23) were given, in kilograms, as:

$$F = 0.858\, p_a\, A - 1{,}058 \qquad (34)$$

Since the area A was about 150 sq cm, the value of f for a unit area equals $0.858\, p_a - \dfrac{1{,}058 \text{ kg}}{150 \text{ sq cm}} = 0.858\, p_a - 7.06$ kg per sq cm. In pounds per square inch, therefore,

$$f = 0.858\, p_a - 100.4 \qquad (35)$$

This equation is similar to Eq. 33*c*. Eq. 35 is redrawn in Fig. 37. For the case in which the oil pressure is zero, the force, f, necessary to rupture a cylinder is equal to the tensile strength, or 100.4 lb per sq in. This tensile strength

---

[43] Superv. Engr., State Dept. of Public Works, Sacramento, Calif.

of the concrete, for some unknown reason, is lower than that expected for good concrete.

Experience has demonstrated that construction materials do not have perfect physical properties as assumed in simple mechanics. Forces acting in one direction have deformations at right angles to the direction of force. The analyst becomes involved in nomenclature when he refers to strains without an accompanying stress, but the foregoing deformations and stresses are real to the extent that failure occurs on a plane when loadings at right angles to the plane become excessive. The various theories as to the cause of failure will not be discussed, but this type of failure has been demonstrated repeatedly.

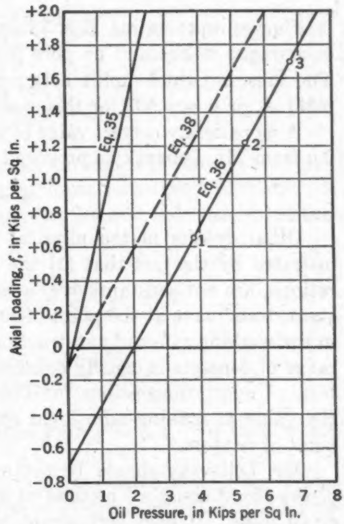

FIG. 37.—(1 KIP = 1 "KILO-POUND" = 1,000 LB)

Frank E. Richart and Anton Brandtzaeg, Members, ASCE, and Rex L. Brown[44] have demonstrated that an external force on the circumference of cylinders, even with all pores sealed, ruptures them in manner similar to the ruptures produced by Mr. Leliavsky's experiments. For a concrete mix of 1:3:5 on 4-in. by 8-in. cylinders, they found that,[45] for oil pressures of 3,830, 5,460, and 6,790 lb per sq in., the unit axial loads at rupture were 660, 1,215, and 1,700 lb per sq in., respectively.

The equation for these three points, in lb per sq in., is:

$$f = 0.351\, p_o - 689 \qquad (36)$$

From Eq. 36 (see Fig. 37), the ratio μ, commonly called Poisson's ratio of the coordinate stresses, can be determined. The external oil pressure may be resolved into two pairs of equal compressive forces, p_o, acting upon two planes at right angles through the axis of the cylinder. Since each pair of forces produces a tensile force, f, acting along the axis of the cylinder which amounts to $\mu\, p_o$, the total force tending to rupture the cylinder is

$$f = 2\,\mu\, p_o \qquad (37)$$

Therefore, from Eq. 36 if p_o is assumed equal to p_a (which is never exactly true), $2\,\mu = 0.351$, or $\mu = 0.175$.

If the concrete for the 1928 and 1942 tests had the same tensile strength, the curves of Eqs. 35 and 36 would have intersected the x-axis at a common point. If a line is drawn through the intersection of Eq. 35 and the x-axis

[44] "A Study of the Failure of Concrete Under Combined Compressive Stresses," by Frank E. Richart, Anton Brandtzaeg, and Rex L. Brown, *Bulletin No. 185*, Univ. of Illinois, Urbana, November, 1928.

[45] *Ibid.*, p. 72.

and parallel to Eq. 36 (Fig. 37), the result for such a line is the equivalent of making the tensile strength of the two materials the same. The equation (see Fig. 37) is:

$$f = 0.351\, p_o - 100.4 \ldots\ldots\ldots\ldots (38)$$

Curves representing Eqs. 35 and 38 (Fig. 37) differ only in that uplift was encouraged in one and no pore pressure or uplift was permitted in the other. The area on which uplift acts must be the difference between 0.858 A and 0.351 A, or $n = 0.507$ for this case.

A more nearly correct value of the uplift factor can be found by subtracting $2\,\mu$ from Mr. Leliavsky's proposed value of n; or:

$$n = 0.85 - 2\,\mu \ldots\ldots\ldots\ldots (39)$$

Other defects in the physical properties of construction material are illustrated by the fact that (1) the modulus of elasticity, E, and (2) Poisson's ratio, μ, are not constants over a large range of loading. If E and μ were constant, tests made at the point of rupture would be sufficiently accurate for use in the working range of construction material. The value of μ for the working range of concrete is usually considered lower than indicated for this particular test. Under "Suggestions for Further Research," Mr. Leliavsky recognized the value of making additional studies based on deformation instead of "at point of rupture."

Mr. Leliavsky should be commended for using the statistical application of the "least-squares" method to avoid the personal equation in "averaging" given data. If engineers would use this method, instead of "averaging by eye" a line through a series of plotted points, they would be able to obtain more consistent results from experimental work.

Since Mr. Leliavsky's reference to the "least-squares" principle is not readily available, a brief derivation follows: If the data available have the form $x_1\,y_1$, $x_2\,y_2$, . . ., $x_N\,y_N$ which plot approximately as a straight line, the equation may be written as:

$$y = a\,x + b - r \ldots\ldots\ldots\ldots (40)$$

in which a is the slope of the line; b is a constant; and r is the error of regression or a coefficient of correlation. Then, $r = a\,x + b - y$; $r^2 = a^2\,x^2 + b^2 + y^2 + 2\,a\,x\,b - 2\,a\,x\,y - 2\,b\,y$; and

$$\Sigma r^2 = a^2\,\Sigma x^2 + N\,b^2 + \Sigma y^2 + 2\,a\,b\,\Sigma x - 2\,a\,\Sigma(x\,y) - 2\,b\,\Sigma y \ldots (41)$$

Let Σr^2 approach zero and take derivatives of Σr^2 with respect to a and b:

$$\frac{d\,\Sigma r^2}{da} = 2\,a\,\Sigma x^2 + 2\,b\,\Sigma x - 2\,\Sigma(x\,y) = 0 \ldots\ldots\ldots\ldots (42a)$$

and

$$\frac{d\,\Sigma r^2}{db} = 2\,N\,b + 2\,a\,\Sigma x - 2\,\Sigma y = 0 \ldots\ldots\ldots\ldots (42b)$$

or

$$a\,\Sigma x^2 + b\,\Sigma x - \Sigma(x\,y) = 0 \ldots\ldots\ldots\ldots (43a)$$

and

$$b\,\Sigma x + N\,b - \Sigma y = 0 \qquad (43b)$$

Solving Eqs. 43 for a and b:

$$a = \frac{N\,\Sigma(x\,y) - \Sigma x\,\Sigma y}{N\,\Sigma x^2 - (\Sigma x)^2} \qquad (44a)$$

and

$$b = \frac{\Sigma x^2\,\Sigma y - \Sigma x\,\Sigma(x\,y)}{N\,\Sigma x^2 - (\Sigma x)^2} \qquad (44b)$$

The slope of the curve representing Eq. 36, through the plotted points 1, 2, and 3, Fig. 37, was determined by the computations listed in Table 14. In Eqs. 44, let $N = 3$, $(\Sigma x)^2 = 16{,}080 \times 16{,}080 = 258{,}566{,}400$; and, substituting other values from Table 14,

$$a = \frac{3 \times 20{,}704{,}700 - 16{,}080 \times 3{,}575}{3 \times 90{,}584{,}600 - 258{,}566{,}400} = 0.351$$

and

$$b = \frac{3{,}575 \times 90{,}584{,}600 - 16{,}080 \times 20{,}704{,}700}{3 \times 90{,}584{,}600 - 258{,}566{,}400} = -\,689.4$$

The resulting equation for a straight line (the form $y = a\,x + b$) then is (see Eq. 36): $f_1 = 0.351\,p_o - 689$.

The writer concurs with Mr. Leliavsky that this paper should serve as a starting point for further studies, and he wishes to emphasize that it is an excellent start toward the solution of an important problem.

TABLE 14.—COMPUTATIONS FOR THE EQUATION OF A LINE TO REPRESENT OBSERVED DATA (EQ. 36, FIG. 37)

W. A. PERKINS,[46] M. ASCE.—Valuable information on the subject of uplift in dams has been added to engineering literature by Mr. Leliavsky. Much thought and care are shown in the design of the testing machine and in the testing procedure. Before a definite method can be established for utilizing these data in the design of gravity dams, however, certain additional information is desirable.

In the laboratory procedure the average pore pressure within the specimen is increased by the control of the fluid pressure, p_i, in the hollow core of the specimen, and by the convergence of the paths of flow of the fluid through the cylindrical test piece. Within a dam, however, the paths of flow are parallel, and there is no counterpressure corresponding to p_i. Consequently, the in-

[46] Hydr. Engr., Sacramento, Calif.

tensity of pore pressure producing uplift within the body of the dam may decrease, with increase of distance from the upstream face, much more rapidly than is indicated by the data produced by the experiments. Valuable information concerning this law of pressure variation could be obtained by the installation of suitable tubes and gages in the galleries of existing dams.

The results of the tests give tensile stresses much lower than are usually obtained with a briquette machine. In Col. 10, Table 2, the average of ninety-five tests was 4.61 kg per sq cm or 65.5 lb per sq in. This is only 20% or 25% of the average values of the tensile strength of mortar specimens of average mixes when broken in the usual manner of determining tensile strength. Furthermore, no allowance is made in the computations for the coordinate tensile stress that is produced by the compressive force on the exterior and interior faces of the cylinder. An application of Mr. Leliavsky's suggested uplift value is described briefly, as follows: Assume a gravity dam with vertical upstream face and uniform batter on the downstream face. Let H_d be the height of dam; γ be the unit weight of water; G be the specific gravity of concrete; m be the downstream batter equal to $\left(\frac{\text{horizontal}}{\text{vertical}}\right)$; and s equal unit stress.

It is easily proved that

$$s = \frac{\gamma H_d}{2}\left(G \pm \frac{2 - G\,m^2}{m^2}\right) \qquad (45)$$

When $G = 2.4$ (an average value) and $m = 0.85$, s at the upstream face $= 75\,H_d - 11.5\,H_d = 63.5\,H_d$.

Taking Mr. Leliavsky's recommended value of 0.85 as the average area subject to uplift it is proper to state that the unit liquid uplift value is 0.85 $\times$ 62.5 = 53 lb per sq ft, or the total uplift for a height of H_d ft is 53 H_d lb per sq ft, leaving a favorable reserve of 10.5 H_d lb per sq ft.

Furthermore, the differential between this type of uplift and the vertical downward pressure increases with distance from the upstream face. As previously indicated, it is logical to assume that the uplift decreases with this distance, whereas the vertical downward pressure increases to 86.5 H_d at the downstream toe.

From the evidence at present available it appears that a gravity dam with a conservative design of thickness equal to 0.85 H_d, which is the practice at the present time, is safe. Likewise, it is the belief of the writer that further information about the law of variation of the pore pressure, due to upstream water pressure, within the body of the dam be obtained before abandoning present conservative methods of estimating uplift.

S. P. Wing,[47] M. ASCE.—The comprehensive and costly experiments, reported by Mr. Leliavsky, on the percentage area of concrete that is effective to hydraulic uplift will remain for many years basic data to which engineers will refer in discussing this factor in dam design. Although future interpretations of his data may change the coefficients he has given by a few per cent, the

[47] Civ. Engr., U. S. Bureau of Reclamation, Denver, Colo.

scatter of his individual determinations from his final value is but $16\frac{1}{2}\%$ as measured by the coefficient of variation. This indicates a reproducibility of results which compares favorably with other types of concrete testing.

The most startling feature of the tests is the extremely low tensile strength of the concrete (Table 2, Col. 10). The derived mean tensile strength of concrete with a water-cement ratio of 0.52, as determined by breaking the cylinders hydraulically, was but 70 lb per sq in., and but 45 lb per sq in. when tested mechanically. (The writer takes the liberty of converting Mr. Leliavsky's metric units to the more familiar English system.)

American tensile tests of concrete (Fig. 38) with 6-in. by 18-in. cylinders, moist cured 180 days, gave unit strengths about seven times the values reported by Mr. Leliavsky. Although some European cements have shown tensile strengths of but 50% of the usual American product,[48] it is possible that the low strengths indicated by Mr. Leliavsky's data may be related either to the form of his test specimen or to some other factor not taken into account in his analysis.

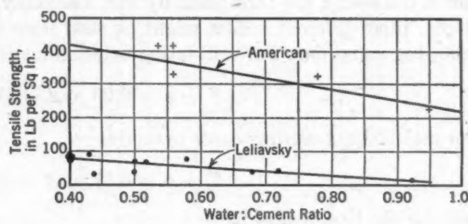

FIG. 38.—TENSILE STRENGTH OF CONCRETE CYLINDERS

The essential procedures of the uplift test, eliminating details, consisted in placing an external compressive load on a 6-in. concrete cylinder equipped with a metal water jacket at its midsection, arranged with a slip joint. By next applying a comparatively high water pressure through the water jacket until the concrete was saturated and then by slowly reducing the external compression load, the concrete was brought to failure in tension by the bursting pressure of the water within the concrete pores. Several cylinders of the same mix, tested at different hydrostatic loads and breaking at different values of the external loads, provided the data needed to relate the two variables. Plots of Y, the external load, as a function of X, the water pressure, multiplied by the gross area of the section, yielded data to which straight-line graphs were fitted by the least-squares method, their equations being of the form:

$$Y = B X + C \qquad (46)$$

It is to be noted that this procedure defines a purely empirical relationship whose validity for use under other conditions depends upon the goodness of fit and upon analysis. It relates the compressive loads to the water pressures at the time of failure in such a manner that errors in estimates of the magnitudes of the compressive loads acting at the time of failure, if made from known applied water pressures, are less on the average than would be obtained were any other straight line fitted to the data. The numerical values of the constants of the equations depend purely on the least-squares solution and not on their

[48] "Comparative Tests of 52 Brands of Portland Cement from 15 Countries," by Eugene V. Barrett, *Proceedings*, A.S.T.M., Vol. 44, 1944, p. 797.

interpretation in terms of physical phenomena. For example, if, instead of expressing Y as a function of X, the pressure X is expressed as a function of Y so as to give the best estimates of the magnitudes of the water pressures needed to break a cylinder under varying external loadings, then a "least-squares" fit of the data locates different lines from those given by Mr. Leliavsky; and their equations solved for Y have different X-coefficients (different uplift coefficients). Alternatively, if, instead of minimizing either the Y-deviations or the X-deviations, the deviations normal to the trend line are minimized, thus giving "the line of best fit,"[49] a third value of the X-coefficient results. If all these coefficients (following the form used by Mr. Leliavsky) were called "uplift" coefficients, their different values might be seen from the $(p_a A)$-coefficients in the following equations: For estimating external loads—

$$F + z = 0.90\, p_a A + 50 \qquad (47a)$$

For estimating bursting water pressures—

$$F + z = 0.97\, p_a A - 130 \qquad (47b)$$

and, for the line of best fit—

$$F + z = 0.93\, p_a A - 30 \qquad (47c)$$

in which F is in kilograms. Unavoidable errors in scaling data from the graph prevent Eq. 47*a* from agreeing precisely with the author's equation for a straight line given in Fig. 24.

A fourth equation, obtained from Eq. 47*c* by transforming into English units and substituting the mean value of the indicated tensile strength z, has been added for later discussion:

$$p_a = 1.08\,(f + 70) \qquad (47d)$$

Eq. 47*d* is thus a function of the unit bursting pressure p_a, in pounds per square inch, substituting a mean value of z. The line of best fit, Eq. 47*c*, indicates an uplift coefficient of 0.93, 0.03 units greater than that given by Eq. 47*a*, the method used by Mr. Leliavsky.

If a superficial interpretation is placed on the coefficients of Eq. 47*d*, this formula indicates that unit water pressures of only 8% in excess of the average unit pressures due to external load plus 70 lb per sq in. were needed to break the concrete. In short the pressures, if acting on the full cross section, were so nearly those required simply to lift the external load that one wonders whether the data do not apply to the condition within the pore space just prior to ultimate failure rather than to the condition at working loads.

Fig. 39, derived from two-dimensional photoelastic studies of tension briquettes,[50] shows a rough estimate of what may have been the distribution of stresses across the section before rupture was reached, and at a state of loading when there was no net resultant tension acting on the cross section, the mean

[49] "Economic Control of Quality of Manufactured Product," by W. A. Shewhart, D. Van Nostrand, Co., Inc., New York, N. Y., 1931, p. 105.

[50] "A Treatise on Photo-Elasticity," by E. G. Coker and L. N. G. Filon, Univ. Press, Cambridge, England, 1931, p. 574.

intensity of water pressure just balancing the mean external load. The diagram indicates that, even if the intensity of water pressure across the section were uniform and its resultant equal to the resultant of the external load for a specimen shaped like that used by Mr. Leliavsky, the interior of the cylinder

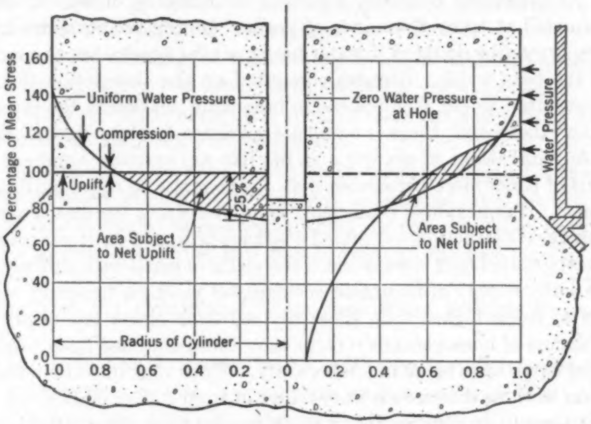

FIG. 39.—PROBABLE UNIT STRESSES WITHIN CYLINDER WITH SUPERIMPOSED LOAD AND WATER PRESSURE BALANCED

would be subjected to a tensile unit stress of approximately 25% of the applied water pressure. If it be assumed that the true ultimate unit tensile strength of pressure-saturated concrete (0.7 of dry concrete) broken under slowly applied tensile loads (0.8 of quick break) is $0.7 \times 0.8 \times 350 = 200$ lb per sq in., then, because of nonuniform stress distribution, balanced interior and exterior loads approximately 800 lb per sq in. would be sufficient to break the concrete without the potential tensile resistance of the entire cross section ever having been effective. Thus a straight line fitted to the data of the higher loads would intersect the axis at the origin, indicating zero tensile strength for the concrete. The data of Fig. 24, if averaged in small groups, suggest that a sag curve (concave downward), conforming with the foregoing comment, might fit the data better.

The writer, finally, would like to touch upon certain practical considerations in connection with "uplift" tests and assumptions based upon permeability experiments made on concrete cylinders up to 12 in. by 24 in. and at pressures up to 400 lb per sq in.

No one who has seen concrete saturated under high pressure and weeping water like a squeezed sponge when placed under load in a testing machine, will question the reality and importance of uplift phenomena. However, it is not generally realized that a surprisingly long time is required to attain complete saturation and to stabilize internal hydraulic pressures, and until these are

stable, tests may lead to wrong inferences. Six days were required in permeability tests on 6-in. by 12-in. cylinders to balance the inflow and outflow of the specimens. In some of the tests by Mr. Leliavsky, with low pressures used during the early stages of the test it is doubtful whether static conditions were reached at the time of break. The time required to saturate a large dam through homogeneous concrete, assuming no cracking of the structure, has been estimated at many thousands of years. During the economic life of the structure, it may be doubted if water pressure ever penetrates as much as one third of the base width. Stresses computed on the assumption the concrete is fully saturated would then appear to bear little relation to the facts.

On the other hand, there is adequate evidence to show that so-called impermeable foundations of granite and the like are actually hundreds or even thousands of times more permeable than the concrete or rolled earth materials above them. Permeability coefficients computed from the discharges of rock tunnels under construction, or from the leakage of from 1 cu ft per sec to 5 cu ft per sec past grouted dam sites, or from the yields of small wells drilled in rock to form the water supply of mountain cottages, all yield permeability coefficients hundreds of times higher than those derived from either laboratory tests of small cylinders of homogeneous rock or than those obtained from concrete and compacted earth tests made in a laboratory. Open rock quarries usually show hair cracks in three dimensions at spacings of from 2 ft to 50 ft apart. Grout cannot be forced any distance into a crack smaller than about 0.005 in. because of the limiting size of the biggest cement particle. Furthermore, the flow from crack at spacings of 2 ft to 50 ft reduced to permeability coefficients, on the basis of gross surface exposed to percolation, yields coefficients that are hundreds of times greater than the laboratory tests. In view of these two facts, the greater permeability of the foundation compared to that of the structure built upon it should be more generally recognized and taken into account in studies dealing with the effect of uplift. There can be little question that, within the foundation of a dam, uplift acting on nearly 100% of the area is a pertinent design assumption; although, of course, the intensities and the distribution of the unit pressures acting may be modified by grouting and drainage, at the option of the designer.

Finally, the writer feels that the extremely low tensile strength of concrete indicated by the Leliavsky bursting tests warrants additional analysis and laboratory investigation unless adequate explanations can be offered in the closure. Many large spillways are now being contemplated in which concrete surfaces are expected to withstand high-velocity flow. At their bends, deflection of the water builds up high hydraulic heads which are reduced immediately downstream to negative values or, at most, to heads corresponding to the depth of the flowing sheet of water. The intervening concrete is thus continuously subjected to a high-head permeability test. If the tensile strength of the concrete is no more than shown by Mr. Leliavsky's tests, the internal bursting forces plus the shear from the high-velocity water may well result in failure of the surface concrete.

It is hoped the following data, needed to clear up certain points of the tests, described by Mr. Leliavsky, can be given in the closure:

(a) Fineness of cement and tensile strengths from briquette tests with the corresponding mix proportions and water-cement ratios.

(b) Size of coarse aggregate in concrete; and method of cure to the time of testing after the initial period of wet curing.

(c) Compressive strength of concrete as tested in standard cylinders or cubes with corresponding mix proportions and water-cement ratios.

(d) Were the reported mechanical tension tests made before or after the concrete specimens had been water saturated?

(e) What was the percentage reduction in tensile strength for those tests where the breaking loads were applied slowly in terms of rapid load strengths?

(f) How was the point of loading at which the concrete failed determined? Fig. 13(b) suggests that failure had started prior to the test loading marked "fracture."

(g) How was the quantity of water percolating through the cylinders measured?

(h) What were the computed values of the permeability coefficients at different water-cement ratios? (Coefficients, in terms of cubic feet per second per square foot per unit gradient, obtained by the Bureau of Reclamation[51] for 6-in. by 12-in. cylinders with $1\frac{1}{2}$-in. aggregate have ranged from 10×10^{-12} for a water-cement ratio of 0.50, to $7{,}000 \times 10^{-12}$ for a water-cement ratio of 0.90).

(i) Give the number of cylinder breaks which occurred near the junction of the lower container, the number in the middle of the test section, and the number near the top sleeve.

(j) Give tabulation of experimental values of F and p_a.

Gordon V. Richards,[52] Jun. ASCE.—The impressive thing about the work reported by Mr. Selim is the extreme simplicity of the method as compared to the complexity of the problem. It requires no great amount of equipment and could be used for problems far more complicated than those presented.

One is led to wonder if it would be possible to find the uplift pressures under a dam where drains were installed. It seems likely that this could be done. As with the models in the paper, the stream-bed pressure upstream from the dam would be represented by a plate maintained at, say, 10 v. The downstream plate could be maintained at zero potential. Between these two (that is, under the foundation of the dam) a third conductor, with a size and shape depending on the type of drainage installed in the dam, might be maintained

[51] Closure of discussion on "An Investigation of the Permeability of Mass Concrete with Particular Reference to Boulder Dam," by Arthur Ruettgers, E. N. Vidal, and S. P. Wing, *Proceedings*, A.C.I., Vol. 32, 1936, p. 385.

[52] Instr., Mech. Eng. Dept., Univ. of California, Berkeley, Calif.

at some intermediate potential depending on the efficiency of the drainage under the prototype.

Possibly, also, the method could be applied without undue difficulty to three-dimensional problems of laminar flow. The only requirements to be met are that the model and prototype be geometrically similar and that the boundary pressures existing in the prototype be duplicated in the model as electric potential. In the case of a three-dimensional model it would be necessary to measure the potential at a point, instead of at a vertical line as is allowed in the two-dimensional problem. Perhaps this could be accomplished by using, for the probe, a well-insulated wire with an exposed copper sphere (a sixteenth or an eighth of an inch in diameter) on the end. With the proper measuring instruments, a three-dimensional model might be explored with the copper sphere. One difficulty with this idea will be the construction of the model in such a way that the liquid is maintained in the right shape. For a dam in a steep ravine, for example, the best method might be to invert the model so that the bottom of the tank containing the liquid represents the ground surface inverted.

Serge Leliavsky Bey.[53]—Those who took part in the interesting discussion of this paper have focused attention on certain important points which otherwise might have remained obscure. In doing so, they have contributed to presenting the subject of this investigation more clearly, thus helping to avoid possible misinterpretation.

The original manuscript from which the paper was condensed was about three times longer than the text finally accepted for publication, with the result that certain points of the solution were left, if not "in the dark," at least "in the shade." This applies particularly to the historical part, which, in the original version, preceded the descriptive account of the tests. Since, in the printed text, this part was deleted, the interpretation of the writer's method lost its historic perspective, and some aspects of the conclusions reached became, therefore, less obvious.

The theoretical "three-dimensional" elastic effect, treated in Mr. Holmes' valuable discussion, was one of these aspects.

According to Mr. Holmes, the failure of the specimens (which is basically due to axial forces) is also affected by the external pressure exerted by the liquid on the lateral surfaces of the porous material. The uplift factor would then be an amount 2μ less than the value computed by the writer (μ being the reciprocal of Poisson's ratio). Assuming that the Brandtzaeg experiments were indeed applicable to the case, the writer's coefficient, $n = 0.85$, would thus be reduced to $n = 0.507$.

Mr. Holmes' point is rather obvious and might easily have been taken into account in the tests, if there had not been specific reasons militating against this procedure. In fact, the objections against introducing the three-dimensional effect in the interpretation of these experiments, as suggested by Mr. Holmes, might have been inferred from the third paragraph following Eq. 16:

[53] Director, Designing Service, Reservoirs and Nile Barrages, Dept., Ministry of Public Works, Cairo, Egypt.

"Messrs. [P.] Fillunger and [Karl] Terzaghi [M. ASCE] have demonstrated beyond any reasonable doubt that the effect of an interstitial hydraulic pressure upon the resistance of a porous solid is negligible, so long as this pressure is equally distributed over the walls of the pores. Since the existing evidence confirming this statement is conclusive, it follows, in so far as the present tests are concerned, that the ultimate resistance of the test piece is not affected, in all the cases in which $p_o = p_i$. However, the cases in which p_i is smaller than p_o remain to be investigated. When this happens the ring-shaped part of the specimen is subjected to stresses similar to those in a pipe of a boiler. Since these stresses are compressive, z could be smaller for higher values of $p_o - p_i$."

Perhaps this text was not sufficiently clear. Perhaps it would have been better to include the more explicit explanation of Professor Terzaghi's tests in the published version, as it was in the original paper. The fact is that, contrary to the views expressed by Mr. Holmes, unprotected porous specimens, subject to hydraulic pressure, do not behave in the manner described in the standard textbooks on elasticity.

The difference between the results obtained by F. E. Richart, A. Brandtzaeg, Members, ASCE, and R. L. Brown at the University of Illinois, Urbana (cited by Mr. Holmes[44]) with "protected" specimens (provided with thin metal mantels), and the behavior of Professor Terzaghi's own "unprotected" test pieces, was used by Professor Terzaghi as the starting point for his uplift theory. It is not the writer's intention to discuss this theory as such, except to state that there is probably no living man whose factual results could carry greater weight than those of Professor Terzaghi. These experiments, published in 1934,[6] have demonstrated that, when the water is allowed to penetrate into the pores, the behavior of the concrete specimen under axial loads is not affected by the lateral, hydraulically applied, external pressure, referred to by Mr. Holmes.

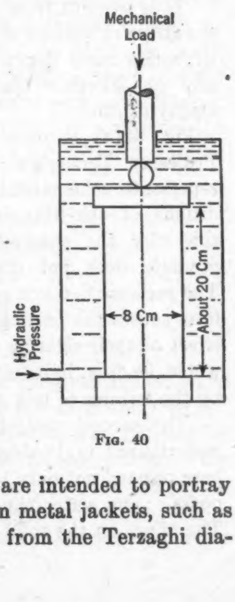

Fig. 40

The Terzaghi test pieces (see Fig. 40) were placed in a vessel, with water under various pressures ranging from zero to 400 kg per sq cm (that is, ten times greater than in the writer's tests), and subjected, at the same time, to an axial load varying from 2.6 tons to 25 tons. The results, at breaking point, are given in Table 15. The values in Cols. 1 are from Professor Terzaghi's experiments with unprotected specimens (that is, similar, in this respect, to the writer's specimens). There is no marked correlation between these data and the pressures, p, appearing in the first column (under which the test pieces were broken). On the other hand, the stresses in Cols. 2 are intended to portray the behavior of concrete specimens provided with thin metal jackets, such as those of the Illinois tests.[44] These values are scaled from the Terzaghi dia-

grams, based upon the Illinois tests, in the well-known graphical computation devised by Mohr. The rapid rise of the breaking limit in Cols. 2 is characteristic of the three-dimensional effect referred to by Mr. Holmes. The contrast between Cols. 1 and 2, Table 15, supplies a quantitative negative reply to the question raised by Mr. Holmes.

TABLE 15.—COMPARISON OF COMPRESSIVE BREAKING STRESSES IN KILOGRAMS PER SQUARE CENTIMETER

(Test Pieces Unprotected in Cols. 1 and Protected in Cols. 2)

Pressure[a] p	Series I		Series II		Series III	
	(1)	(2)	(1)	(2)	(1)	(2)
0	580	580	532	532	66.3	66.3
100	630	860	..	..	67.8	353
200	646	1,148	534	1,102	67.0	636
300	404	1,431	645	1,390	66.5	922
400	604	1,722	454	1,678	67.1	1,210

[a] Water pressure in the test vessel, in kilograms per square centimeter.

The physical explanation of these results will be almost obvious if the analyst will ignore conventional assumptions made in textbooks on elasticity, and will follow the modern views on the subject. In other words, instead of the imaginary, continuous structureless elastic solid contemplated by the mathematicians since the time that Navier, Lamé, Cauchy, and Poisson laid down the bases of classical elasticity, the analyst must visualize the material as an elastic structure, containing both solids and voids (see Fig. 41). This has been the approach of Messrs. Fillunger, Terzaghi, Hoffman, and other modern thinkers. Fig. 1 illustrates the significant aspect of the difference between the two conceptions.

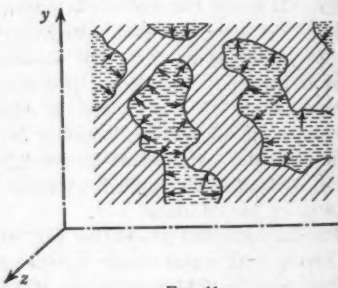

FIG. 41

It is evident from Fig. 41 that the stress conditions in porous elastic solids must depend substantially on whether the pores are empty or full.

Fig. 42(*a*) is reproduced from Professor Terzaghi's paper[6] and represents schematically the conditions of the Illinois tests. In this case the external hydraulic pressure does not differ in its action from a mechanically applied load. The pressure is taken entirely and exclusively by the solid material and, therefore, causes the particles to be pressed against each other. The accumulative effect of their relative displacements results in the elastic deformation of the whole, leading, in its ultimate stage, to the three-dimensional effect exemplified by the failures of test pieces in the Illinois tests (see Cols. 2, Table 15).

The second case, illustrated by Fig. 42(*b*), demonstrates the principles materialized in Professor Terzaghi's experiments. The external pressure is here resisted not only by the particles but, also, by the water contained in the pores. The water thus participates in resisting the externally applied load. The effect on the solid material must therefore be much smaller; but what is

even more important is the fact that, although each solid particle is subjected to a certain uniform compression, there is now no prevailing tendency for one particle to be pressed against the other (except in the proportion of $(1 - n)$ to 1, which is very small indeed). Thus, the chief factor producing strain and

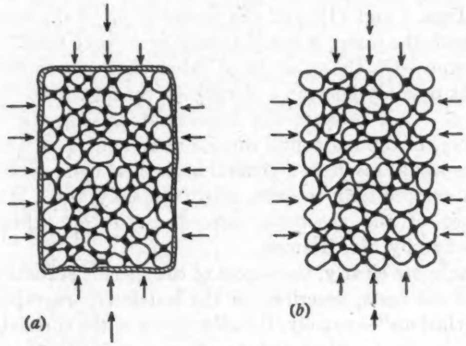

FIG. 42

fracture is negligible in this case; therefore, the pressure can be raised almost indefinitely, without affecting the mechanical resistance of the material (as shown by the Terzaghi tests[6] listed in Cols. 1, Table 15).

The point, thus demonstrated by Professor Terzaghi—namely, the absence of the three-dimensional effect in unprotected porous materials subject to uniform hydraulic pressure—was observed by Fillunger as early as 1913;[7] except that in the latter case, instead of an axial compression, the hydraulic effect upon unprotected concrete specimens, was combined with axial tension. The conclusions were precisely the same, however, as might be seen from the following data, which represent average breaking stresses, for twelve specimens each, of:[14]

Hydrostatic pressure, in atmospheres	Tensile resistance, in kilograms per square centimeter
0	36.1
100	32.4
200	31.6

The significant conclusion is that the resistance of concrete against axial overload is practically the same at the bottom of the sea as in the free air; the fact, therefore, that in the writer's machine the specimen is surrounded by water under a certain pressure, has no elastic effect on the axial resistance of the material tested. There remains only the main axial effect of the interstitial water pressure in the pores of the material, which varies gradually from p_a at the plane of rupture to zero at the top of the specimen, and therefore produces

an accumulative vertical action on the walls of the pores, causing the specimen to rupture. Under these circumstances, the writer cannot concur in the idea of introducing a secondary "three-dimensional" effect in the interpretation of his tests, in the manner suggested by Mr. Holmes.

There is another aspect of the same problem, however, which Mr. Holmes does not mention. The writer has shown that, when the pressure, p_o, in the container (see Figs. 7 and 11), and the pressure, p_i, in the inner space of the specimen, are both the same, it is not necessary to take the three-dimensional effect into account. On the other hand, when these pressures are not equal, this effect might possibly become a significant consideration (to the extent of the difference $p_o - p_i$), because the interstitial pressures would then vary, from pore to pore, in the horizontal direction, and the accumulative action of these differences would result in a general horizontal compression of the entire cylinder. This compression, in turn, might possibly affect the axial vertical tensile resistance of the specimen, according to the "three-dimensional" principle referred to by Mr. Holmes.

This explains, more clearly, the object of the specific statistical examination of the results of the tests, described in the last few paragraphs of the paper preceding "Conclusions"—namely, the calculation of the correlation and regression coefficients for Δy (vertical distance from a point to the average line in Fig. 24) and the difference $p_o - p_i$.

Had such a correlation been found to exist it might easily have been taken into account, by a correction based on the regression coefficient; but, as stated in the text, the results of the calculation showed that the correlation in question did not exist. (The calculated values of these coefficients were, respectively, 0.068 and 0.0016.) Even from this rather remote standpoint, therefore, the three-dimensional effect was found to be absent.

This conclusion is also confirmed by the results of Rudeloff's experiments,[13] represented in Fig. 25. In this particular case the specimen (which in other respects was generally similar to Fig. 3) was provided with an impermeable mantel, on the same principle as in the Illinois tests; but, in spite of that, the three-dimensional effect did not exist. The axial tensile breaking load was found to be independent of the hydraulic pressure in the container. The following average values of the tensile resistances of "protected" cylindrical specimens were obtained by Rudeloff:[13]

Hydrostatic pressure, in atmospheres	Tensile resistance, in kilograms per square centimeter
5	7.50
10	8.35
15	7.55
20	7.32

Although these are actual facts which, in themselves, constitute an exhaustive reply to the question under review (in so far as the main uplift problem

is concerned), it will nevertheless be relevant to the discussion to explain the apparent contradiction, between the evidence of the Illinois tests on the one hand, and Rudeloff's and the writer's experiments on the other. In fact, the first point that comes to one's attention is that the main axial effect is compression in one case, and tension in the other two cases. The failure is therefore a "shear failure" or a "pseudo shear failure" in the Illinois tests, and a "tension failure" in Rudeloff's and the writer's experiments. Apart from all other considerations, a glance at Fig. 26 will suffice to show that the plane of fracture in the writer's tests is almost exactly perpendicular to the axial breaking force, F, which substantiates the principle of a tension failure, in contradistinction to a rupture by compression in the Illinois tests.

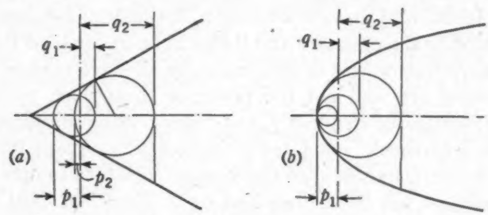

FIG. 43

The difference in the mechanics of the two cases is shown in Fig. 43, of which Fig. 43(a) shows the earlier views, with Mohr's critical lines being represented by straight lines. For every compressive breaking stress, q_i, acting at right angles to the main load, there is a different axial tensile limit, p_i. L. Prandtl appears to have been the first to suggest[54] that the critical lines in such diagrams should not be straight, as in Fig. 43(a), but curved, as in Fig. 43(b). It will then be obvious that the compressive limit, q_i, may vary in rather wide limits without affecting the corresponding tensile breaking stress, p_i. When both stresses are compression, however, the interdependence between the critical limits remains valid, as in the earlier diagrams.

This explains, theoretically, the actually observed difference between the Illinois tests[44] and the writer's experiments (with reference to the difference $p_e - p_i$). Thus, to represent both these experiments in the same chart as is done in Fig. 37 is definitely objectionable. From whichever point the question is considered, there is, consequently, no reason for altering the original conclusions, in order to take into account the "three-dimensional" effect. The writer is indebted to Mr. Holmes, nevertheless, for having raised a most interesting point, and thereby provided an opportunity for an explicit reply.

He is also grateful to Mr. Holmes for having explained in detail the derivation of the formulas he used in finding the empirical straight lines representing the results of his tests for every individual group of specimens. To conserve space, this development, which was based on the least-squares principle, was not given in the writer's paper, for it was believed to belong to elementary mathematics. It is rather unfortunate that in developing these formulas Mr. Holmes changed the signs in basic Eq. 2, which resulted in the second constant of the final equation becoming negative. There is no advantage in

[54] Report to the Congress of Physicists and Physicians, by Ludwig Prandtl, Dresden, 1908.

this sign convention because the force z is essentially positive, and a negative sign may be misleading.

In his exceedingly interesting contribution, Mr. Perkins raised a number of important questions. In regard to the convergence of the paths of filtration in the specimen of the paper, as opposed to the would-be parallel lines in a dam, it should be noted that the main flow lines, correlated with the process of failure in the writer's specimen, are vertical. They occur in the material enclosed in the upper lining of the test piece, and are created by, and are a function of, the full difference $p_a - 0$. On the other hand, the convergent streamlines referred to by Mr. Perkins, are only a secondary consideration, depending on the difference $p_a - p_i$, which, as already stated, is negligible as a cause of failure. Apart from that consideration, the lines of seepage are only important in relation to the pressures and it should be understood that the object of the writer's experiments was to determine the effective area on which the interstitial pressures act, and not the pressures themselves, for these pressures have been investigated frequently, and "may now be considered as belonging to the scope of a textbook" (as stated in the second paragraph following Eq. 5). In addition to the references cited in the paper,[17,18,19,20] a comprehensive investigation on the subject has been presented by I. Houk, M. ASCE, and B. A. Bakhmeteff, Hon. M. ASCE.

Regarding the low breaking stress under mechanical tension, the specific series which were marked "S" in Col. 2, Table 2, were meant to constitute conditions occurring in masonry dams (in which indeed the resistance against tension was very small) and were prepared accordingly (see heading, "Procedure and Significance of Tests"). Even in the other series, the general tendency was to approximate current field practice, which does not always coincide with the usual laboratory methods.

The more important point, however, was not in the preparation of the test pieces, but in the testing procedure. As reported in connection with Fig. 19, the effect of the time factor had a large influence upon the observed breaking stress. The dotted points at $p_a = 0$ in Fig. 19, in contradistinction to the point of intersection of the average line with the vertical axis, gave a measure of this effect. Assuming that the compound material was from 60% to 80% as strong as the corresponding laboratory mortar briquette, and that the effect of the time factor was about 2.5 (see Fig. 19), the series marked "C" (concrete) (Col. 2, Table 2) represented a nominal tensile resistance of from 21 to 28 kg per sq cm, which harmonized well with the standard values adopted in Egypt. On the other hand, the general consistency of the observed tensile resistances was confirmed by their obvious quantitative correlation with the various factors on which they must logically depend, such as the method of mixing and the intensity of ramming, the water-cement ratio, etc.

The writer wishes, further, to concur with Mr. Perkins' conclusion, that "* * * a gravity dam with a conservative design of thickness equal to 0.85 H_d * * * is safe." This, indeed, is an excellent summary of the writer's numerical results.

Turning now to Mr. Wing's discussion, the writer wishes to place on record the pleasure he had in reading and studying this pertinent contribution. The first question raised by Mr. Wing—the apparently low resistance of concrete—has already been answered; but his second point concerning the application of the "least-squares" method, deserves to be explained in greater detail. Eqs. 13 and 14, which are used for finding the constants n and z appearing in the equations of the average lines, are not symmetrical with respect to x and y. The result may, therefore, be affected by the assumed notation; it thus appears to depend on an arbitrary element.

In certain specific cases of engineering practice, this might indeed be of importance, particularly when the recorded observations of the two variables investigated, are not equally precise. As an instance, consider the case of a discharge-level curve, for a section of a large river. In applying the "least-squares" method to this case, the levels should be taken as the independent variable, x, and the curve will then be computed in such a manner that the sum of the squares of the deviations of the individual discharges, y, is a minimum.

Furthermore, when the subtangent angle of the average line ("regression coefficient") differs greatly from 45°, the smaller and larger amplitudes must correspond, respectively, to the y-axis and the x-axis. In the case under consideration, however, the precision of both variables is practically the same, and, also, the subtangent angle of the average line is almost 45°. Consequently, the choice of the variables in this case is immaterial.

The differences in the values of the coefficients in Eqs. 47*a*, 47*b*, and 47*c*, are not substantial numerically, and would not have affected the argument even if they had been physically significant; but, such as they are, they depend on an obvious inconsistency—namely, whichever of the two variables is denoted, respectively, by x or y, the entire computation, from start to finish, must be based on the same notation, whereas Mr. Wing uses the values of z, determined by the writer (for the individual series) on one assumption, but calculates the average curve for ninety-five points, on another assumption. This must naturally affect the result (particularly the second constant).

In regard to Fig. 39, attention is called to the difference between load and stress. For point loads or surface loads, this is indeed elementary and obvious, but in examining the effect of volume loads (such as gravity and uplift) it frequently occurs that one is mistaken for the other, as is the case with the convex curve on the right side of the quoted diagram. This curve is acceptable as representing the uplift pressure, but not as the stress, due to this uplift pressure.

These stresses could agree with the curve assumed by Mr. Wing only if the block of concrete above the section analyzed, were built of an infinite number of concentric rings, having no fixed contact with each other, and capable, therefore, of transmitting no vertical shear. Apart from the inherent physical impossibility of such an extreme assumption, it is also objectionable from the purely theoretical, formal standpoint, because, in that case, the compressive load which is mechanically applied to the upper lining could not be transmitted to the concrete core.

The argument represented by the compression curve appearing in the same figure, is also unacceptable, because overstressing at the edges of the section is the result of re-entrant angles, and the degree of "re-entrancy" is much greater in a standard concrete briquette, considered by E. G. Coker and L. N. G. Filon,[55] than in the writer's specimen. Had this effect indeed been significant, it must have resulted in all the writer's test pieces breaking close to the lower lining, which is by no means the case.

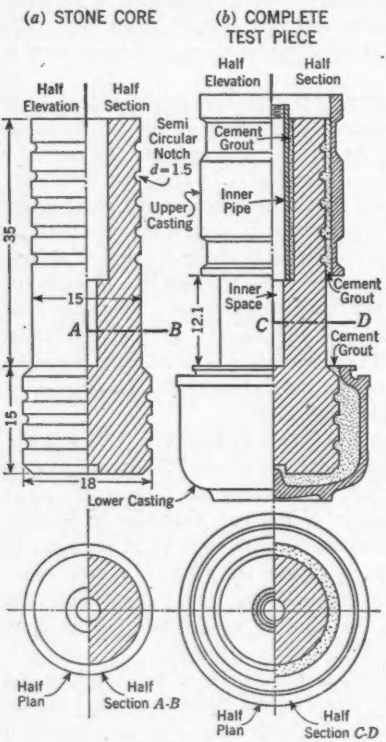

Fig. 44

Thirdly, and finally, the stress distribution in Fig. 39, even if it had been true, would not have altered the writer's conclusions, because of the flow of concrete which causes the redistribution of stress intensities when local overstressing occurs. This is the chief point of the modern theory of re-entrant angles in dams, expounded by John H. A. Brahtz.[56]

The next point in Mr. Wing's discussion concerns the time factor, in so far as it affects the conditions of seepage in actual dams. The contention is that, according to laboratory tests with specimens of concrete, the speed of the percolating water is so slow that it would require years for a filtering particle to reach the downstream face of the dam. Had this indeed been the case, the effect of the uplift pressure would have been confined to only a part of the total area of the section—close to the upstream face of the dam.

This contention cannot be accepted for the simple reason that water is actually seen to appear on the downstream face of many dams, in the form of seepage and sweating, in spite of the fact that quite a large percentage must be evaporated. This does not refer to narrow dams only, but even to such conservative designs as the Assuan and Gileppe dams.

It is suggested that Mr. Wing may possibly be overestimating the value of laboratory results, as a practical forecast of the conditions of seepage in nature. In this connection attention is called to a statistical examination of filtering

[56] "The Stress Function and Photo-Elasticity Applied to Dams," by John H. A. Brahtz, *Transactions*, ASCE, Vol. 101, 1936, p. 1240.

tests with concrete specimens reported by M. Mary[57] in which a wide dispersion of results was observed. What actually occurs in nature seems to be that, adjacent to an almost impermeable section of the dam, there may be a very pervious mass of material, and the designer, therefore, must consider the worst conditions.

In regard to the next point raised by Mr. Wing—the importance of the filtering in the rocky foundations beneath the dam, as compared to seepage in the dam itself—the writer wishes to explain that his method is not confined to compound materials only, such as those used in building dams, but applies also to natural rocks forming the foundations. The specimen is then prepared in the manner shown in Fig. 44, the core being made of the rock to be tested, and grouted in the respective castings. The results obtained in this manner in the writer's machine for Cairo limestone are shown in Fig. 45. These experiments were conducted after the completion of the investigation described in the paper, and, therefore, were not included in the ninety-five points analyzed therein; but they are consistent with the earlier tests.

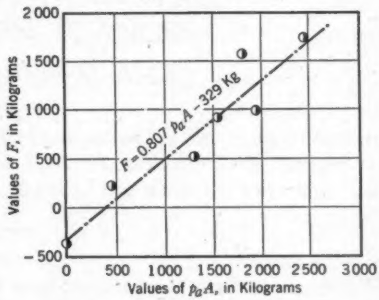

Fig. 45

It was rather interesting to observe that a core prepared from the ignaceous granite of Assuan, and tested in the same manner, proved to be the only material not affected by internal uplift. The writer agrees, nevertheless, with Mr. Wing that, because of the numerous fissures and decomposed seams existing in natural foundations, the uplift must be included in the design even in this case.

Acknowledgment.—For the experiments on which this paper is based, in June, 1946, the writer was awarded the degree of Philosophiae Doctor by Fouad First University, Giza, Cairo, Egypt.

Mohamed Ahmed Selim,[58] Assoc. M. ASCE.—By his discussion, Mr. Richards has contributed to the practical application of the electric-analogy method in solving problems of two-dimensional and three-dimensional nature. The writer might add that such an application was made at the Laboratory of the Mechanical Engineering Department, University of California at Berkeley, during and after the period of his research; namely, the fall of 1940. Two problems were set up, one concerned with the velocity of air currents and their effect on weather forecasts, and the second with the oil stored in petroleum

reservoirs. It is unfortunate that the results of such work have not been presented to the engineering world because of wartime restrictions.

Meanwhile, much work has been done since 1933 by the Ministry of Public Works in Egypt in connection with the lengthening of floor for Assiut Barrage on the Nile. Recent books have shown an increasing confidence in the electric-analogy method of solving the difficult problems of flow through porous media.

The writer is very grateful for Mr. Richards' interest and comments.

STRENGTH OF THIN STEEL COMPRESSION FLANGES

By George Winter,[1] M. ASCE

With Discussion by Messrs. Fred T. Llewellyn, Jacob Karol, Robert L. Lewis and Dwight F. Gunder, L. C. Maugh and L. M. Legatski, Bruce G. Johnston, Edward L. Brown and Don S. Wolford, and George Winter.

Synopsis

The production of light structural steel shapes from sheet steel, by cold forming and spot welding, necessitates the development of special design methods adapted to the peculiarities of such members. One of the questions of most practical importance is that of the strength and behavior of thin, wide flanges in compression. This paper reports the results of, and conclusions drawn from, an extensive experimental investigation of this problem. The strength, general behavior, and deformation of two types of structural elements are investigated—(A) members with compression flanges both of whose longitudinal edges are stiffened adequately (such as top flanges of inverted U-beams); and (B) members with compression flanges only one of whose longitudinal edges is stiffened (such as either half of a flange of an I-beam). Results of these tests are evaluated in terms of formulas and charts by which the strength, deformation, and general behavior of such members can be predicted under load conditions.

General

The thickness of ordinary hot-rolled structural steel sections cannot be decreased beyond a certain minimum, because of limitations inherent in the rolling process. This fact, in the past, has all but prevented the economical use of steel for small-scale structures such as residences, small commercial and manufacturing buildings, and for many secondary members such as floors with moderate loads in larger structures. In view of the low loads occurring in such members, available rolled sections are unduly heavy for the purpose and therefore are unable to compete with other materials more adaptable to such conditions.

Note.—Published in February, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Asst. Prof., Civ. Eng., Cornell Univ., Ithaca, N. Y.

However, great advances have been made in forming structural shapes from sheet steel which can be obtained in all desirable thicknesses.[3] Outstanding examples of this type are the many kinds of steel roof and floor decks that are manufactured in various shapes and with thicknesses ranging from 14 gage (0.0766 in.) to 24 gage (0.0245 in.). The development of automatic spot welding has further increased the possibilities of using sheet steel for structural purposes. It is now possible, technically and economically, to form extremely thin I-shapes by joining two cold-formed, sheet-steel, channels by automatic spot welding in the web. Other shapes, such as thin-walled U-beams and box beams, likewise can be formed from cold-bent sheet steel. This development opens new applications for the use of steel in buildings and other structures. The possibilities of mass production inherent in the processes of cold forming and of spot welding make such members particularly suitable for prefabrication.

A number of design practices developed over the years in connection with the usual rolled sections will need revision in their application to thin-walled members. Although the problems of this kind are familiar in airplane manufacturing, they are new to the designer of the conventional type of steel structures. One of the most important of these problems is that of the behavior of thin steel members in compression. Thickness is a factor of very minor importance in members subject to tension; but thin sheets in compression will buckle at rather low stresses. This fact must be taken into account in the design of the compression flanges of thin-walled beams or in the design of the entire cross section of thin-walled columns. An investigation of the behavior and strength of such thin-walled compression members is reported in this paper. The findings are based in part on those of other investigators in this field, particularly in airplane design, and in part on tests reported in detail hereinafter.

Two types of compression flanges were investigated: (A) Flanges that are stiffened along both longitudinal edges such as the compression flanges of thin-walled I-beams with stiffening lips at the outer edges and the flanges of inverted U-beams and box beams which are prevented by the two webs from buckling out of their initial plane along both joints (that is, along both longitudinal edges); and (B) flanges that are stiffened only along one longitudinal edge such as either half of the compression flange of a thin-walled I-beam, stiffened only by the web, but free to distort at the outer, unsupported edge. The ranges of dimensions for the specimens (identified herein as types A and B) are given in Table 1. Since the behavior of these two types of flanges was found to be fundamentally different, the two types will be discussed separately.

Type A. Compression Flanges Stiffened Along Both Longitudinal Edges

Notation.—The letter symbols introduced in this paper are defined where they first appear and are assembled alphabetically, for convenience of reference, in the Appendix. Discussers are requested to adapt their comments to the notation as published herein.

[3] "Light-Gage Steel for Peacetime Building," by Milton Male, *Engineering News-Record*, October 18, 1945, p. 525.

Equivalent Width of Thin Flanges.—The thin rectangular plate subjected to compressive forces in the plane of the plate has been analyzed extensively by G. H. Bryan and others. The theoretical critical stress at which buckling occurs was thus found to be:[3]

$$s_c = \kappa \frac{\pi^2 E}{12\,(1-\mu^2)} \left(\frac{t}{b}\right)^2 \quad \text{..........................} (1)$$

in which E is the modulus of elasticity; μ is Poisson's ratio; t is the thickness of plate; b is the width of plate perpendicular to the direction of compression; and κ is the numerical factor depending upon the ratio of length to width of the plate and the conditions of edge support.

TABLE 1.—RANGE OF FLANGE DIMENSIONS (IN INCHES) FOR THE TWO TYPES OF STRUCTURAL ELEMENTS INVESTIGATED

Type	Width, b		Thickness, t		Depth, h		Ratio, b/t	
	From:	To:	From:	To:	From:	To:	From:	To:
A	3.40	10.10	0.0237	0.1478	1.49	8.00	14.3	170.0
B	1.43	12.0	0.0368	0.1077	2.0	8.00	9.3	108.0

These investigations are based on the assumption of ideally plane plates loaded precisely in the central plane. They use the "small deflection theory of plate bending"; that is, they assume that the significant deflections at buckling are of the order of the thickness of the plate, or less. In principle the formulas are derived on the same grounds as is the Euler formula for column buckling.

Experiments, with plates in compression, conducted by several investigators,[4,5] reveal, however, a fundamental difference between the practical significance of the Euler critical stress for columns and the critical stress given by Eq. 1 for plates. Whereas long columns actually fail at, or slightly below, the Euler stress, plates supported longitudinally along both edges have been found to carry compressive stresses considerably above the critical. L. Schuman and G. Back[4] summarize their experiments qualitatively as follows:

> "It is seen that for only the very narrow and thick plates do the Bryan loads approach or exceed the maximum loads found in the tests. For the wide, thin plates, the Bryan load is as low as 1/30 of the maximum load * * *.[6]
>
> "In most of the plates the buckling [that is, the formation of waves] was gradual * * * showing no sudden change. In some of the thick and narrow specimens, however, there was no appreciable buckling until the load approached the maximum. Owing to lack of ideal conditions, such as initial curvature, all plates buckled [but did not fail] before the Bryan load was reached."[7]

[7] *Ibid.*, p. 531.

Thus, while in the column field the Euler load is actually the maximum load a column can reach, for thin plates the Bryan load[8] is found to be of little practical consequence, except for very narrow ones.

Physically, the difference between the significance of the critical loads for free columns and for edge-supported plates is easily visualized as follows: Once a column starts deflecting at or near the Euler load, the deflection continues to increase because of the increasing bending moment caused by that same deflection. The column, then, fails very quickly, literally "getting away from its load" by unrestrained motion. On the other hand, in an edge-supported plate deflections are possible only in the central parts, the edges and parts adjacent to them being kept straight by the supports. Thus, the plate cannot "get away from its compression load" by unrestrained deflection such as that in columns. The central, more highly distorted, regions of the plate decrease in their resistance, thus throwing more of the total compressive force toward the stiffened edges. The plate reaches the limit of its carrying capacity only when these stiffened outer parts are stressed to the yield point. This action occurs at a load higher than the critical—that is, higher than that load at which, theoretically, small deflections start to occur in the plate. For these reasons, in columns, a small deflection at the Euler load produces almost immediate failure, whereas in plates small deflections merely result in a redistribution of the compressive stresses across the width of the plate. The "small deflection" (Bryan) theory of plate buckling, therefore, gives results of only very limited practical significance.

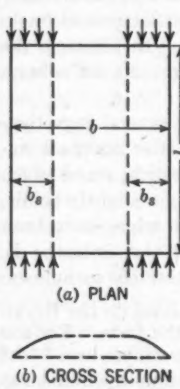

FIG. 1.—THIN PLATE IN COMPRESSION (ACCORDING TO THEODOR VON KÁRMÁN, M. ASCE)

An exact mathematical treatment of plates in compression on the basis of the "large deflection theory" is extremely difficult. Attempts in this direction have failed to give practically significant results, except for the one case of the circular plate uniformly compressed around the perimeter.[9] However, in 1932 Theodor von Kármán,[10,11] M. ASCE, suggested a semi-empirical approach to this question which, subsequently elaborated by others, proved to be extremely useful. Professor von Kármán took account of the fact that, in a plate compressed beyond the Bryan stress, the central strip (Fig. 1), most heavily distorted by wave formation, cannot be counted on to carry an appreciable part of the compressive load. On the other hand, two strips, adjacent to the edges, are held in line by the edge stiffeners and will withstand most of the compression. Thus, with only the two strips of width b_s each being effective, the actual plate of width b is equivalent to the fully effective narrower plate of equivalent width $b_e = 2\, b_s$ (Fig. 1). By rather intuitive

analytical reasoning this width was assumed to be

$$b_e = 1.9\, t \sqrt{\frac{E}{s_y}} \quad \text{.......................(2a)}$$

in which s_y is the yield point of the material. To test the validity of this hypothesis, tests were made by E. E. Sechler[5,12] on thin plates of various metals. He found Eq. 2a to hold except that instead of the fixed constant 1.9 a variable coefficient C resulted in better agreement with the tests. Thus:

$$b_e = C\, t \sqrt{\frac{E}{s_y}} \quad \text{.......................(2b)}$$

This coefficient was found to depend on the parameter $\sqrt{E/s_y}\ (t/b)$. Fig. 2(*a*) shows the results of Mr. Sechler's tests, representing the experimental values of C plotted against this parameter. (The considerable scattering

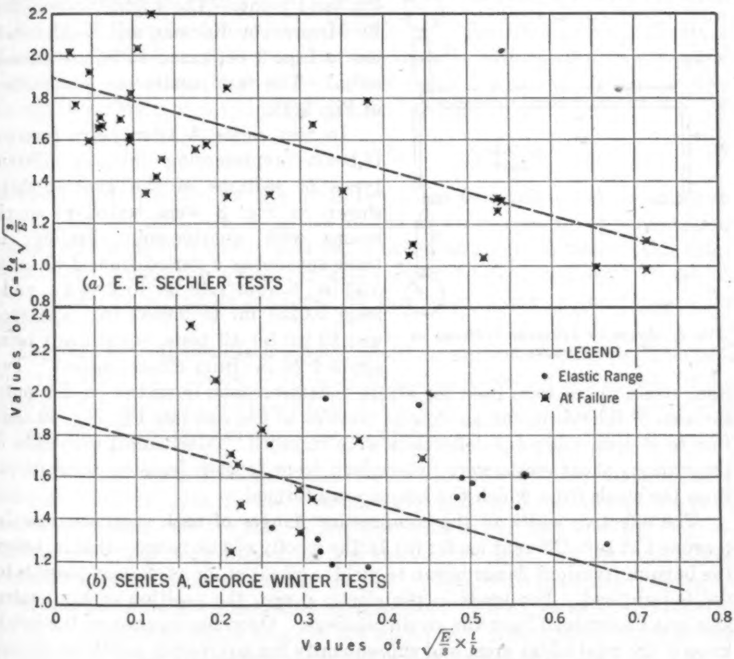

FIG. 2.—EXPERIMENTAL DETERMINATION OF EQUIVALENT WIDTH

noticeable in Fig. 2(*a*) is a feature common to all compression tests on thin plates and is probably caused by the influence of inevitable deviations from true shape of such specimens.) Only for the very small values of the parameter (that is, for extremely wide and thin plates) does C approach 1.9; for the

[12] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York and London, 1st Ed., 1936, p. 402.

remainder of the range a smaller C is applicable. In airplane design it is common practice either to use an average value of $C = 1.7$ or to determine an appropriate value from the results of Mr. Sechler's tests.[13]

The tests by Messrs. Schuman and Back and those by Mr. Sechler were made on individual thin compression plates. To determine whether the equivalent width approach could be recommended for wider use in the field of structural engineering, it appeared desirable to institute further tests to investigate: (1) Whether thin compression plates representing component parts of structural members (such as compression flanges of thin-walled beams) performed in the same way as disjointed, individual plates; (2) whether a simple sufficiently accurate expression could be found for determining the equivalent width for design purposes; and (3) whether such an expression applied to the state of ultimate failure only or whether the same, or similar, expressions could be used at stresses below the yield point. (The original information by Messrs. von Kármán and Sechler leading to Eqs. 2 pertained to failure stresses only.) The test results are summarized in Fig. 2(*b*).

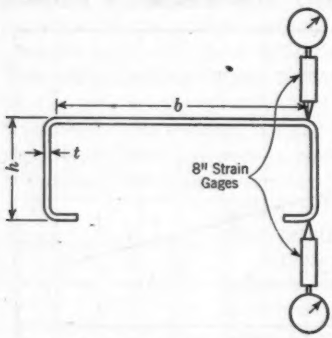

FIG. 3.—SHAPE OF INVERTED U-BEAMS OF TEST SERIES A

In test series A twenty-five inverted U-beams representing thirteen different types of sections of the general shape shown in Fig. 3 were tested as simple beams with quarter-point loading. In these specimens b varied from 3.40 in. to 5.33 in., h from 1.49 in. to 2.46 in., and t from 0.0237 in. to 0.0589 in. The span was 80 in. for all tests, equal loads being applied 20 in. from either support. Two 8-in. strain gages were used for strain measurements, mounted on the outer surfaces of the specimens, as close as possible to the web (see Fig. 3). In addition to strains, midpoint deflections were recorded. Mechanical properties of the various sheet steels were determined from tension tests on coupons cut from the steels from which the beams were formed.

The effective width of the compression flanges of each specimen was determined at two different loads: (*a*) In the wholly elastic range—that is, before the bottom (tension) flange began to yield; and (*b*) at, or as close as possible to, the failure load. For loads in the elastic range, the position of the neutral axis was determined from the strain readings. Once the location of the axis is known, the equivalent area, and subsequently the equivalent width, of the top flange is determined from the usual condition that the moment of the area of the cross section about the axis is zero; that is,

$$\Sigma(A_n\, y_n) = 0 \qquad \text{(3a)}$$

in which A_n represents the subareas into which the section is divided for con-

[13] "Airplane Structures," by A. S. Niles and J. S. Newell, John Wiley & Sons, Inc., New York, N. Y., 3d Ed., 1943, Vol. 1, pp. 291 and 329.

venience of computation; and y_n, the distances of the centroids of these areas from the neutral axis. In Eq. 3a all quantities are known except the effective area of the compression flange and, consequently, it is possible to determine the equivalent width of that flange. For determining the equivalent width at the failure load the position of the neutral axis was again determined from strain measurements. In this case strains were measured as close to failure as possible, at loads which were 5% or less below the ultimate. However, since the stress distribution at failure is that in Fig. 4(b) rather than that in Fig. 4(a),[14,15] Eq. 3a cannot be used in this case. Since the stress at this stage of loading is of uniform yield-point intensity over the entire section (compression above the axis, tension below), the condition that the sum of all stresses over the entire section is zero yields the simple expression,

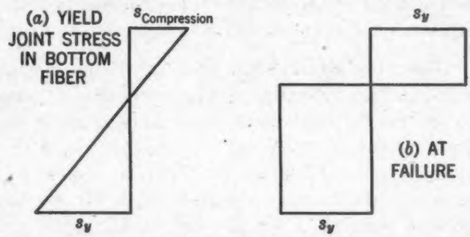

Fig. 4.—Stress Distribution in an Unsymmetrical Section

$$\Sigma A_n = 0 \quad \ldots\ldots\ldots\ldots (3b)$$

in which A_n is positive for the areas below the axis and negative for those above. Eq. 3b, then, can be solved for the effective area of the compression flange. (This method tacitly assumes equal yield points in tension and compression, an assumption which cannot be checked experimentally. However, the consistency of results obtained on this basis seems to justify such an assumption.)

Once the equivalent widths were obtained experimentally, the coefficients C were computed from Eq. 2a. These coefficients are plotted in Fig. 2(b) in the same manner as are Mr. Sechler's data in Fig. 2(a). Comparing these two sets of data, the following conclusions can be drawn:

1. The experimental points in Fig. 2 were obtained by three fundamentally different methods. Mr. Sechler's results (Fig. 2(a)) refer to ultimate loads of individual plates. On the other hand, the points in Fig. 2(b) refer to compression flanges representing integral parts of structural shapes; and, whereas half of the latter refer to ultimate loads (at the yield point), the other half are obtained at stresses far below the yield point, ranging from 7,700 lb per sq in. to 21,500 lb per sq in., depending on the shape of the specimen. Despite this diversity, the agreement between the results of the two investigations is remarkably close.

2. Whereas Mr. Sechler's results (Fig. 2(a)) refer to failure stresses only, the fact that the points in Fig. 2(b) obtained at low stresses are located in the same general way as those obtained at the ultimate load indicates that Eq. 2b

[14] "Strength of Materials," by S. Timoshenko, D. Van Nostrand Co., Inc., New York, N.Y., 2d Ed., 1941, Pt. 2, Fig. 234, p. 371.

[15] Discussion by George Winter of "Theory of Limit Design," by J. A. Van den Broek, *Transactions*, ASCE, Vol. 105, 1940, Fig. 24, p. 674.

can be used not only at the yield point but likewise in the elastic range, that is:

$$b_e = C\,t\sqrt{\frac{E}{s}} \qquad (4)$$

in which s is any stress at or below the yield point. (It is likely that at very low stresses the equivalent width so obtained is somewhat on the conservative side.)

Once the relationship between the coefficient C and the parameter indicated in Fig. 2 is rather firmly established experimentally, it appears desirable to express the equivalent width b_e in a simple explicit formula rather than to determine it by using Fig. 2 in conjunction with Eq. 4. For this purpose the averaging straight line was drawn in Fig. 2. This line was so drawn as to represent the average values of both Mr. Sechler's tests (Fig. 2(*a*)) and the present tests (Fig. 2(*b*)). The experimental values scatter rather regularly around that line. The equation of this averaging straight line is

$$C = 1.9 - 1.09\sqrt{\frac{E}{s}}\left(\frac{t}{b}\right) \qquad (5)$$

By substitution of this expression for C in Eq. 4, the following equation is obtained for the equivalent width b_e:

$$b_e = 1.9\,t\sqrt{\frac{E}{s}}\left[1 - 0.574\left(\frac{t}{b}\right)\sqrt{\frac{E}{s}}\right] \qquad (6)$$

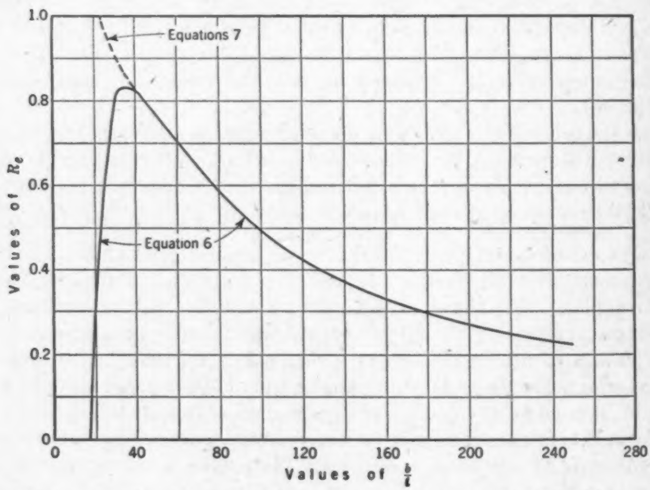

FIG. 5.—RATIO $R_e = b_e/b$ FOR THE PARTICULAR CASE OF s = 30,000 LB PER SQ IN. AND E = 30,000,000 LB PER SQ IN.

Thus, b_e, expressed as a multiple of the plate thickness t, depends on two parameters, the thickness-width ratio t/b of the flange and the strain δ at the supported edge (since $E/s = 1/\delta$).

The relationship expressed by Eq. 6 is shown graphically in Fig. 5 for the particular case $E = 30{,}000{,}000$ lb per sq in. and $s = 30{,}000$ lb per sq in. In Fig. 5 the ratio of the equivalent to the actual width, $R_e = b_e/b$, is plotted against the width-thickness ratio of the flange, b/t. In the medium and high range of b/t the equivalent width ratio decreases with increasing b/t, as would be expected. For the low range of b/t, however, b_e computed from Eq. 6 decreases with decreasing b/t, which is obviously impossible physically. It must be concluded, therefore, that Eq. 6, which was established from tests in the medium and high range of b/t, is limited in its application to that same range. (In series A the range of b/t tested extended from 64 to 170.)

To investigate the behavior of compression flanges with rather small width-thickness ratios b/t, a special series B of tests was instituted. The specimens were built-up I-beams formed by two channels, of the general shape shown in Fig. 6, with width-thickness ratios ranging from 14.3 to 56.0. The depths of these specimens varied from 3.94 in. to 7.97 in.; the widths, from 3.93 in. to 8.01 in.; and the thicknesses, from 0.0599 in. to 0.1478 in. For each half of the flange, stiffening along one edge is provided by the web, whereas the other edge is stiffened by the turned-down lip, in contrast to the U-beams of series A, where both longitudinal edges were stiffened by webs. Beams were loaded in a manner similar to that of series A except that the two equal loads were applied at distances of about 0.4 L from the respective supports rather than at the quarter points of the span L. The magnitudes of the equivalent widths were determined experimentally from strain-gage readings in the same manner as discussed previously. The results of this investigation are given in Table 2(a) where average results of two tests of each type of beam are recorded. In Table 2, b is the free, horizontal width of half of compression flange measured between toes of transition radii; t is the thickness of metal; and s is the stress, in pounds per square inch, at which strain measurements were made to determine the test values of b_e. The "test" values of b_e (Col. 4, Table 2(a)) are those determined from strain measurements; and the "chart" values are those determined from Fig. 7 for the b/t-values and the s-values of the table.

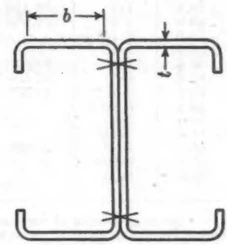

Fig. 6.—Series B

The accuracy of the determination of b_e is somewhat impaired in this series by the following fact: In these beams the compression flanges represent a rather small percentage of the total cross-sectional area. For this reason a moderate change in the equivalent area of the compression flange will change the position of the neutral axis by a much smaller percentage than the area itself changes, and will therefore cause a very small change in the strains recorded by the gages. Consequently, the accuracy of determining b_e from such tests is much smaller than the accuracy of the strain-gage readings proper.

The most important conclusion to be drawn from the b_e-values in Col. 4, Table 2(a), is that flanges of this type are fully effective ($b_e = b$) for values of b/t smaller than from about 20 to 30. From these values upward, the equivalent widths b_e are consistently smaller than the actual width b. For small

[a] Average results of two tests of each type of beam, except types I-14, I-16, I-18, I-19, and I-20 which are the average of three tests each.

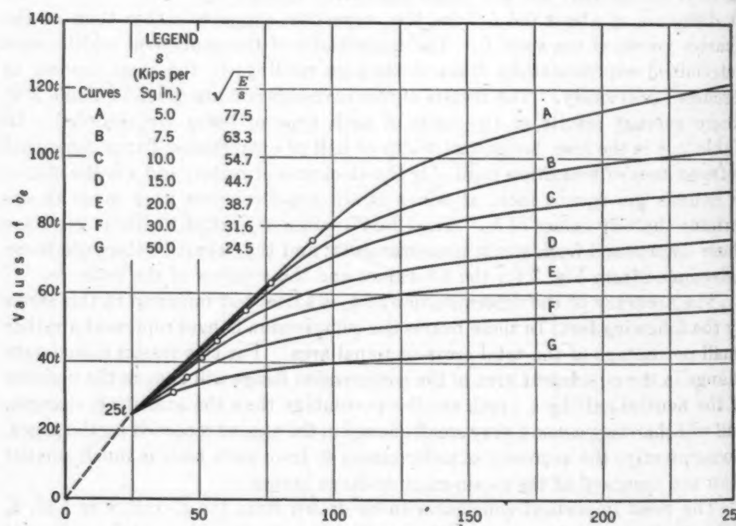

FIG. 7.—CHART FOR DETERMINING THE EQUIVALENT WIDTH b_e

values of b/t it appears reasonable, therefore, to draw a transition curve from $b/t = 25$, for $R = 1$, tangent to the curve representing Eq. 6 as is done in broken lines in Fig. 5. It is not unlikely that a more extensive investigation of b_e in this range of b/t would show a somewhat different shape of this transition curve. However, since in this region compression flanges are nearly fully effective (b_e close to b), the details of the shape of this transition line are of little practical consequence.

In practical design the use of Eq. 6 in the medium and high range of b/t in conjunction with the transition line in the low range just discussed is somewhat cumbersome. For this reason the chart in Fig. 7 was drawn for design purposes. The curves in Fig. 7 allow the equivalent width b_e to be read directly for any ratio b/t and for any practically important value of the stress s. The curved part of each line in this chart represents the values obtained from Eq. 6 and the straight parts in the low range were drawn as lines tangent to the curves and ending at $b_e = 25$ for $b/t = 25$. (The point of tangency, indicated by small circles on Fig. 7, is found from

$$\left(\frac{b}{t}\right)_1 = \frac{1.0906\frac{E}{s} + \sqrt{\left(1.0906\frac{E}{s}\right)^2 - 27.265\frac{E}{s}\left(1.9\sqrt{\frac{E}{s}} - 25\right)}}{1.9\sqrt{\frac{E}{s}} - 25} \quad \text{(7a)}$$

and the equation of the straight lines in the range of low b/t is

$$b_e = \left[\frac{1.0906}{(b/t)^2_1}\frac{E}{s}\left(\frac{b}{t} - 25\right) + 25\right]t \quad \text{(7b)}$$

in which $(b/t)_1$ is defined in Eq. 7a.) The chart is drawn for steel members, with $E = 30{,}000{,}000$ lb per sq in., but it can also be used for compression flanges made of other metals. In this case, instead of using the stress s indicated by the respective curves, the value $\sqrt{E/s}$ should be determined for the particular case and the corresponding curve found in the chart.

For the medium and high range of b/t the validity of Eq. 6, and of the curves derived from it, appears to be well established by the tests summarized in Fig. 2. Nevertheless, it is desirable to obtain more information on the low range—that is, on the validity of the straight-line parts of the respective curves. For this reason for all tests given in Table 2(a), the equivalent width ratios b_e, as obtained from Fig. 7, were determined and entered in Table 2(a). A comparison of these values (Col. 5, Table 2(a)) with those obtained from the tests (Col. 4, Table 2(a)) shows, with a very few exceptions, good agreement throughout this range (see Col. 6, Table 2(a)). Any significant deviations are on the conservative side; that is, the equivalent width, determined from Fig. 7, is equal to or somewhat smaller than that obtained from tests. For this reason it is believed that the chart, over its entire range, can safely be recommended for design purposes.

For practical use the findings incorporated in Fig. 7 should enable the designer to determine: (a) The ultimate load for a member of given configuration

and material; and (*b*) for such a member, the deformation for a given loading, particularly the deflections of transversely loaded beams. In Tables 2(*b*) and 3 test results are reviewed in the light of these practical requirements.

Ultimate Loads.—To ascertain whether the equivalent-width concept permits a satisfactory prediction of ultimate loads, Table 2(*b*) gives the comparison of ultimate loads obtained from tests with those computed on the basis of the full, unreduced cross section and with those obtained by considering the equivalent width of the compression flanges. Tension tests were made on specimens cut from the steel from which the beams were formed. Equivalent widths were then determined from Fig. 7 for the yield points so obtained. Section moduli S were computed both for the full, unreduced cross section and for the reduced cross section—the latter by using the equivalent instead of the actual width of the compression flanges. The ultimate moments were then obtained from

$$M_u = s_y S \qquad (8)$$

Table 2(*b*) contains not only the results of series B but also those of a special, additional series C of I-beam tests (types I–14 to I–20). These beams were shaped in a manner similar to those of series B except that the tension flange was made about 20% wider than the compression flange and the beams were loaded at the third points. The depth of all beams of series C was 8 in.; the widths of the top flanges varied from 4.50 in. to 10.10 in.; and the thicknesses, from 0.0447 in. to 0.0755 in.

In Cols. 8 and 9, Table 2(*b*), M_1 is the ultimate moment computed from the section modulus of the full, unreduced cross section; M_2 is the ultimate moment computed from the section modulus obtained by substituting the equivalent width of the compression flange for the actual width; M_t is the average test-failure moment of the "identical" beams of the given type.

It is to be noted from Col. 9, Table 2(*b*), that the behavior of beams I–15 and I–17 is rather different from that of all others in that these beams failed at moments considerably above both M_1 and M_2. These two beams were formed of the same steel and this steel was the only one tested which showed the following peculiarity in the tension tests: Instead of revealing a definite yield point by the usual criterion of arrest of load or drop of the beam, this steel showed only a more rapid increase of strain with increasing stress at about 36,400 lb per sq in. In other words, the stress-strain curve of this steel had no horizontal part at the yield point. The absence of this horizontal part seemingly accounts for the fact that the outer fibers were stressed considerably higher than the rather indefinite yield point, before the beams actually failed.

A study of Table 2(*b*) reveals that, in the low range of b/t, the difference between M_1 and M_2 for this type of I-beams is rather insignificant. This is caused by the fact that the equivalent width in this range is very close to the actual (b_e is close to b in Fig. 7). Since, in addition, the compression flanges are only a small part of the total cross section, a small change in width changes the section modulus only insignificantly. In this range (say, to $b/t = 40$) both M_1 and M_2 are rather close to M_t and somewhat on the conservative side. (For other types of cross sections, if the compression flange represents a more

substantial part of the entire area, the reduction in width may become practically important even in the low range of b/t.)

For b/t larger than about 40, M_1 becomes significantly and increasingly larger than M_t, whereas M_2 agrees with M_t rather satisfactorily throughout this range. If the values for the beams with b/t larger than 30 are averaged (with I-15 and I-17 omitted for reasons previously cited) the following average values are obtained: $M_1/M_t = 1.18$ and $M_2/M_t = 1.00$. In other words, if beams in this range were designed on the basis of the full, unreduced cross section, they would be underdesigned by an average amount of 18%, whereas, if they are designed on the basis of the equivalent width, a satisfactory and safe design would be obtained.

A similar comparison of ultimate moments for the inverted U-beams of series A is somewhat complicated by the nonsymmetry of the cross sections. Since the neutral axes of such sections are rather close to the compression flange, the stress in this flange will be rather low at loads at which the tension flange reaches yield-point stress. For this reason the beam will continue to carry increasing loads until the top flange, and with it practically all the cross section, is stressed to the yield point. The stress distribution is that of Fig. 4(b) and only then does the beam fail. (This somewhat novel concept of failure of steel beams has gained wide acceptance in recent years and was verified extensively by E. Volterra[16] and others. For the I-beams of series B and C discussed previously, this concept is of no importance because (a) these sections are closer to symmetry so that both flanges reached yield-point stress at about the same load; and, more important, (b) once the compression flange and a considerable part of the turned-down lips begin to yield, the latter become unstable and cause the ultimate breakdown of the beam. In the beams of series A, however, restraint of both edges of the compression flange is provided by complete webs which, therefore, do not become unstable until practically all the cross section reaches yield-point stress.) For these reasons the ultimate moments for series A are computed on the basis of the stress distribution of Fig. 4(b) by methods outlined previously.[14,15]

The symbols in Table 3(a) are the same as those in Table 2(b) except that M_1 is the ultimate moment computed for the stress distribution of Fig. 4(b) for the full, unreduced cross section; and M_2 is the ultimate moment computed in the same manner but by substituting the equivalent width of the compression flange for the actual width. A study of Table 3(a) reveals that M_1 in all cases is considerably larger than M_t, whereas M_2 in all cases is in rather satisfactory agreement with the test value. The average values are: $M_1/M_t = 1.36$; $M_2/M_t = 1.03$.

Summarizing the results of these seventy-one tests on thirty-three different types of I-beams (Table 2) and inverted U-beams (Table 3), it is notable that a conventional design procedure based on the full, unreduced cross section would result in definitely, and in many cases highly, unsafe values whereas an analysis based on the equivalent width concept (Fig. 7) results in very satisfactory agreement between computed and observed values.

[16] "Results of Experiments on Metallic Beams Bent Beyond the Elastic Limit," by E. Volterra, *Journal*, Institution of Civ. Engrs. (London), Vol. 20, 1942–1943, p. 1.

Deflections.—Any rational method should enable the designer to predict not only the strength of his structure, but also the magnitude of its deformation under load. In this case, then, the equivalent width approach should furnish a method of predicting deflections of beams with thin, wide compression

flanges. For such a prediction, it is only logical to compute the moment of inertia on the basis of the equivalent width of the compression flange, rather than on the basis of the full width, the equivalent width being determined from Fig. 7 for the stress corresponding to the load at which the deflection is desired. This approach, however, is somewhat approximate for the following reason: The stress in the compression flange of a freely supported beam is not constant along the span; it varies from zero at the supports to a maximum at or near the center. Fig. 7 indicates that the equivalent width decreases with increasing stress. Consequently, a beam with constant, thin-walled cross section actually has a varying effective moment of inertia, depending on the local magnitude of the compression stress, with a maximum at the supports and a minimum at the place of maximum moment. A full analysis of the test data taking account of this variation not only would be cumbersome but would also exceed the amount of effort a designer may reasonably be expected to devote to determining deflections. For this reason, deflections for the reduced cross section in Table 3(*b*) were determined for the minimum equivalent width—that is, the width corresponding to maximum moment. In the tests of series A, because of quarter-point loading, since the entire center half of the beam is stressed uniformly by the maximum moment, the error so introduced is rather small and the results obtained should be expected to be somewhat on the conservative side; that is, the computed deflections should be somewhat larger than the measured ones.

In Table 3(*b*) actual and computed deflections are compared at two different loads: (*a*) In the purely elastic range (at loads of from about 75% to 90% of those which cause the bottom fibers to reach yield-point stress); and (*b*) at the

loads that cause the bottom fiber to yield. It will be remembered that at this latter load practically all the cross section including the top flange is stressed considerably below yield-point intensity.

Table 3(*b*) gives average results of the same number of specimens of each type as does Table 3(*a*). The deflections d are defined as follows: d_1 is the deflection computed on the basis of the moment of inertia of the full, unreduced cross section; d_2 is the deflection computed on the basis of the moment of inertia determined by substituting the equivalent width of the compression flange for the actual width; and d_t is the deflection measured in the test.

Table 3(*b*) shows that deflections computed from the full, unreduced cross section throughout are smaller than measured deflections, particularly for the larger values of b/t. On the other hand, deflections computed on the basis of the equivalent width agree very satisfactorily with the measured deflections throughout the entire investigated range of b/t.

A similar comparison for the tests of series B and C is less revealing in its details. The b/t-ratios for these series are rather low (see Table 2(*b*)), causing the equivalent widths to be only slightly smaller than the actual widths. Also, the compression flanges of the I-beams represent a much smaller part of the cross section than do those of the U-beams of series A. For both these reasons the moments of inertia of the beams are little affected by the decrease of the equivalent width—indeed, less than the section moduli of these same beams. Therefore, only the average values of the deflections in the elastic range are given for these two series. For the beams of series B and C with b/t larger than 30 (that is, those for which the difference between equivalent and actual width is at all significant), the following averages were found: $d_1/d_t = 0.925$ and $d_2/d_t = 0.996$. For these beams, too, the deflections computed from the equivalent widths agree much better with the measured ones than do those computed from the unreduced cross section. (In analyzing the deflections of series B and C, account was taken of the part of the total deflections caused by shear stresses. This part amounted in some beams to as much as 6.7% of the total deflection. In the tests of series A the part of the deflection caused by shear is negligible because of the large span:depth ratios of these beams.)

Summarizing, the determination of deflections from the unreduced cross section would lead to a design which (just as with regard to strength) is in error on the dangerous side, whereas deflections determined from the equivalent width of the compression flanges are confirmed very satisfactorily by experiment.

Distortion Under Load and at Failure.—The compression flanges of all beams in the range of medium and large b/t developed very slight waviness at loads considerably less than the ultimate. At loads of the order of half of the ultimate the amplitude of these approximately quadratic waves, however, was so small that the distortion produced could not be considered of any structural consequence. In fact, so minute was the distortion that it escaped photographic recording, although wave formation could be detected by touch and was visible by careful inspection.

Failure occurred when one of the waves developed into a definite wrinkle; usually such development occurred within a very small load increment. Two

views of such beams in the medium range of b/t (I–15 and I–17, Table 2) after failure are given in Fig. 8. The local, wavelike distortion of the compression flange is clearly visible. It is also noticeable that adjacent parts of the flanges are practically undistorted: The minute waves, which, before failure, were

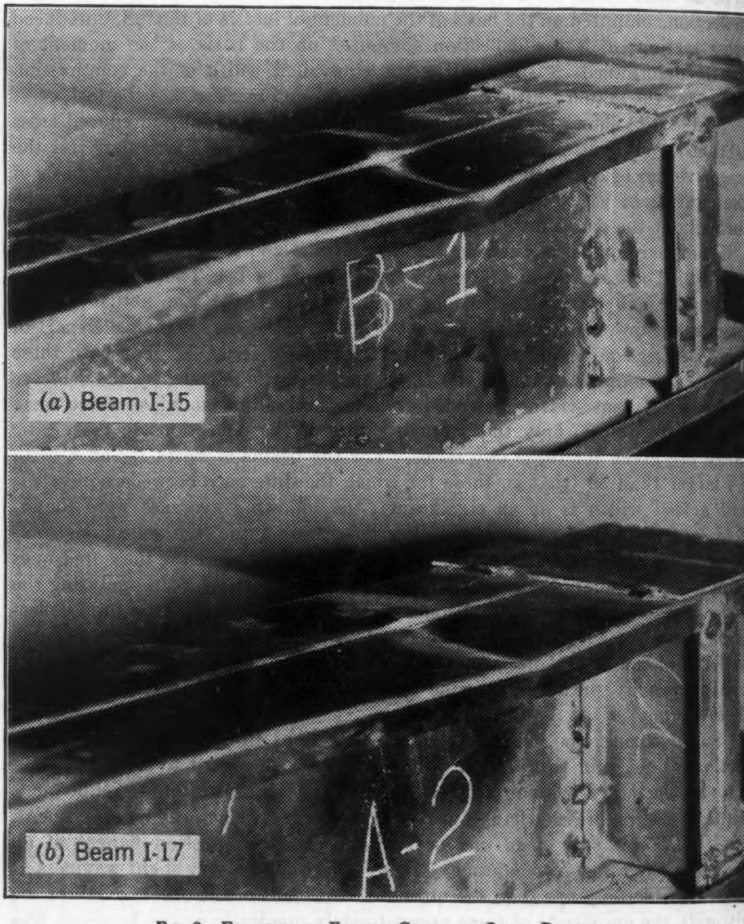

FIG. 8.—EXAMPLES OF FAILURE CAUSED BY LOCAL BUCKLING

present over the entire flange of the beam between loads did not cause any permanent distortion and disappeared after unloading, except for the one wave that resulted in failure. Turned-down lips remained straight up to failure loads, except for the widest of the I-beams (I–19 and I–20) in which the lips showed some slight wavelike departure from the initially straight shape all

along the center parts of the beams at loads below the ultimate. Possibly the lips of these two types of beams were not rigid enough to fully stiffen the flanges and somewhat stiffer lips may have raised the ultimate loads slightly (see Table 2(*b*)).

Type B. Compression Flanges Supported Along One Longitudinal Edge

Elements of this type occur in I-beams or channels not furnished with stiffening lips at the outer edges, so that flanges are stiffened by the webs along the joints of these two elements, but are free to distort out of their planes at the other, unstiffened edge.

To investigate the behavior of such flanges, two series of tests were made: (1) I-beams (designated by I–B); and (2) struts (designated by I–S).

1. In series D, seventeen types of beams of the general shape shown in Fig. 9(*a*) were tested—principally three "identical" specimens of each type. Most of the beams were 8 in. deep; a few of them were 4 in. deep, within shaping tolerances. Widths of top flanges ranged from 1.43 in. to 9.90 in., widths of bottom flanges from 1.93 in. to 10.18 in., and thicknesses from 0.0368 in. to 0.1035 in. The beams were tested on various lengths of span, depending on their width, to avoid beams so slender that they might buckle laterally before reaching full local strength. The beams were loaded by two equal loads, symmetrically located with respect to the center of the beam, at a distance from each other varying from 21 in. to 36 in. Ultimate loads, deflections, and strains were measured in these tests in the same manner as in the preceding series.

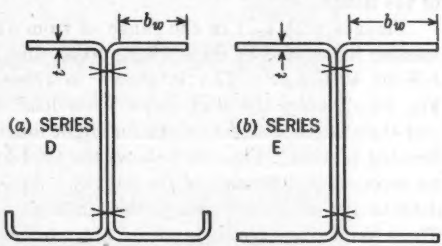

Fig. 9.—Shapes of I-Sections with Unstiffened Outer Edges of Compression Flanges

2. In series E, twenty-two types of struts (designated by I–S) of the general shape shown in Fig. 9(*b*) were tested in compression—mostly three "identical" specimens of each type. The narrower struts were 2 in. deep and the wider ones 4 in. deep, within shaping tolerances. Widths of flanges ranged from 1.56 in. to 12.00 in.; thicknesses, from 0.0368 in. to 0.1077 in.; and lengths of struts, from 15 in. for those with the narrowest flange widths to 63 in. for those with largest flange widths. The struts were tested with end attachments providing knife-edge support centered as precisely as possible in the plane of the web; and the aforementioned lengths were so adjusted as to keep the L/r-ratio in the direction of the least radius of gyration within the range of from 35 to 50. This was done to prevent failure of the struts due to column buckling rather than due to local failure. As a further safeguard against failure by bending or column buckling, deflections were measured at midlength both in the direction of the web and perpendicular to it. Thus, eccentric loading and conse-

quent bending, if they occurred, were detected at low stresses; and, in such cases, the loading was realined before the strut was tested to failure. This procedure, in conjunction with the small L/r-ratios insured the full development of local compressive strength rather than over-all buckling strength in these tests. In addition to ultimate loads and deflections, strains were measured by applying two 8-in. gages opposite each other in the center line of the web (see Figs. 10 and 11).

Since the results of both series of tests with regard to the behavior of the compression flanges were identical, the strut tests will not be separated from the beam tests in the following discussion, except for the nomenclature.

General Behavior and Types of Failure.—The tests revealed three rather different types of behavior under load and of final failure, depending on the ratio b_w/t of the compression flanges, in which b_w is the free projection of compression flange, measured from toe of radius to outer edge.

Flanges in the lowest range of b_w/t, up to about 12, as expected, failed by simple gradual yielding with little or no distortion perpendicular to the plane of the flange.

Flanges with b_w/t in the range of from 12 to 33 behaved and failed in a manner illustrated by Figs. 10(a), 10(b), and 10(c), in which a strut specimen I–S–10 with $b_w/t = 27.1$ is shown in three consecutive stages of loading. Fig. 10(a) shows the stud under a low load of 1 kip; flange faces are plane and their edges straight except for slight inherent inaccuracies obtained in the forming process. Fig. 10(b) shows the stud under a high load of 14 kips, with no perceptible distortion of the flanges. At a somewhat higher load (16 kips), definite distortions are seen in the upper part of the front flange of Fig. 10(c). These "kinks" are purely localized, the remainder of the flanges being essentially undistorted. The strut failed finally at a load of 18,600 lb after developing some more kinks of the same character. This strut and other struts (particularly in the range of b_w/t from about 20 to 33) carried considerably larger loads at failure than those in which the first kinks developed. Nevertheless, the load at which such kinks first appear must be regarded as the limit of structural usefulness for the particular element, and the subsequent discussion, therefore, is based on this local buckling rather than on the ultimate strength.

Finally, compression flanges in the range of b_w/t from 42 to 109 (the largest ratio of all specimens tested) behaved in the manner illustrated in Fig. 11. (No data are available for the range of b_w/t from 33 to 42.) Fig. 11 presents views of a strut specimen I–S–15 with $b_w/t = 42.6$ under increasing load; and Fig. 11(a), with a load of only 1 kip applied, shows the flanges being plane except for slight manufacturing distortion. However, at one half of the ultimate load, Fig. 11(b), taken at a load of 21 kips, shows slight regular waves beginning to develop in the flanges along the entire length. At further increased loads (31 kips and 39 kips), Figs. 11(c) and 11(d) show the amplitude of these waves gradually increasing, the regularity of the pattern being preserved. Finally, the strut failed at a load of 42 kips; and Fig. 11(e), taken after failure, shows that one of the previously developed waves had suddenly enlarged into a definite "kink" and produced failure. Whereas this particular strut did not

(a) P = 1 KIP
(b) P = 21 KIPS
(c) P = 31 KIPS
(d) P = 39 KIPS
(e) P = 42 KIPS

develop any perceptible distortions at loads less than about 50% of the ultimate, struts in the higher range of b_w/t developed distinct regular wave patterns at much smaller fractions of the ultimate load, down to less than 20% of the ultimate for the largest values of b_w/t.

The compression flanges of the beams of series D behaved in precisely the same manner in the respective ranges of b_w/t as did those of the struts of series E.

Three practical qualitative conclusions are to be drawn from these findings:

1. Flanges with b_w/t smaller than 12 do not buckle; they fail by yielding and can therefore be designed for full yield-point strength (for quantitative verification see the next section).

2. Flanges with b_w/t from 12 to about 30 (to stay slightly on the conservative side since no data are available for the range of from 33 to 42) will remain undistorted and serviceable until sudden buckling (kinking) occurs in the flanges. Despite the fact that such flanges may carry higher loads after kinking, the design criterion in this range of b_w/t should be the local buckling stress.

3. Flanges in the still higher range of b_w/t, although capable of carrying considerable stress, become distorted so seriously at loads far below the ultimate that they cannot be regarded as structurally useful except if used at extremely low design stresses.

The series of photographs in Fig. 11 is interesting in still another respect: It illustrates pictorially the concept of the equivalent width of thin flanges. Regular, wavelike distortion does not preclude considerable carrying capacity of the flange. On the other hand, a flange so distorted is not able to carry as much stress as the same flange if it were kept straight, say, by a system of stiffeners. After distortion occurs, moreover, the parts of the flange close to the web, kept essentially plane by the latter, will carry the main part of the total compression force in the flange, whereas the most highly distorted outer regions carry a rather small part of this force. Precisely this situation is idealized in the von Kármán concept of the equivalent width (Fig. 1). Compression flanges with both edges stiffened, like those discussed in the preceding section, behave in exactly the same manner, the only difference being that there the amplitude of the waves is limited to a much smaller magnitude by the combined action of both stiffeners as compared with that of flanges with one edge free. The idealization of this situation by the von Kármán concept is, simply, as follows: In the case of a flange with, say, both edges stiffened, the actual distribution of compression stresses over the width is of the character shown in Fig. 12. For convenience of design computation, the area under this stress curve is replaced by the equal area of the sum of the two dotted rectangles, whose altitude is the maximum actual stress at the stiffeners. Consequently,

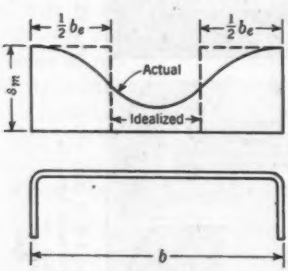

Fig. 12.—Stress Distribution Over the Width of a Stiffened Compression Flange

the maximum computed stress of a beam designed or analyzed according to this concept is equal to the actual maximum, and therefore governing, stress of the real, nonuniform stress distribution—all that is required for a rational design procedure.

Determination of Buckling Stresses.—In all cases in which formation of kinks was observed, the term "limiting stress" in this paper pertains to that stress at which the kink or kinks were first noticed. In the low range of b_w/t, failure occurred either by simple yielding, or by buckling (bending) of the entire specimen, or, in the case of specimens I-B-4, by an intermediate action between kinking and yielding. In these cases the limiting stress was determined as that at which irregularity of behavior appeared as a marked departure from the straight line in the load-deflection curve and the load-strain curve. In all cases stresses were computed by standard procedure—that is, by dividing the actual load (for struts) or moments (for beams) by the area or section modulus, respectively. These cross-sectional properties were computed from the full, unreduced dimensions of the sections. The justification for this procedure is given subsequently. Table 4, gives the results of the tests for the specimens

TABLE 4.—LIMITING STRESSES, s_l, AND ULTIMATE STRENGTHS, s_u, OF COMPRESSION FLANGES SUPPORTED ALONG ONE EDGE ONLY

with b_w/t less than 33.1—that is, for those which showed sudden formation of kinks (flange buckling) without preceding noticeable wave distortion. Table 4, therefore, covers the structurally useful range of b_w/t.

In Table 4, b_w is the free projection of compression flange measured from toe of radius to the outer edge; s_u is the ultimate strength computed for struts from $s_u = P_u/A$ and for beams from $s_u = M_u/S$, A and S, respectively, being the area and the section modulus of the full, unreduced cross section; s_{lt} is the limiting stress, computed in the same manner as s_u but from the test loads at which local buckling occurred; and s_{lC} is the limiting stress computed from Fig. 13 which is discussed in detail subsequently.

Type I–S–3 was the smallest in cross section of all those given in Table 4—its total flange width being only 1.56 in.; its depth, 2.01 in.; and its length, 15 in. These small dimensions made an accurate centering of the load extremely difficult with the available apparatus and, in addition, made it im-

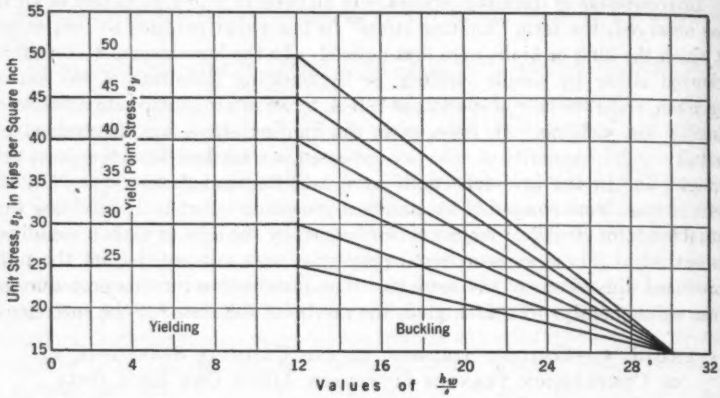

FIG. 13.—CHART FOR DETERMINING THE LOCAL BUCKLING STRENGTH FOR A GIVEN YIELD POINT s_y, FREE WIDTH OF PROJECTION b_w, AND FLANGE THICKNESS t, AS GIVEN BY EQ. 10

possible to control the accuracy of loading by measuring deflections in the direction of the least radius of gyration because the strain gages (see Fig. 10) left no space for the deflection-measuring device. The low value of s_u as compared with that of s_y seems to indicate that this strut was subject to considerable bending caused by eccentric loading, which provoked premature failure as compared with pure concentric loading.

Type I–B–3, the narrowest of those included in Table 4, with a total flange width of 1.48 in. and a depth of 7.95 in., failed very markedly by lateral bending (due to the large difference of the two principal moments of inertia) rather than by local buckling or yielding. This is the reason for the low values of s_u and s_{ll} in this case (see Table 4).

In Fig. 14, the values of s_{ll} are plotted against b_w/t. The curve representing the formula,

$$s_c = 0.5 \frac{\pi^2 E}{12 (1 - \mu^2)} \left(\frac{t}{b_w} \right)^2 \dots\dots\dots\dots\dots\dots\dots (9)$$

is shown by the solid line. Eq. 9 gives the theoretical, critical buckling stress for a long, narrow plate simply supported along one longitudinal edge and unsupported along the other.[3] Fig. 14 suggests that, in the higher range of b_w/t—from about 25 upward, local buckling (kinking) occurs at stresses equal to, or somewhat larger than, those given by Eq. 9. At lower values of b_w/t, however, buckling occurs at stresses considerably below s_c. This situation is analogous to that in the case of column buckling where failure loads are found to be considerably below the Euler loads for values of L/r less than about 100. To develop a procedure for predicting limiting stresses in this range of b_w/t, the

average yield point was computed from Table 4—specimens with $s_y = 49,400$ lb per sq in. being excluded from the averaging because of the high value of this yield point as compared with all others. The average value of s_y so obtained is 34,800 lb per sq in. Since flanges with b_w/t less than about 12 failed by

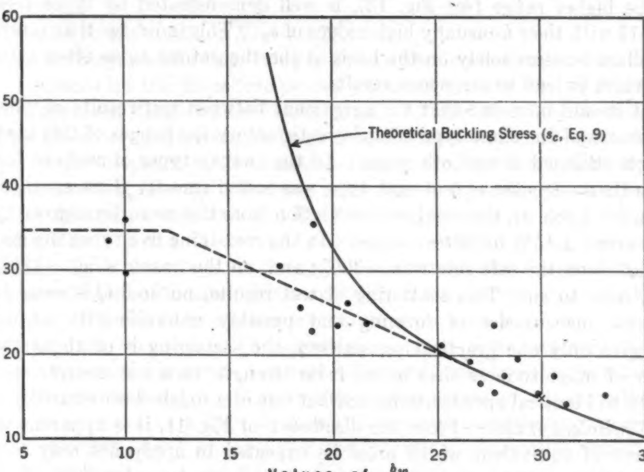

FIG. 14.—OBSERVED VALUES OF LOCAL BUCKLING STRENGTH s_{lt} PLOTTED AGAINST THE RATIO b_w/t; SERIES D AND E

yielding rather than by buckling, it seemed logical to presume that the dotted straight line in Fig. 14 (starting with the average s_y at $b_w/t = 12$ and ending with s_c at $b_w/t = 30$) would approximately represent the values of s_{lt}. The distribution of experimental points around that line indeed suggests that such may be the case. Fig. 14, however, is not sufficient evidence to prove the accuracy of this approach, because the yield points of the test specimens varied over a wide range from 29,200 lb per sq in. to 49,400 lb per sq in., whereas the dotted line in Fig. 14 refers to the average yield point only.

If the assumption is correct that a straight line, drawn from s_c at $b_w/t = 30$ to s_y at $b_w/t = 12$, determines the limiting stresses satisfactorily, then the limiting stress for each specimen should be found, according to its particular yield point, from Fig. 13. (The equation of the straight lines in Fig. 13, between $b_w/t = 12$ and $b_w/t = 30$ is

$$s_{lC} = s_y - \frac{s_y - 15{,}050}{18}\left(\frac{b_w}{t} - 12\right) \qquad (10)$$

from which the limiting stress can be computed in that range. For the few specimens with b_w/t larger than 30, the limiting stress s_{lC} entered in Table 4 is the critical stress according to Eq. 9 (see also Fig. 14).) The values so computed from Fig. 13 are entered under the heading s_{lC} in Table 4 and a comparison of these with the test values is given in the last column of Table 4.

This last column (Table 4) reveals rather satisfactory agreement, except for types I–S–3 and I–B–3. The reasons for the peculiar behavior of these two types was discussed previously. The influence of the yield point on the limiting stress, very pronounced in the low range of b_w/t, but gradually decreasing in the higher range (see Fig. 13), is well demonstrated by types I–S–8 and I–S–13 with their unusually high values of s_y. This indicates that a prediction of failure stresses solely on the basis of the theoretical s_c, as often attempted, is certain to lead to erroneous results.

It should be noted that the agreement between test results of "identical" specimens of the same type is not as satisfactory for flanges of this kind as for flanges stiffened along both edges. Of the twenty types of sections for which more than one specimen of each type was tested (mostly three specimens of a type, see Table 4), the maximum deviation from the mean for a given type did not exceed ±15% for fifteen types. In the remaining five types the maximum deviation on the safe side was +30%; and, on the unsafe side, −17%. The data refer to s_{ll}. This scattering of test results, no doubt, is caused by inevitable inaccuracies of forming and possibly nonuniformity of material. (To give only one practical comparison, the scattering is of about the same order of magnitude as that found from strength tests on concrete specimens mixed to identical specifications and cut out of a finished structure.[17])

Equivalent Width.—From the discussion of Fig. 11, it is apparent that the concept of equivalent width must be expected to apply not only to flanges stiffened along both edges but also to those with one edge free. Therefore, should not the evaluation of test series D and E be based on the equivalent areas of the compression flanges rather than on the unreduced cross sections as was done in Table 4?

In an academic thesis prepared under the writer's supervision,[18] E. A. Miller, Jun. ASCE, has computed the equivalent widths from the strain observations of series D and E in a manner similar to that previously discussed in connection with series A. This investigation was not limited to the practically useful range of b_w/t but included all specimens of these series with ratios of b_w/t up to 109.

Mr. Miller showed that expressions similar to Eq. 6 could also be developed in this case to express the equivalent width b_e. He found that the expression,

$$b_e = 1.25\, t \sqrt{\frac{E}{s}} \left(1 - 0.333\, \frac{t}{b_w} \sqrt{\frac{E}{s}} \right) \qquad (11a)$$

which is valid to about $t/b_w \sqrt{E/s} = 1.55$, represented rather accurately the average values found experimentally. Since results showed considerable scattering, a more conservative expression was developed, which, with a very few exceptions, gives a good approximation for the lowest values of b_e obtained

[17] "Properties of Job-Cured Concrete at Early Ages," Report of Committee 107, *Journal*, A.C.I., September–October, 1936, Tables 2 and 5, pp. 46 and 51.

[18] "A Study of the Strength of Short, Thin Walled Steel Studs," by E. A. Miller, a thesis presented to the faculty of the Graduate School of Eng., Cornell Univ., Ithaca, N. Y., in October, 1943, in partial fulfilment of the requirements for the degree of Master of Civil Engineering.

experimentally. This expression is

$$b_e = 0.8\,t\sqrt{\frac{E}{s}}\left(1 - 0.202\,\frac{t}{b_w}\sqrt{\frac{E}{s}}\right)\ldots\ldots\ldots\ldots\ldots(11b)$$

which is valid to about $t/b_w\ \sqrt{E/s} = 1.75$.

On the basis of these findings it is possible to decide whether, in determining buckling stresses by the procedure of the preceding section, the equivalent or the full, unreduced flange width should be used. This question, obviously, is of greater practical significance for large than for small values of b_w/t. It will therefore be investigated for the suggested upper limit of the useful range of b_w/t—namely, for $b_w/t = 30$. For this value the local buckling stress, according to Figs. 13 and 14, is found from Eq. 2*b* to be 15,100 lb per sq in. For this value of s, Eqs. 11*a* and 11*b* for $b_w/t = 30$ give, respectively, $b_e = 28.2\,t$ and $b_e = 25.2\,t$. In other words, in the practically important range of b_w/t the maximum reduction of flange width is only 6% on the average (Eq. 11*a*) with a maximum of 16% from the more conservative expression Eq. 11*b*.

Hence, in the range of b_w/t to about 30, computations based on the full, unreduced flange width are as accurate as can reasonably be expected—considering that (1) the degree of scattering of the values of the experimental buckling stresses makes a high accuracy of computation illusory; and (2) a reduction in width of 6% or even 16% results in a much smaller reduction of the significant values of A and S for ordinary sections in which the compression flanges of type B represent only a moderate part of the entire cross section. The introduction of an equivalent width, in this case, would unduly complicate computations without any significant improvement of the validity of results.

Thus, Eqs. 11 appear to be practically valuable only in establishing the foregoing conclusion. They may become significant in connection with further analytical research in this field, in testing future theoretical expressions for the equivalent widths of flanges of this type.

Conclusion

The experimental evidence presented in this paper indicates that the strength and general behavior of thin steel compression flanges is satisfactorily accounted for in the following manner:

1. Flanges Stiffened Along Both Longitudinal Edges.—Flanges with values of b/t to about 25 were found to fail by simple yielding, the full area of the flange being effective—that is, the stress is of uniform magnitude across the width. For flanges with larger values of b/t, deflections and ultimate loads computed by considering the compression flanges fully effective were found to err on the dangerous side.

Replacement of the actual flange width by an equivalent width determined from Fig. 7 resulted in very satisfactory agreement between observed and computed ultimate loads and deflections. Locations of neutral axes, as determined experimentally from strain measurements, showed good agreement with locations computed on this basis.

Within the investigated range of dimensions, distortions of such flanges at loads below the ultimate were very limited and of little, if any, practical significance.

2. Flanges Stiffened Along One Longitudinal Edge.—Flanges with ratios of b_w/t to about 12 failed by simple yielding, the full area of the flange being effective. In the range of b_w/t from 12 to about 30, local sudden and pronounced flange buckling was found to occur at stresses determined from Fig. 13. Local flange buckling did not precipitate immediate failure; indeed, ultimate loads of some specimens were as high as twice the load that produced local buckling, stresses being computed in all cases from the full, unreduced flange width. For practical purposes, however, it was held that loads resulting in local buckling must be regarded as reaching the limit of structural usefulness.

In the range of b_w/t larger than about 30, wavelike gradual flange distortion was observed to occur at stresses rapidly decreasing with increasing values of b_w/t. The distortions, even at rather small fractions of the ultimate loads, were so pronounced as to make such members useless for most structural applications, except at extremely low design stresses.

From strain measurements it was found that the area of such flanges was only partly effective. This phenomenon resembles the behavior of the flanges under conclusion 1. An expression for the equivalent width, as determined from strain measurements, is given in the text.

It is not contended that the findings of this investigation, as expressed chiefly in Figs. 7 and 13 necessarily represent the final answer to the question of the strength of thin compression flanges. Being rather analytically inclined himself, the writer is perfectly aware of the limitations inherent in such purely experimental results, unsupported as they are by any more rigorous theoretical analysis.

It so happens, however, that the rigorous treatment of buckling of thin plates along classical lines of elastic stability[19] proved to be of little practical value. The reasons for this situation have been stated in the paper. Attempts by various investigators to go beyond the simple, classical approach have so far failed to give practically significant results and have led, in most cases, to rather contradictory conclusions.

Under these circumstances the only feasible approach seemed to be that of a rather extensive experimental investigation and an attempt to express the results of such test work by formulas or graphs that would agree reasonably well with test results. The situation is comparable with that of earlier column investigations in the range in which the Euler formula is invalid. The simple formulas then developed, mostly of straight-line character, served their purpose rather well until such time as more accurate and more involved approaches, such as the secant formula, could be developed.

It is hoped that a similar situation may obtain with regard to the topic of this paper and that the limited results of this investigation may serve their practical purpose until such time as more general and exact treatments will become available.

ACKNOWLEDGMENTS

The tests and conclusions reported herein are part of an extensive investigation of thin-walled steel structures sponsored jointly by the American Iron and Steel Institute and Cornell University, in Ithaca, N. Y.,[2] under the general supervision of Prof. W. L. Malcolm, M. ASCE, director, School of Civil Engineering, the writer being in active charge of the work. The writer wishes to express his sincere appreciation of the unfailing patient cooperation and valuable suggestions of Director Malcolm and of the members of the technical subcommittee of the Committee on Building Codes of the Steel Institute—in particular that of Milton Male, M. ASCE, chairman; B. L. Wood; and F. E. Fahy, Assoc. M. ASCE.

In conducting the test work and the computations the writer was ably assisted by the following McMullen Graduate Scholars (in chronological order): C. A. Dunn, Assoc. M. ASCE; Capt. G. G. Green, R. L. Lewis, and E. A. Miller, Juniors, ASCE; and R. H. J. Pian. Their individual contributions, overlapping as they are as to time and topic, cannot readily be separated. The writer wishes to thank all these collaborators for their conscientious and devoted cooperation and their many helpful suggestions.

APPENDIX. NOTATION

The following letter symbols, used in the paper, conform essentially to American Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials (ASA—Z10a—1932), prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932:

A = area of cross section; A_n = area of one of n subareas;

b = width of a plate of type A perpendicular to the direction of compression:

  b_e = equivalent width;

  b_s = width of a strip, part of the total width;

  b_w = width of the free projection of a compression flange of type B, measured from the toe of the radius to the outer edge;

C = a variable experimental coefficient; as a subscript, C denotes "computed";

d = deflection, with subscripts t denoting "by test," etc.;

E = Young's modulus of elasticity;

h = depth of beam section;

L = span lengths;

M = moment, with subscripts t denoting "by test" and u denoting "due to ultimate loads";

P = axial compression load (P_u = load at ultimate strength);
r = least radius of gyration;
S = section modulus;
s = unit stress:
  s_C = computed stress;
  s_e = critical stress;
  s_l = limiting stress;
  s_m = maximum stress;
  s_u = ultimate strength;
  s_y = yield-point stress;
t = thickness of plate;
y = coordinate distance; y_n = centroidal distance to an area A_n;
δ = strain, or unit elongation;
κ = a numerical factor depending upon the ratio of length to width of the plate and the conditions of edge support; and
μ = Poisson's ratio.

DISCUSSION

FRED T. LLEWELLYN,[20] M. ASCE.—This scholarly, yet not pedantic, study is peculiarly interesting to the writer because, prior to 1939, he was a member of the American Iron and Steel Institute committee sponsoring the Cornell University (at Ithaca, N. Y.) tests on which the paper is largely based. In 1933, the writer suggested the concept of effective (or equivalent) widths as applied to thin metal sections, such as the one illustrated by Fig. 12. He first collated the published proportions of a number of such sections, whose efficiency was fairly well established by industrial use; and next he endeavored to harmonize the results with the nonorderly and all-too-few tests then available.[21]

TABLE 5.—COMPARISON OF EQUIVALENT WIDTHS b_e/t

Investigator	Conditions of Fixity[a]		
	(1)	(2)	(3)
George Winter......	12	25	$E\,t/(s\,b)$
F. T. Llewellyn.....	10	30	100

[a] Conditions of fixity:
(1) One edge fixed and one edge free;
(2) One edge fixed and one edge lipped; and
(3) Both edges fixed. The ratio $E\,t/(s\,b)$ is based on Eq. 2b and Fig. 2.

A comparison of the values then tentatively suggested by the writer, with the much more adequately supported values now given by Professor Winter, is offered in Table 5. The conditions of fixity are not quite identical in both cases, but an effort has been made to classify them along comparable lines. The author is asked to state whether the surprising value, $\frac{E\,t}{s\,b}$, is correctly assigned in Table 5.

Although this rough comparison tends to confirm the safety of many miscellaneous sections in commercial use, the design of all thin-walled sections, of course, should be placed on a common and broad foundation. The present paper is welcomed as a valuable step in this direction—the development of a standard design specification for the products in question.

In view of the author's expressed inclination toward analytical methods, his restraint in, and happy application of, their use are to be applauded. Professor Winter's academic citations are few, but pertinent. In former years, when the writer was tempted to try and go "highbrow," he used to recall a warning from the field of art criticism. On one page of a revised edition of John Ruskin's works, the text was footnoted about as follows:

> "In the first edition of this book there was here a quotation from Aristotle, in the Greek. I inserted it to show I had read Aristotle. Having accomplished that purpose, it is now omitted."

The present paper affords a very suitable balance of the academic with the practical, to which Mr. Ruskin's self-irony could not possibly apply. The author does not need to apologize for approaching the subject from an experi-

[20] Baton Rouge, La.
[21] "Light-Gage Flat-Rolled Steel in Housing," by F. T. Llewellyn, A.I.S.C., 1937, p. 29.

mental rather than a classical standpoint. Is it not true that all physico-mathematical theory must be converted into conventional forms that are valid only within the boundaries of everyday practice? Thus, the writer would expect Figs. 7 and 13 to receive most attention from actual designers of thin-walled sections.

It is hoped that these casual, but quite appreciative, comments by an "old timer" may be of as much interest to the author, and fellow engineers, as the paper was to the writer.

JACOB KAROL,[22] ASSOC. M. ASCE.—Despite the fact that millions of formed sheet channels with and without stiffening lips have been used as bending members in airplane control surfaces, there has been no definite design procedure whereby a stress analyst could determine their ultimate strength. The paper by Professor Winter, therefore, is a timely and important contribution to the field of elastic stability.

The writer's procedure in determining the strength of symmetrical formed sheet channels in bending has been to compute the ultimate strength of the

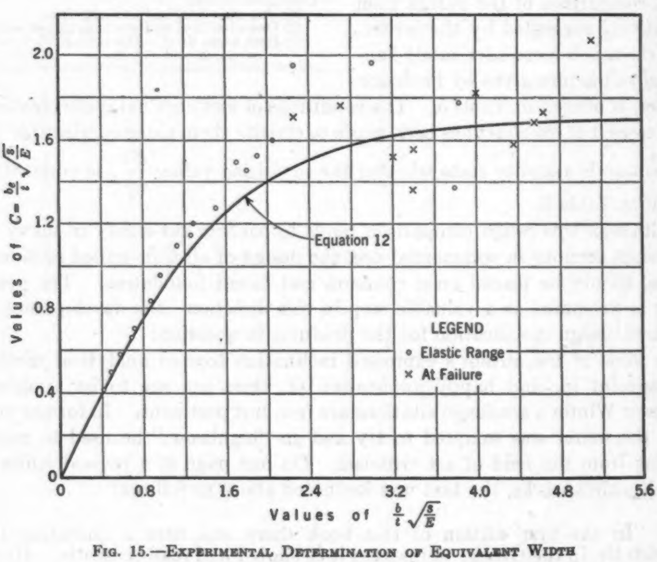

FIG. 15.—EXPERIMENTAL DETERMINATION OF EQUIVALENT WIDTH

component elements of the section on the compression side, to obtain the resisting moments about the centroidal axis, and then to double their sum to obtain the total resisting moment. It is interesting to note that this procedure is similar to that presented in the paper.

[22] Design Engr., Howard, Needles, Tammen & Bergendoff, Kansas City, Mo.

It will be shown that, by plotting the test data for the type A members (compression flanges stiffened along both longitudinal edges) in a slightly different manner, the relationship between the variables is clarified, and it becomes readily apparent that a simple expression can be written for the experimental coefficient C which is applicable over the entire range of $\frac{b}{t}$.

The data from Fig. 2 have been plotted with C as ordinates, but with the inverse parameter $\frac{b}{t}\sqrt{\frac{s}{E}}$ as abscissas in Fig. 15. To indicate the relationship in the low ranges of the inverse parameter, the writer has also plotted the results of the special series B tests, given in Table 2, in Fig. 15. Since $C = \frac{b_e}{t}\sqrt{\frac{s}{E}}$, by definition (see Eq. 4, the ratio of C to the inverse paramenter is really $\frac{b_e}{b}$ for each test point. The data indicate that, for the low ranges of the inverse parameter, the value of C should be nearly equal to the inverse parameter,

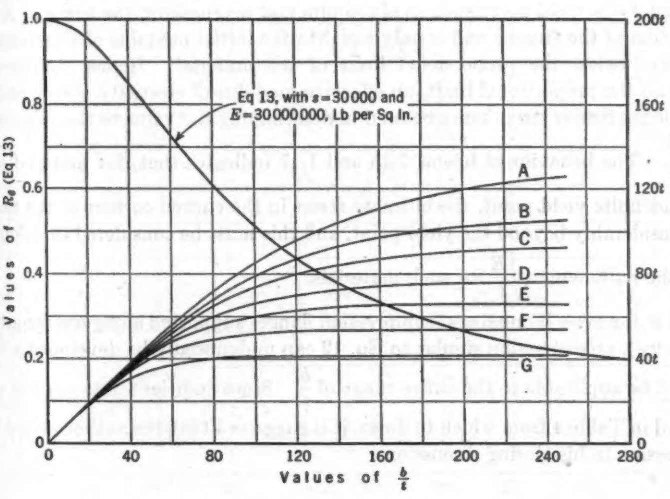

FIG. 16.—CHART FOR DETERMINING EQUIVALENT WIDTH b_e

whereas, for the high ranges of the inverse parameter, the value of C is practically constant. The following expression fulfils these conditions and gives results practically identical with Eq. 6:

$$C = 1.7 \tanh\left(\frac{1}{1.7}\frac{b}{t}\sqrt{\frac{s}{E}}\right) \qquad (12)$$

Eq. 12 is shown as a solid line in Fig. 15. The ratio of the ordinates to the abscissas in Fig. 15 is

$$R_e = \frac{b_e}{b} = \frac{\tanh\left(\frac{1}{1.7}\frac{b}{t}\sqrt{\frac{s}{E}}\right)}{\frac{1}{1.7}\frac{b}{t}\sqrt{\frac{s}{E}}} \qquad (13)$$

Eq. 13 is plotted for the particular case of s = 30,000 lb per sq in. and E = 30,000,000 lb per sq in. in Fig. 16, using $\frac{b}{t}$ as abscissas and R_e as ordinates. This curve (marked "Eq. 13") corresponds to Fig. 5 and shows that the value of R_e approaches 1 for small values of $\frac{b}{t}$, as it should.

Eq. 13 has been used to plot a family of curves similar to those in Fig. 7 (the legend in Fig. 7 applies to Fig. 16), and the resulting chart for equivalent width is also shown in Fig. 16. Although the author recommends the use of the chart for other metals than mild steel, it should be noted that, for metals with an indefinite yield point such as aluminum and magnesium, the value of E is a function of the stress s and is only equal to the initial modulus of elasticity for stresses below the proportional limit of the material. Hence, for stresses beyond the proportional limit, an effective modulus of elasticity corresponding to the particular stress must be used in determining the value of the parameter $\sqrt{\frac{E}{s}}$. The behavior of beams I-15 and I-17 indicates that, for material with an indefinite yield point, the ultimate stress in the curved corners of the flange is considerably beyond the yield point, and this must be considered in calculating the parameter $\sqrt{\frac{E}{s}}$ for such materials.

For the type B members (compression flanges supported along one longitudinal edge), an expression similar to Eq. 12 can undoubtedly be developed which would be applicable to the entire range of $\frac{b}{t}$. Since sufficient data are not presented in Table 4 from which to do so, it is suggested that the author derive the expression in his closing discussion.

ROBERT L. LEWIS,[23] JUN. ASCE., AND DWIGHT F. GUNDER,[24] ASSOC. M. ASCE.—A basis for the design of structural members fabricated from thin sheets of steel has been presented by Professor Winter. Any design procedure should be kept as simple as is consistent with safe and economical practice. With this thought in mind the writers have examined the proposed development, hoping to find a somewhat simpler approach for the designer. It should

[23] Prof. and Head, Civ. Eng., Colorado Agri. and Mech. College, Fort Collins, Colo.

[24] Prof. of Graduate Eng., Colorado Agri. and Mech. College, Fort Collins, Colo.

be emphasized that it is infinitely more simple to view a problem of this nature in retrospect, and that any contributions which this paper may make will owe their origin to the basic work of Professor Winter.

The author presents experimental evidence that confirms E. E. Sechler's data showing that the constant term in the von Kármán formula, Eq. 2*a*, should be replaced by a variable coefficient C which is a function of $(t/b)\sqrt{E/S}$. This leads to the expression $b_e = C\,t\sqrt{E/S}$ (Eq. 2*b*). Dividing both sides by b, Eq. 2*b* reduces to the dimensionless form,

$$\frac{b_e}{b} = \frac{C\,t}{b}\sqrt{\frac{E}{S}} \qquad (14)$$

As stated by the author, C appears to be a function of $(t/b)\sqrt{E/S}$. Hence Eq. 14 can be expressed as

$$\frac{b_e}{b} = \frac{t}{b}\sqrt{\frac{E}{S}}\,f_1\,\frac{t}{b}\sqrt{\frac{E}{S}} \qquad (15)$$

which merely states that

$$\frac{b_e}{b} = f\left(\frac{t}{b}\sqrt{\frac{E}{S}}\right) \qquad (16)$$

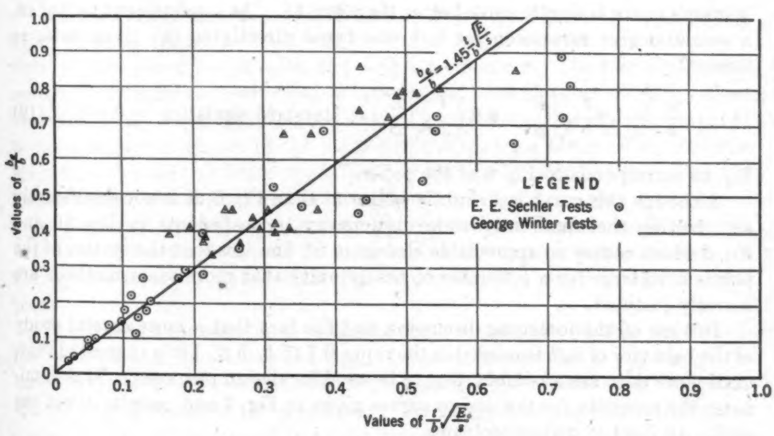

FIG. 17

Referring to Fig. 2 in which experimental values of the coefficient C are plotted against the parameter $(t/b)\sqrt{E/S}$, it will be noted that

$$\frac{C\,t}{b}\sqrt{\frac{E}{S}} = \frac{b_e}{t}\sqrt{\frac{S}{E}} \qquad (17a)$$

and

$$\frac{t}{b}\sqrt{\frac{E}{S}} = \frac{b_e}{b} \dots\dots\dots\dots\dots\dots\dots\dots\dots (17b)$$

The experimental values shown in Fig. 2 were read as carefully as possible from the graph and all values of the coefficient were multiplied by corresponding values of the parameter, thus obtaining the experimental values of b_e/b.

These values were plotted against the parameter $(t/b)\cdot\sqrt{E/S}$ as shown in Fig. 17. As a first approximation to the function $f[(t/b)\sqrt{E/S}]$ the best straight line was fitted to these data by the method of least squares. Its equation is:

$$\frac{b_e}{b} = 1.45\frac{t}{b}\sqrt{\frac{E}{S}}; \quad 0 \leqq \left(\frac{t}{b}\right)\sqrt{\frac{E}{S}} \leqq 0.7 \dots\dots\dots (18)$$

In order to compare Eq. 6 with Eq. 18 the test values of Fig. 2 were plotted in Fig. 5 and on a graph of Eq. 18. Standard deviations from each curve were computed. The standard deviation from Professor Winter's curve was found to be 0.084 and that of the straight line was 0.113. The difference in standard deviations is caused by the wide scatter of three points of the Sechler data for which the value of b_e/b was approximately equal to 1. Although it is felt that with the limited data available the straight-line approximation is probably as satisfactory as any other, the F-test for goodness of fit does show that Professor Winter's curve is significantly better than Eq. 18. As a refinement to Eq. 18, a second-degree expression for b_e/b was fitted directly to the given data, as follows:

$$\frac{b_e}{b} = 1.8\frac{t}{b}\sqrt{\frac{E}{S}} - 0.9\left(\frac{t}{b}\sqrt{\frac{E}{S}}\right)^2; \text{ standard deviation} = 0.082 \dots (19)$$

Eq. 19 corresponds to Eq. 6 of the paper.

Although this curve is a slightly better fit than Eq. 6, it is not significantly so. Noting the apparently wide discrepancy in coefficients in Eq. 19 and Eq. 6 which causes no appreciable change in fit, one sees that the scatter of the points is so large for a b_e/b-ratio of nearly unity that more exact methods are scarcely justified.

In view of the foregoing discussion and the fact that a more careful study of the behavior of b_e/b is needed in the range $0.7 \leqq b_e/b \leqq 1$ it is suggested that, until more data are available, Eq. 18 be used for design purposes. This eliminates the necessity for the design curves given in Fig. 7 and permits direct use of Eq. 18 itself in design problems.

In conclusion the writers would like to call attention to a few mechanical improvements which could be made in the paper:

1. Fig. 7 would perhaps be more useful if the ordinates were values of b_e/b rather than of b_e/t.

2. The number of significant figures is misleading in several places, as, for example, in Eqs. 7 where an approximate value of 25 is used in combination with coefficients such as 1.0906.

3. Averages of the ratios d_1/d_t and d_2/d_t were the criteria used to judge the validity of using the equivalent width as a basis for determining deflections. Actually, it is the standard deviations of the values of d_1/d_t and d_2/d_t about these means which are the more significant measures. In the light of these deviations, the use of b_e for the calculations of deflections is far more superior than is indicated in the paper.

4. Finally, not only in this paper but in all publications it would be extremely helpful if standard deviations were included whenever mean values or fitted curves are used, since these give the reader a much more accurate picture of the reliability of the results.

L. C. MAUGH[25] AND L. M. LEGATSKI,[26] ASSOCIATE MEMBERS, ASCE.—For many years structural engineers have recognized the danger of subjecting thin elements to high compressive stresses; but, in general, they have avoided, rather than solved, the problems that are associated with the instability of such elements. However, industry is demanding that engineers remove the restrictions imposed by specifications and take advantage of any economy that may be obtained by the use of thin sheet metal. This interesting and timely paper is unusually important, therefore, inasmuch as it is related to the development of new specifications for the design of such structural members. Consequently, any discussion of the paper cannot logically ignore the problems that are presented, if design methods follow the procedures recommended by the author.

The basis of the solution recommended by Professor Winter is the equivalent width method, originally developed for the design of aircraft structures from tests on thin sheet panels with and without stiffeners. Most of these tests were made on specimens with large b/t-ratios and with E-values much less than those for steel. Consequently, the boundary effect was so large as compared to the primary resistance of the plate element that the latter effect could be ignored. The edge or boundary effect has commonly been evaluated (as the author states) by considering the strength of two-edge strips that are assumed to be unaffected by the central section between them. Even for such elements with large b/t-ratios, it would be more logical to consider each edge strip, in Fig. 1, as a separate plate rather than to combine the strips to form a single plate.

The principal question involved in the paper seems to be whether the equivalent width transformation is the best solution to the problem. Although the author rejects the Bryan formula[8] for calculating the resistance of the actual element, he does use it for determining the strength of the equivalent plate. Certainly, Eq. 2b is derived from the same basic differential equation as the general Bryan formula, that is,

$$\frac{\partial^4 \eta}{\partial x^4} + 2\,\frac{\partial^4 \eta}{\partial x^2\,\partial y^2} + \frac{\partial^4 \eta}{\partial y^4} = -\,\frac{s}{D}\,\frac{\partial^2 \eta}{\partial y^2} \qquad (20)$$

[25] Associate Prof., Civ. Eng., Univ. of Michigan, Ann Arbor, Mich.

[26] Research Engr., Dept. of Eng. Research., Univ. of Michigan, Ann Arbor, Mich.

in which η is the lateral displacement and $D = \frac{E t^3}{12(1 - \mu^2)}$. Furthermore, there is no fundamental reason why the differential equation cannot be satisfied by superimposing the wave displacements involved in the edge resistance on the sine series ordinarily used for deriving the primary resistance of the plate.

The question arises, therefore, as to whether the ultimate strength of a thin element does not also depend on the primary resistance, as well as on the edge

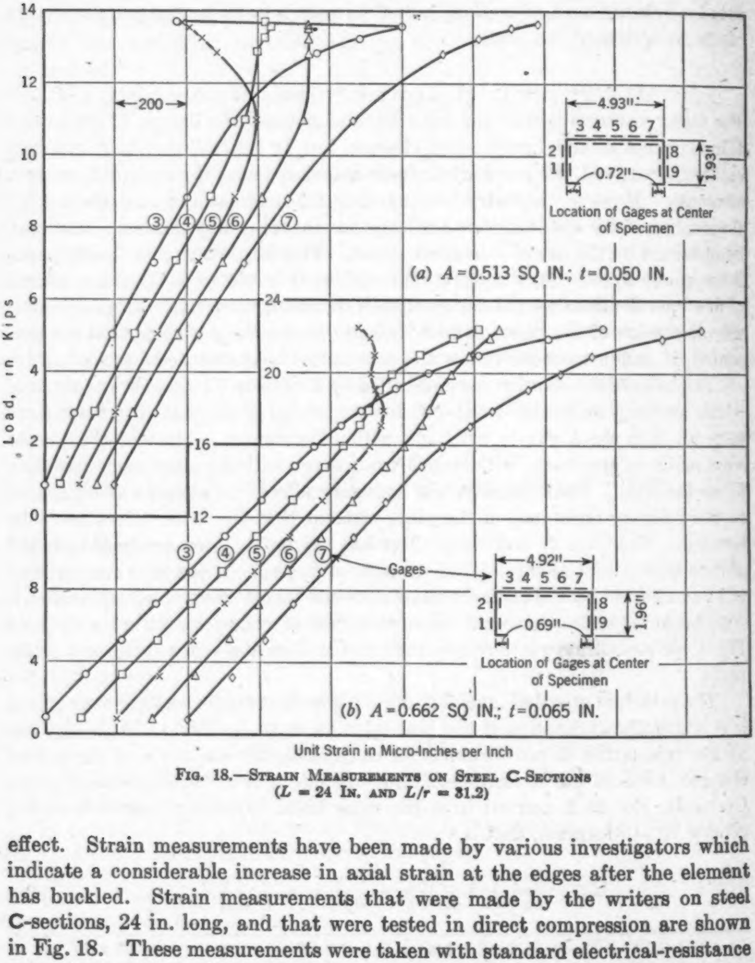

FIG. 18.—STRAIN MEASUREMENTS ON STEEL C-SECTIONS (L = 24 IN. AND L/r = 31.2)

effect. Strain measurements have been made by various investigators which indicate a considerable increase in axial strain at the edges after the element has buckled. Strain measurements that were made by the writers on steel C-sections, 24 in. long, and that were tested in direct compression are shown in Fig. 18. These measurements were taken with standard electrical-resistance gages fastened in pairs to both faces of the plate elements and connected in

series to give the average axial strain. In Fig. 18(*a*) where the web has a b/t-ratio of about 98, gage 5 at the center shows some reduction as the load approaches its ultimate value. Gages 4 and 6, adjacent to the center, remained practically constant, whereas gages 3 and 7 near the corners increased considerably. In Fig. 18(*b*) where the b/t-ratio of the web is about 75, gage 5 remains practically constant, gages 4 and 6 show some increase, and gages 3 and 7 show considerable increase as the ultimate strength of the specimen is approached. Because of the biaxial state of stress on elements near the center, the longitudinal stress is not directly proportional to the strain measurements shown. Nevertheless, the action in these specimens not only indicates an addition to the strain close to the corners but also shows that the primary resistance of the element is a definite and continuous phenomenon that may fluctuate but does not disappear as the ultimate strength of the specimen is reached. The author has not shown any distribution of strain across the compression flange of his specimens; nor has he stated whether such information was obtained.

A better approach would be to superimpose the edge effect on the primary resistance, whenever the element becomes unstable at a unit stress less than the proportional limit of the material. Above the proportional limit, a formula that considers the variation in E should be used and the edge effect neglected. For such assumptions, the ultimate strength of an element would be

$$s_u = s_c + s_e \qquad (21)$$

in which s_c is the critical stress of the element, and s_e is the average edge effect. It is assumed that s_c is less than s_p, the proportional limit. To determine s_e, the edge effect, it will be assumed that the resistance of the material near the boundary is approximated by that of a thin plate, supported at one edge and free at the other. The strength of this plate will be calculated from the usual formula; and, furthermore, the average unit stress on the edge plate will be taken equal to the proportional limit s_p. A mathematical investigation has indicated that this condition approximates closely the maximum resultant force that can be sustained by the assumed edge plate. Therefore, the width, b_e, of this edge effect will be such that:

$$s_p = \frac{K_1 E}{(b_e/t)^2} \qquad (22)$$

or

$$b_e = t \sqrt{\frac{K_1 E}{s_p}} \qquad (23)$$

The total additional resistance F' of both edges is, therefore,

$$F' = 2\,(s_p - s_c)\, t^2 \sqrt{K_1} \sqrt{\frac{E}{s_p}} \qquad (24)$$

and the average increase in stress over the element, due to the edge effect, is

$$s_e = \frac{F'}{b\,t} = \frac{2\,(s_p - s_c)\,\sqrt{K_1}}{\left(\dfrac{b}{t}\right)} \sqrt{\frac{E}{s_p}} \quad \text{(25a)}$$

The critical stress s_c is given by the Bryan formula:

$$s_c = \frac{K\,E}{\left(\dfrac{b}{t}\right)^2} \quad \text{(25b)}$$

The values of K and K_1 vary with the degree of restraint at the edges. For simply supported edges, $K = 3.62$ and $K_1 = 0.452$. These values give the following equation for the ultimate strength of an element that is simply supported at the edges:

$$s_c = \frac{3.62\,E}{\left(\dfrac{b}{t}\right)^2} \quad \text{(26a)}$$

and

$$s_u = s_c + \frac{1.35\,(s_p - s_c)}{\left(\dfrac{b}{t}\right)} \sqrt{\frac{E}{s_p}} \quad \text{(26b)}$$

It is suggested that the proportional limit, s_p, be taken as five eighths of the yield-point stress, s_y, to allow for variation of material in the specimens.

The values obtained from Eq. 26*b* have been compared with the experimental results that were obtained by L. Schuman and G. Back in their comprehensive series of tests. The theoretical values as shown by the solid lines[27] in Fig. 19 agree satisfactorily with the test results for large values of b/t, but are somewhat high for the smaller values. This condition is not surprising as the initial curvature in the specimens would have the greatest effect on the primary resistance of the stiffer elements. For steel plates with b/t-ratios less than 80, the edge effect could well be ignored. The dotted lines in Fig. 19 represent the critical stress s_c. The equations of the solid lines in Fig. 19 are, for $s_c > s_p$—

$$s_u = \frac{3.62\,E\,\dfrac{s_y}{s_y - s_p}}{\dfrac{3.62\,E}{s_y - s_p} + \left(\dfrac{b}{t}\right)^2} \quad \text{(27)}$$

[27] "Strength of Rectangular Flat Plates Under Edge Compression," by L. Schuman and G. Back, *Technical Report No. 356*, National Advisory Committee for Aeronautics, 1931, Figs. 9(*b*) and 10.

and, for $s_e < s_p$—

$$s_u = \frac{3.62\,E}{\left(\frac{b}{t}\right)^2} + \frac{1.35\,(s_p - s_e)\,\sqrt{E/s_p}}{\frac{b}{t}} \qquad (28)$$

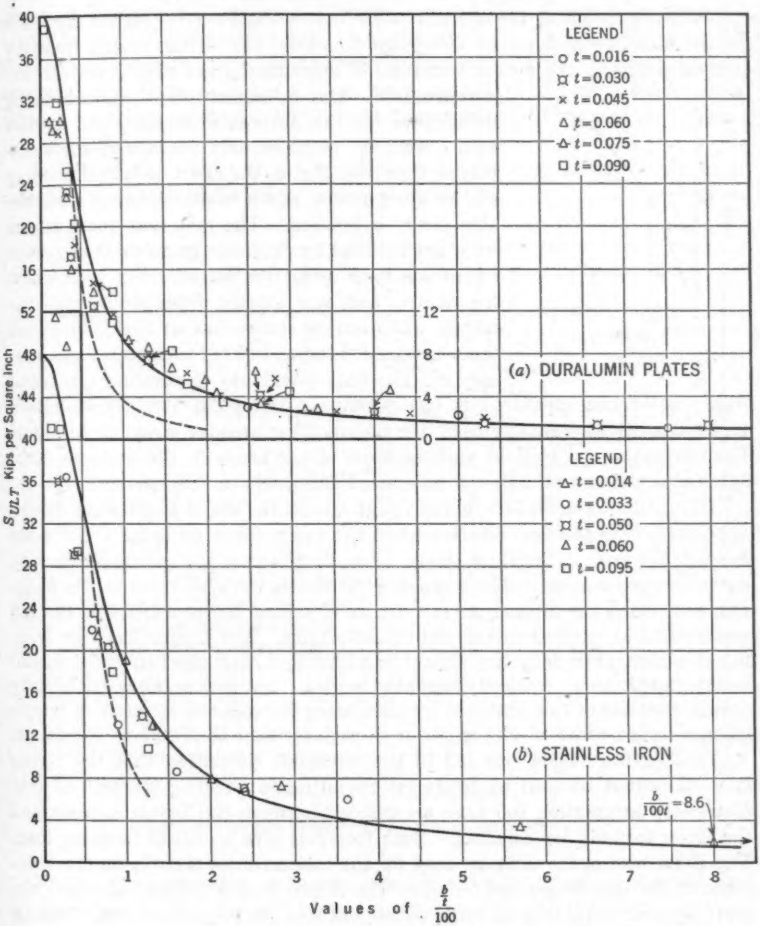

FIG. 19

The author has based his design procedure on the use of Eq. 2b in which the coefficient C is represented by a function of $\sqrt{\frac{E}{s}} \times \frac{t}{b}$. To the writers, this variation is tantamount to assuming that the coefficient must correct the

equation for other factors as well as for imperfections in the specimens and apparatus. The scatter of points in Fig. 2 could indicate many things besides deviation from shape such as variation in edge restraint of the element, inaccuracies in the determination of the neutral axis and of stress distribution over the beam, and neglect of the primary resistance of the element.

Without accepting the effective width concept as the most logical approach to the stability problem in light-gage members, the writers would question several points in the author's method of determining the effective width experimentally. The instrumentation appears to be inadequate for the purpose of locating the neutral axis. With the gages on only one side of the member, as shown in Fig. 3, the effect of lateral bending and twisting action, which could introduce considerable error, is ignored. The fact that these effects were not nullified by duplicate gages on the opposite edge casts some doubt on the accuracy with which the neutral axis was located from strain measurements. The author states that at the failure load the neutral axis is again located from strain measurements. The only possibility of securing this result from the strains measured is by assuming a triangular strain distribution under conditions that approach the assumed rectangular stress distribution. For unsymmetrical sections such as those of test series A, the writers cannot agree that the neutral axis can be located accurately in this manner.

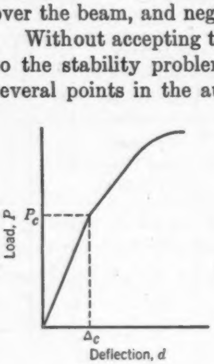

FIG. 20

In calculating deflections of light-gage beams, the use of an effective section appears to offer the best solution when the compression elements are stressed beyond the critical buckling stress. Fig. 20 shows a typical load-deflection curve for such a beam. The ordinate P_c indicates the load at which the flange elements reach the critical stress. Up to this load the properties of the full section should be used in calculating deflections. For higher loads an additional increment of deflection should be added to d_c, and this increment should be calculated using a reduced moment of inertia. For steel sections, sufficiently accurate results can be obtained by calculating the reduced moment of inertia using a flange width of $20\,t$ adjacent to each element that stiffens the flange.

Perhaps the author was led to the erroneous conclusion that the Bryan formula cannot be used to determine the ultimate buckling strength of thin plates—by attempting too close an analogy between the Bryan formula and the Euler formula for columns. Both formulas give a critical buckling load. The Euler load is the ultimate load for the column since there is no other element of strength to prevent failure. The Bryan load is the load at which the plate element forms into buckling waves, but it is not the ultimate load because a boundary or edge effect remains as an additional element of strength. If the Bryan load alone is compared to the ultimate load, the agreement is good for b/t-values up to about 50 for duralumin and 80 for steel, nickel, and monel metal. For larger b/t-values, the Bryan load is low (as indicated by the statement of Messrs. Schuman and Back, referred to by the author under the heading, "Type A. Compression Flanges Stiffened Along Both Longitudinal Edges:

Equivalent Width of Thin Flanges"). This condition occurs because the boundary effect is small as compared to the effect of the Bryan load within the foregoing values of b/t, whereas, for larger b/t-values, the reverse is true.

BRUCE G. JOHNSTON,[28] M. ASCE.—The tests[29] made at Lehigh University at Bethlehem, Pa., by Lloyd Cheney, Jun. ASCE, and the writer, supplement the results presented in Fig. 14 of the paper by Professor Winter. In the Lehigh University tests, the flanges of both carbon and silicon steel 10WF49 sections, each from a single rolling, were planed to different thicknesses, thereby providing a range of width to thickness ratios with a minimum variation in yield point.

Details of the tests will not be discussed, since they have already been reported,[29] but the results are summarized in Fig. 21.

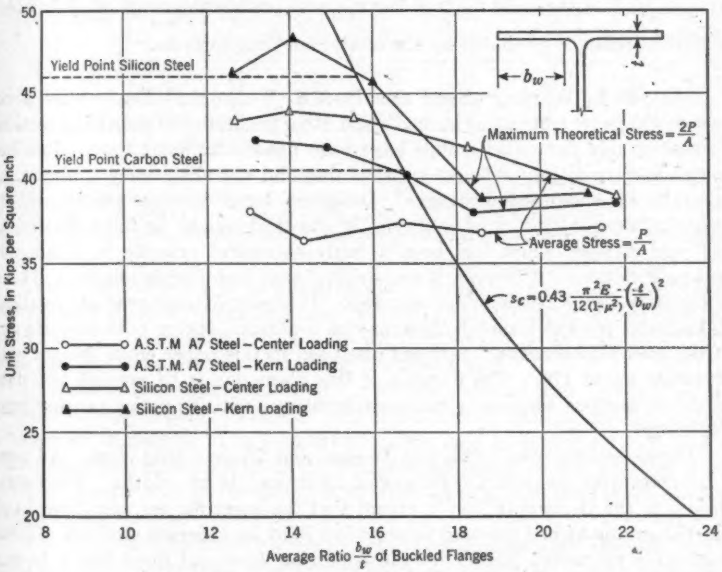

FIG. 21.—STRESS IN BUCKLED FLANGE AT MAXIMUM LOAD

For a very long plate, with one longitudinal edge simply supported and the other free, S. Timoshenko[30] gives a coefficient of 0.46 in the elastic buckling formula, whereas the author quotes a factor of 0.50 in Eq. 9. Professor Timoshenko's coefficient is based on Poisson's ratio of 0.25, corresponding

[28] Associate Director, Fritz Eng. Laboratory, Lehigh Univ., Bethlehem, Pa.

[29] "Steel Columns of Rolled Wide Flange Section," by Bruce Johnston and Lloyd Cheney, *Publication No. 190*, A.I.S.C., November, 1942.

to neither steel nor aluminum, for which coefficients of 0.43 and 0.41 are obtained[31,32] for Poisson's ratios of 0.30 and 0.33, respectively. These differences are somewhat academic, since the buckling strength will be affected by the torsional stiffness of the thick section at the juncture of the web and flange, and by the bending stiffness of the web, which may be negative or positive. However, if no account is to be taken of these effects, the question arises as to whether a coefficient of 0.43 is not preferable to one of 0.50.

In the tests at Lehigh University, in the case of large values of $\frac{b_w}{t}$ the web was thicker than the planed flanges, providing a partly fixed edge, and yielding effective coefficients even greater than 0.5; in fact, the buckling in all the tests was plastic rather than elastic. The results presented in Fig. 21 are self-explanatory and show that flanges of rolled shapes may be expected to develop at least 90% of the yield point of the material, within the range of $\frac{b_w}{t}$ in which plastic buckling is predicted by the elastic buckling formula.

EDWARD L. BROWN,[33] ESQ., AND DON S. WOLFORD,[34] ESQ.—More accurate methods for computing strength and other properties of structural sections formed of thin flat-rolled metals have been needed for some time. Previous methods were mainly deficient because they did not adequately evaluate the strength of compression flanges. Designers have become accustomed to assuming certain maximum multiples of the thickness to be fully effective in stiffened flanges, which has been a fairly successful practice in reasonably compact sections. However, it was evident that such simple relations did not adequately define behavior for all cases. Professor Winter presents relations in his paper by which such flanges may be evaluated, taking both b/t-ratio and stress level into account. Sections discussed in this paper cover flanges with b/t-ratios up to 170. The purpose of this discussion is to present test data made on sections containing compression flanges with b/t-ratios ranging from 242 to 429.

These sections were formed of 18-gage and 20-gage mild steel. All were 3 in. deep with compression flanges of 12-in. and 16-in. widths. They were similar to the U-beam in Fig. 3, except that the lower flanges were lipped and one flange was turned outward to provide a joint for adjacent sections. These tests were sponsored jointly by the American Iron and Steel Institute and Cornell University at Ithaca, N. Y., and were made under Professor Winter's supervision. They were witnessed by the writers of this discussion who also made the calculations and analysis of the results.

Four identical pairs of each type of section were subjected to quarter-point beam loading using an 80-in. span. Deflections and strains in top and bottom

fibers were observed as load was applied and released at successively higher values. The yield-point load was assumed to be that which first caused a large increase in residual deflection upon release of load.

Section properties were computed for each type of section using (1) gross section and (2) effective section. The effective widths were determined from curves computed by Eq. 6, carried out to b/t-ratios in the range needed. The measured tensile yield strengths of the steels used were taken into account. Computed and observed deflections and loads are compared in Table 6.

TABLE 6.—COMPARISON OF ACTUAL AND COMPUTED VALUES

Type	Dimensions, in Inches			Deflection,[b] in Inches			Load, in Pounds[c]

Average ratio, $\frac{\text{computed value}}{\text{test value}}$				...	1.14	0.63	...	0.935	1.340

[a] The ratio of width (between webs) to thickness. [b] Deflections are at working stress level, assumed as the yield point divided by 1.85. [c] Loads are for a single section and are at the yield point.

Computed loads based on effective-width properties averaged 6.5% lower than observed loads, indicating good correlation tantamount to safe and efficient design. Gross section properties led to expected loads that were higher than actually obtained, and were therefore misleading.

Deflections shown in Table 6 are at working stress levels, determined by dividing the yield point by 1.85. It is the deflection at this stress level that is pertinent in design. The moment of inertia used to determine deflection is based on the effective width of the compression flange at the working stress level. A larger part of the flange is effective at this level than is effective at the yield-point stress level.

The calculated deflections averaged 14% greater than those observed in the test, which is reasonable. Deflections calculated by gross section properties were only 63% of those observed in test, which shows that such an approach is not reliable.

Top and bottom strains were approximately equal at the yield loads, placing the neutral axes near mid-depth where computations using properties based on effective widths indicated they should be, rather than near the compression flange as indicated by gross properties.

In summary, these additional tests and correlations show definitely that the relations given by Professor Winter for determining the effective widths of compression flanges, stiffened along both edges, enable the designer to compute design loads and deflections quite accurately at b/t-values at least as high as 429.

George Winter,[35] M. ASCE.—Since the publication of this paper, the concept of the effective width has been adopted in two structural design specifications: The Specifications for the Design of Light-Gage Steel Structural Members, American Iron and Steel Institute, April, 1946, and the February, 1946, edition of the Specifications for the Design, Fabrication, and Erection of Structural Steel in Buildings, American Institute of Steel Construction. In the latter code, Sections 18*c* and 18*d* make use of an effective width, although in a greatly simplified manner. The writer does not claim any credit for these latter sections. He merely wishes to note the increasing acceptance of this concept in structural design.

The gracious comments of Mr. Llewellyn are deeply appreciated, particularly coming, as they do, from an "old-timer," with such thorough and long-standing interest in this particular field. To Mr. Llewellyn, credit is due for having first proposed the use of an effective width in structural design of light-gage members.[21] Although the values originally suggested by Mr. Llewellyn underwent inevitable correction by subsequent investigation, they were amazingly close to over-all averages, considering the dearth of information on the subject more than a decade ago. Although Mr. Llewellyn differentiated between edges supported by webs, and those stiffened by lips, the writer found that flanges stiffened either way developed the same strength, provided the rigidity of the lip proper was sufficient to furnish full support. This statement holds at least for the range of b/t of the beams of Table 2—that is, for the lipped flanges tested in this investigation.

The only contribution that undertakes to challenge the writer's approach to the problem (merely with regard to flanges stiffened along both edges) is that by Messrs. Maugh and Legatski. To evaluate the contentions contained therein, it appears necessary to clarify some obvious misunderstandings, the source of which the writer is unable to trace.

In summarizing their discussion, Messrs. Maugh and Legatski state that "Perhaps the author was led to the erroneous conclusion that the Bryan formula cannot be used to determine the ultimate buckling strength of thin plates * * *." Three lines farther, however, they write:

> "The Bryan load is the load at which the plate element forms into buckling waves, but it is not the ultimate load because a boundary or edge effect remains as an additional element of strength."

This is exactly what the writer maintained in his discussion of fundamentals (paragraph preceding Eqs. 2), where he stated that,

> "The central, more highly distorted, regions of the plate decrease in their resistance, thus throwing more of the total compressive force toward the stiffened edges * * *. This action [failure] occurs at a load higher than the critical—that is, higher than that load at which, theoretically, small deflections start to occur * * *."

These two statements are exactly identical in content, and the writer is at a loss to understand wherein lies his "erroneous conclusion."

[35] Associate Prof., Civ. Eng., Cornell Univ., Ithaca, N. Y.

In the concluding paragraphs, the statement, "Without accepting the effective width concept as the most logical approach * * *" seems to indicate that Messrs. Maugh and Legatski know of, or have developed, a method which dispenses with that concept. Actually, the approach they propose is likewise based on an effective width, implicitly for stress determinations (see Eq. 23), and explicitly for deflection computations. The writer, again, is at a loss to understand the quoted statement.

From an analytical point of view, contrary to the contributors' contention, Eq. 20, from which the Bryan formula is derived, is no longer applicable, once the critical stress is exceeded. Under such conditions, it is necessary to consider the so-called large deflection theory; that is, Theodor von Kármán's differential equation,[36,37] in which F is the stress function:

$$\frac{\partial^4 \eta}{\partial x^4} + 2\,\frac{\partial^4 \eta}{\partial x^2\,\partial y^2} + \frac{\partial^4 \eta}{\partial y^4} = \frac{t}{D}\left(\frac{\partial^2 F}{\partial y^2}\frac{\partial^2 \eta}{\partial x^2} + \frac{\partial^2 F}{\partial x^2}\frac{\partial^2 \eta}{\partial y^2} - 2\,\frac{\partial^2 F}{\partial x\,\partial y}\frac{\partial^2 \eta}{\partial x\,\partial y}\right)\ldots(29)$$

which depends not only on the external compression force, but also on the deformations. It is the extreme complexity of Eq. 29 which is the reason that a solution, so far, has been obtained for circular plates, only. In other words, once the critical stress is exceeded, the plate assumes a new state of equilibrium, which is governed by factors greatly different from those which determine the Bryan load. Eq. 20 does not hold for this state of equilibrium, because, in this state, the stress s is not uniaxial and constant throughout the flange.

An analytical investigation[38] of the stresses above the critical, by means of approximate strain energy methods, not only shows the stress distribution to be exactly of the type of Fig. 12; it also indicates that, contrary to the assumption made by Messrs. Maugh and Legatski, the stress in the center is not constant and equal to the Bryan stress. For very wide and thin plates (as Professor Timoshenko has shown[39]), the center strip of an edge-compressed plate is subject to tension, rather than to the Bryan compression stress. The same result, in a rigorous manner, was obtained by Messrs. Friedrichs and Stoker for a circular plate.[9]

To summarize: The writer did not maintain, as is stated by Messrs. Maugh and Legatski, that the center strip is free of stress. This is evident from Fig. 12, whose validity is borne out by the contributors' own strain measurements (for which the writer is grateful indeed as collateral evidence). However, he does maintain that the stress at the center strip is not constant and equal to the Bryan stress, which is again confirmed by the contributors' own stress measurements (Fig. 18(a)). These show a decrease of the center stress by about 40% of its maximum value with increasing loads, even at a b/t-ratio as moderate as 98.

In view of the theoretical complexity of the problem, the writer pursued a frankly semi-empirical method. Messrs. Maugh and Legatski propose instead

[36] "Encyklopaedie der Mathematischen Wissenschaften," Vol. IV/4, 1910, p. 349.

[37] "Theory of Elastic Stability," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York and London, 1st Ed., 1936, p. 323.

[38] *Ibid.*, pp. 390–395.

[39] *Ibid.*, p. 395, Fig. 207.

a semi-analytical approach, based on a number of arbitrary assumptions, one of which is discussed herein (that is, center-strip stress equals Bryan stress). Another such assumption is that of taking the proportional limit as five eighths of the yield point, which was apparently necessary to make the equations fit the Schuman and Back results. Even for steels, the so-called "proportional limit," is a completely fictitious quantity, whose value depends primarily on the investigator and his instrumentation.[40] In sharply yielding steels, in addition, the error introduced by equating the proportional limit to the yield point is almost always negligible as compared with inevitable errors, due to other unknown but important factors (edge restraint, initial distortion, etc.).

In their method, Messrs. Maugh and Legatski like the writer, introduce an effective width, b_e, relating it, however, only to the part of the stress in excess of the supposedly constant critical stress. Their final answer is given in terms of a mean stress, s_u, related to the entire unreduced flange area.

For designing members in uniform compression, it may be irrelevant whether the actual stress distribution, Fig. 12, is replaced by a uniform mean stress, or by the writer's equivalent width, related to the maximum stress.

For designing members in flexure or eccentric compression, however, it is necessary to determine the actual maximum edge strain; because it is that strain which governs the location of the neutral axis, without which stresses

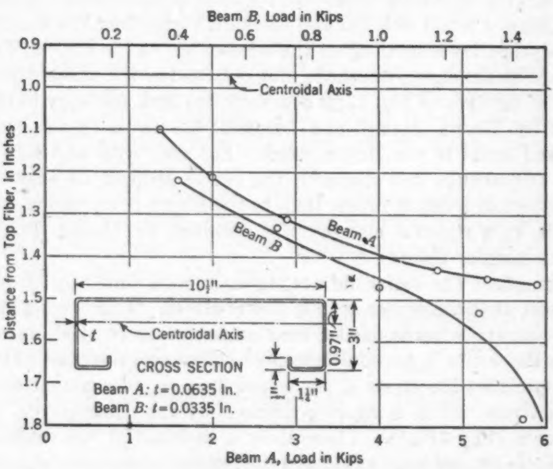

FIG. 22

cannot be computed. The writer's method allows this determination, the contributors' does not. The latter, therefore, would determine flange stresses by the ordinary flexure formula, using the centroidal axis. How far the actual neutral axis, as determined by strain measurements, can deviate from the

[40] "Stress, Strain and Structural Damage," by H. F. Moore, *Bulletin No. 10*, Univ. of Illinois, Urbana, Vol. 37, 1939, pp. 17–18.

centroid is shown in Fig. 22. The results there given were obtained on two beams of practically identical over-all dimension, but with different sheet thicknesses. The error that would result in using the centroidal axis instead of the actual neutral axis for design computations is evident from the figure.

This situation is implicitly conceded by Messrs. Maugh and Legatski in their statement that, for deflection computations, an equivalent width must be used. For reasons not indicated this width, for deflection computations, is different from the width used implicitly by the contributors for stress computations, as given in Eq. 23. Effective widths, locations of neutral axes, and deflections are interrelated purely geometrically, inasmuch as they are all functions of the magnitudes of the extreme fiber strains. If an effective width approach is necessary for determining deflections (that is, neutral axes), it is physically contradictory to maintain, on the other hand, that stresses can be computed from unreduced widths. This is tantamount to stating that a beam has two neutral axes—one, referred to the unreduced section, governing stresses, and another, referred to the reduced section, governing deflections. In the writer's proposed method, the same approach applies to both stress and deflection determinations.

Parenthetically, the contributors' method (computing deflections by (*a*) using an unreduced moment of inertia to find part of the deflection, (*b*) computing a critical stress, and (*c*) determining a second, reduced moment of inertia for finding the additional deflection) is certainly more cumbersome than that proposed in the paper. It results, qualitatively, in the same behavior as that found by the writer; that is, the effective moment of inertia (in the contributors' case, the weighted mean between the full and the reduced one) decreases with increasing b/t and increasing stress. It is rather doubtful, however, whether the arbitrary effective width of $40\,t$ for the reduced moment of inertia, given without justification or empirical verification, leads to reasonably accurate results. For the wider flanges (as used in many commercial decks with high b/t) where the critical stress is very low, the use of $40\,t$ will be found to lead to erroneous results on the conservative (uneconomical) side in determining deflections at design loads—that is, at stresses of from 10 to 20 kips per sq in. (For such conditions effective widths in this investigation were found to be of the order of $60\,t$ to $80\,t$ as compared with the contributors' $40\,t$.)

With regard to the contributors' criticism of test methods, the writer will agree to the extent only that (1) strain measurements on light-gage sections are plagued by various disturbing influences not present in more solid members; and (2) that it is always possible to think of other methods of instrumentation that could have been used. With regard to the latter, however, the time element is an important consideration. In this investigation, it was necessary to cover a very wide range of dimensions, which can be done on a large number of specimens, only. The investigator is limited, therefore, to such measurements as will furnish the most pertinent data. This, it is believed, was achieved by the methods selected. The collateral, confirmatory evidence provided by Messrs. Maugh and Legatski, by different test methods, is therefore doubly welcome.

The contributors' statement that twist and lateral deflection may have distorted the measurements, can be discounted, except for possible microscopic effects. Beams of the shape of Fig. 3 have no tendency toward lateral deflection, particularly if loaded through rollers with axes perpendicular to the axis of the specimen. In fact, to deflect laterally, they would have to overcome the contact friction at the load points. Not only can it be shown by computation from known friction coefficients that this is impossible, but any such sliding motion would immediately manifest itself by a scraping sound, as the writer observed frequently in tests of an entirely different nature. Twist, on the other hand, was prevented by a loading arrangement, which forced the beam into parallel vertical displacement. It is evident that effects of the magnitude of those of Fig. 22, consistently obtained on a great number of specimens, cannot be ascribed to details of instrumentation. Finally, the problem of the linearity of strain distribution in such specimens, even if it were open to question, appears to be irrelevant. The location of the neutral axis, as used in the proposed methods, is merely a means to determine, in design computations, the relative magnitude of the top and bottom strains. Since these strains were measured directly, even a curvilinear transition would not affect the results of such design computations. In addition, however, no reason for a curvilinear strain distribution is given by the contributors; nor is any apparent to the writer, particularly since strain measurements were made in the center part of the quarter-point loaded beams, that is, in a region of pure bending.

Two of the contributions (Messrs. Lewis and Gunder's, and Mr. Karol's) do not question the findings of this investigation, but concern themselves mainly with the mathematical form of Eqs. 6 and 7. Formulas such as these are developed with due consideration to simplicity of application. In this particular case, it was imperative, for simplification of design, to delimit a range of b/t, for which the full width can be used (up to $b/t = 25$). Although, theoretically, the establishment of such a definite limit is questionable, it is completely justified practically. This is why seemingly elaborate mathematical expressions had to be chosen, which result in $b_e = b$ for this limit, independently of the stress. The mathematical complexity of the formulas is relatively irrelevant, since designers will work from graphs such as Fig. 7, rather than from equations. In addition, Mr. Karol's Eq. 13, which involves a hyperbolic function, for that reason, will not be found very convenient by most designers.

Mr. Karol's cautioning remark regarding the use of the writer's chart (Fig. 7) for materials other than steel is to the point, and should be considered in such applications.

The writer gladly accepts Messrs. Lewis and Gunder's justified criticism of the statistical method used in this paper. It is quite true that more sensitive devices, such as standard deviations, should be used in determining the accuracy of fit of empirical formulas.

The writer appreciates the painstaking work of Messrs. Lewis and Gunder in replotting Fig. 2. He does not believe that Eq. 18 should be used practically, despite its simplicity. On the one hand, as the contributors state, goodness of fit of Eq. 18 within the tested range is not as satisfactory as that of Eqs. 6

and 7. Also, tests conducted since the publication of the paper showed Eq. 6 to be applicable satisfactorily for values of b/t up to 400 and more (see con tribution by Messrs. Brown and Wolford). In this range of high b/t, Eq. 18 would err on the conservative side up to about 25%. On the other hand, Eq. 19 is identical in structure with Eq. 6, except for minor differences in the constants, and, as stated by the contributors, is not significantly better. The writer is grateful for the fact, established by Messrs. Lewis and Gunder, that, despite his somewhat cursory methods of curve fitting, he apparently managed to arrive at expressions which are as accurate as those developed by more sensitive statistical means.

Professor Johnston furnishes interesting additional material on flanges stiffened along one edge, by reference to his and Professor Cheney's earlier tests on wide flange sections.

The failure criterion used by Messrs. Johnston and Cheney differs from the writer's in that they noted merely the ultimate loads, whereas the writer considered also the stress at which local wrinkling was first noted. Therefore, Professor Johnston's results should be compared with the values of the ultimate stress, s_u in Table 4. In the range of b/t, common to both investigations (that is, up to about 21), it is seen from Table 4 that the writer obtained ultimate stresses of 0.8 to 0.9 of the yield point, with very few exceptions. This is in general agreement with Professor Johnston's findings of a 90% yield-point strength. The somewhat lower values obtained by the writer on thin gage specimens are probably due (*a*) to greater edge restraint in the H-sections, as noted by Professor Johnston, and (*b*) to the better forming accuracy of the milled H-beam flanges, as compared with cold formed sheet steel elements. The writer's colleague, Professor Cheney, volunteered the information that in many of the tests cited by Professor Johnston, development of slight waves and kinks was noticed at loads below the ultimate, which is in agreement with the findings of this investigation.

The writer wishes to thank the American Rolling Mill Company for releasing for publication the test data given in Messrs. Brown and Wolford's contribution. These data furnish important, supplementary evidence, since the b/t-ratios of these specimens, 242 to 429, are far beyond the range of those discussed in the paper. The test results given in Table 6, as well as conclusions by Messrs. Brown and Wolford, confirming the validity of the proposed method in this high range of b/t, speak for themselves. It is seen that the determinations made on the basis of Eq. 6, if compared with test results, are slightly on the conservative side, both for deflection and for strength. The deviations are small and within the range of discrepancy observed in most structural testing, but they point to one factor that should be emphasized in closing.

The behavior of thin compression flanges is naturally influenced by the amount of rotational edge fixity provided by adjoining elements, such as the webs in Fig. 3. A reasonably simple design method cannot be expected to take explicit account of this involved factor, particularly since, in the great number of tests, its numerical effect was found to be small. The amount of restraint

provided in the very wide flanges by the shallow webs of Messrs. Brown and Wolford's specimens is rather large, as compared with a number of other beams in this investigation, with a consequent strengthening effect reflected in the test results.

The proposed methods, therefore, merely claim to represent average conditions of restraint. However, it is important to note that, despite a great variety of conditions of support and restraint obtained in these tests, deviations computed from observed results were within narrow limits, acceptable in practical work.

Paper No. 2306

FACTORS CONTROLLING THE LOCATION OF VARIOUS TYPES OF INDUSTRY

By Charles P. Wood,[1] Esq.

With Discussion by Messrs. Harold M. Lewis, R. F. Goudey, and Charles P. Wood.

Synopsis

Any discussion of factors controlling the location of industry must take into account new and potent influences, resulting from World War II, which have disrupted a normal way of life and have changed the scope of future industrial activities. Revolutionary improvements in methods and equipment will be the constructive results of research and manufacturing experience growing out of the war effort. New reservoirs of labor and new potential manufacturing areas have been created by the development of war industries remote from established industrial centers. A reorganized distribution system, already geared up to export tremendous quantities of material from all parts of the United States through both Pacific and Atlantic ports, will facilitate decentralized and diversified industrial operations.

New opportunities, improved processes, and other causes of progress are familiar experiences in the American business and manufacturing field. The period from 1914 to 1940 seemed at one time to include a cycle of war and depression and recovery. The greatest war in history promptly followed, and resources and markets, once thought to be assured for the future, are no longer to be taken for granted. Factors that affect the location of industry are subject to changeable influences.

The Prospect of Changed Conditions

The rearrangement of the industrial pattern in the United States has been predicted from time to time without sufficient allowance for practical considerations. In defining the elements that have most to do with the location of industries, care must be taken to avoid categorical statements. The younger generation of engineers should study the history and economics of industries,

Note.—Published in March, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Industrial Engr., Lockwood Greene, Engrs., Inc., New York, N. Y.

as well as the technical theories, to guard against the mistakes of their predecessors.

Too many industrial plans are still dependent on the same way of life that was in effect during the past generation. The most important changes affect markets, transportation, labor, and management. Changes in processes and equipment are radical and far reaching, but they will be much easier to make than the changes that depend on providing a new kind of industrial environment for workers and a new system of distribution. Perhaps the greatest difference between the old and the new is the conception of time.

The soldiers, sailors, Wacs, and Waves of World War II will form the dominant element of management and of the working force as well as of the domestic market. Some of them made the trip from India, the Philippines, Japan, and China within two days—the same time their parents were brought up to think would be required to go from New York, N. Y., to Houston, Tex., or from Chicago, Ill., to San Francisco, Calif. This conception of time is affected by other innovations developed during World War II. Short cuts made possible by electronics and radio, seeing in the dark with radar, automatic devices for doing what formerly depended on the human senses and labor, and airborne freight—all these have combined to change much that once made up the requirements which affect the location of industries.

Fundamental Requirements

In spite of all these innovations and improvements, many old difficulties remain unsolved and the factories of the future will require power and labor, transportation facilities, and a supply of materials. Discrimination should be made between the type of enterprise that is tied to rigid requirements and the one that is free to follow the lines of least resistance.

The basic industries, which process raw materials in large bulk, are still confined to locations where transportation of raw materials to the plant and transportation of finished products to the market can be accomplished with greatest economy. Transportation in the broad sense includes power transmission lines, pipe lines for oil and gas, and facilities for assembling labor, as well as freight carriers. The conversion from raw material to the final product generally proceeds in separate steps which may occur at several different locations, depending on the nature of the product and the market to be served.

The Steel Industry

The steel industry offers the best example of integration, because the manufacturing process can be traced from definite sources of raw material to a variety of products without departing from the main channels of commerce and industry. Ore and coking coal for the manufacture of pig iron can be assembled most economically at certain blast furnaces. The larger plants, of course, carry the processes through to the steel ingot and on to the rails, plates, sheets, structural shapes, rods, and wire. Steel plants away from the blast furnaces take advantage of local supplies of scrap and fuel in combination with transportation facilities. Plants must be located to insure economical distribution

of the product, as well as delivery of pig iron from the blast furnace to the open hearth or electric furnace whenever the local supply of scrap is not sufficient.

After steel has been made into rods, wire, plates, sheets, and structural shapes, it is sent to the fabricating plant, whose location depends entirely on the local market or on local resources that make manufacturing most economical. For example, Detroit, Mich., consumes steel for automobiles; New Britain, Conn., steel for hardware, and Newport News, Va., steel for ships. The location of these factories and shipyards is governed by factors different from those that govern the location of the steel plant. In some places conditions are favorable for blast furnaces and steel mills (Fig. 1), as well as for miscel-

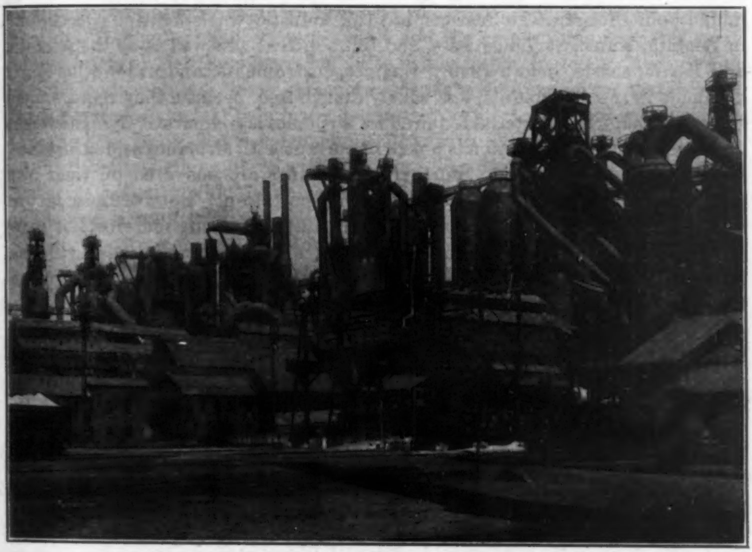

FIG. 1.—"IN SOME PLACES CONDITIONS ARE FAVORABLE FOR BLAST FURNACES"
(General View of Blast Furnaces, Carnegie-Illinois Steel Company)

laneous manufacturers of steel products, including ships—for example, Sparrows Point, Md., where blast furnaces on the coast are supplied with imported ore and domestic fuel. The Great Lakes area, using domestic ore and fuel, offers similar advantages, except that the size of ships built on the lakes is limited by the width and depth of the Welland Canal. Blast furnaces and steel plants operating on the Pacific Coast are handicapped by high transportation cost of fuel, and to a lesser extent that of ore. The scale of operations in peacetime, however, will depend on local markets and the location of bases for freight rates, as well as on transportation costs and competition.

PROCESSING INDUSTRIES

Portland cement, lime, sugar, flour, and coffee roasting offer examples of processes in which transportation again is a controlling influence. Milling-in-

transit rates have served to prevent concentration of such processing industries around the comparatively few inland sources of raw materials or at seaports. The effect of these rates is to make it possible to manufacture the product somewhere between the source of material and the market—the exact location depending on the loss in bulk during the various processes and the best centers of distribution.

The Airplane Industry

The airplane industry grew up on the Pacific Coast very much as the automobile industry did in Detroit—that is, through the ability and enterprise of local individuals. The war accelerated the manufacture of airplanes at inland points for strategic reasons, but this industry was operating successfully in Wichita, Kans., St. Louis, Mo., and Buffalo, N. Y., as well as on the Atlantic and Pacific coasts, before 1940. Engines, instruments, and some other parts are made in separate plants, less widely distributed, because they require more skilled mechanics. Material required for airplanes is comparatively lightweight and the cost of transportation is not so important with airplanes as, for instance, with the heavy machinery. Furthermore, planes are delivered on their own power independently of existing surface transportation. Both of these factors tend to make the location of airplane manufacturing plants more or less independent of the sources of material and of surface transportation. Nevertheless, progressive management is probably the main reason why airplane manufacturers have broken away from traditional limitations.

The airplane industry developed its own force of skilled labor more effectively than did other industries which followed one another into districts where a supply of skilled labor was known to exist. Most of the workers in airplane factories are young men and women who have become sufficiently skilled without going through a long apprenticeship. Even airplane engine factories, where a nucleus of highly skilled mechanics is required, were operated in wartime at places where few comparable precision operations had been performed before. The industry deserves the distinction of leading the way to decentralization of manufacturing by a combination of boldness and ability which is characteristic of the younger element in management.

Miscellaneous Small Industries

Miscellaneous machinery manufacturing may follow the example of the airplane industry to a certain extent, and may show a preference for locations that serve the market although retaining other essential advantages, such as a supply of skilled mechanics. Again, improved transportation is a factor and skilled labor will find it easy to follow opportunities for employment and better living conditions. This discussion should include also industries which are composed of small units, comprising a large number of individual plants with a large combined volume of products and a large number of employees. In a plan for the industrial development of a district, these smaller, diversified industries become more important than the industries characterized by large and impressive individual plants. Manufacturers of garments and textile specialties—shoes, radio, electrical appliances, styled products, and novelties—

are dependent primarily on labor, markets, and distribution. The cost of transporting raw materials and the cost of power (which are vital to the success of some industries) are not among the most important factors in these industries. Studies to determine the location of some of the comparatively small plants are more difficult than corresponding studies in which a few large items clearly determine the most important considerations. In these smaller plants, involving smaller expenditures for each of a larger number of items, every slight advantage has to be considered, because success or failure may depend on any one of a number of slight advantages over competitors.

The Textile Industry

The textile industry came to New England from England because management and mechanical skill were available and the climate was supposed to be suitable. However, the effect of climate has been eliminated by humidifying and air conditioning systems, which are standard equipment for textile mills. In the Southeast the textile industry began to take advantage of lower operating costs, and the Southeast became competitive with New England as New England had become competitive with Europe. The cost of labor is important in the textile industry which is one of the industries that can train skilled operators within a comparatively short time. Therefore, locations where labor is plentiful, with a consequently low cost, are sought. The Southeast offered a supply of good textile labor at comparatively low wages, with other conditions favorable to the industry; and so cotton mills migrated from New England to the South, causing southern mills to constitute the greater part of the cotton textile industry. When these mills were built, wages were extremely low in the South and the regulation of working hours was comparatively lax or liberal. The costs of power, construction, food, and shelter also were low. Since the adoption of uniform national laws governing wages and working hours, southern mills no longer enjoy a competitive position based primarily on low wages and long hours. The better mills do not depend on these differentials, because good management and productive labor can overcome them. Uniform wage-and-hour laws have put the textile industry on a different basis with respect to location. In fact, markets and distribution facilities should be more important factors in the location of textile mills.

The textile industry is comparable to the steel industry with respect to the relationship between manufacturing yarns and fabrics in the basic plants and to the distribution of these materials throughout a wide variety of manufacturing operations, whose locations are controlled by influences different from those which affect the basic plants. For example, cotton mills convert raw cotton into yarn. Some mills make a variety of yarn to be shipped to plants that weave specialities in comparatively small quantities. The larger mills, making large quantities of standardized products, combine weaving with spinning in a completely balanced plant. After the fabrics have been woven, they are finished in bleaching, dyeing, and printing plants which are generally separate from the mill. The products of these finishing plants are distributed to the garment makers and miscellaneous fabricators and consumers. The manufacture of rayon yarn is a chemical operation with locational requirements

different from the requirements of weaving plants. Rayon yarn is made in comparatively large plants and rayon weaving is widely distributed. Both rayon and wool manufacturing fall into the same general divisions as cotton—namely, yarn manufacturing, weaving, finishing, and the conversion of finished fabrics into marketable products.

Textile yarn manufacturing requires power and labor at competitive rates, together with large manufacturing sites in localities where conditions contribute to reasonable living expenses. Weaving plants have the same requirements for power and labor at competitive rates, especially in the larger units, but their requirements are more flexible. Textile finishing plants require large supplies of soft water and good transportation facilities from the mills and to the market—thus they are found in, or accessible to, distribution centers. The final products are made in plants of various sizes generally situated where they serve the market to best advantage. This accounts for the concentration of needle trades in the large cities, especially New York, which is the largest market for textile products.

Shoes, Radio, and Appliances

The shoe industry, which began in New England and later expanded westward, enjoys more freedom than the textile industry in the choice of plant location, because it consists in the main of smaller units. It is another major manufacturing industry in which plant location will be influenced, by markets and distribution facilities, in the future more than it has been in the past.

Manufactures of radios, household appliances, and numerous other attachments for the convenience and amusement of the individual provide a variety of employment for labor released by war industries and by the Army and Navy, irrespective of manufacturing locations. This condition should have a stimulating effect on the creation of new enterprises and on employment in areas not formerly considered active in the industrial field.

Statistical References

The "Census of Manufactures"[2] includes statistics from which industries can be classified according to their requirements for labor, fuel, and power. More than four hundred classes of industry are listed including the sum spent for wages, fuel, and power; the number of male and female employees; and the value added by manufacture in each class. Another convenient reference is "Industrial Location and National Resources."[3]

Statistics from the census can be used to compute the number of wage earners, the wages paid, and the cost of fuel and power per unit of value added by manufacture. A study of these results will show which industries employ the largest number of workers, pay the highest wages, or spend the most for fuel and power on the basis of value added by manufacture. It may be assumed that these industries will seek locations where labor, fuel, and power are available on the most economical basis. Intelligent inspection of the

[2] "Census of Manufactures," U. S. Dept. of Commerce, Washington, D. C.

[3] "Industrial Location and National Resources," National Resources Planning Board, U. S. Govt. Printing Office, Washington, D. C., 1943.

industries so segregated should eliminate cases for which statistical results are not confirmed by practical requirements. Further study of these computations will show certain coincidences. Two or three of these elements—for example, wages paid, number of employees, and cost of fuel and power—may combine to indicate preferences for locations having corresponding advantages.

When the number of wage earners alone is relatively high and the wages paid do not exceed the average, it may be assumed that the industry is not especially dependent on highly paid or skilled labor. Where the reverse is true and the wages paid are comparatively high although the number of employees is comparatively low, the industry probably requires skilled or high-priced labor.

The cost of fuel and the cost of electric power should be combined for general classifications because the census does not go into sufficient detail to discriminate between industries that generate all or part of their power and others in which the processes or local conditions make purchased power more economical. Generally, power is cheap where fuel is cheap, and so the combined expenditure for power and fuel is an index to the advantages of locations where these two items are available at a low cost.

The census also shows the number of male and female employees in various classes of industry. Selecting those industries in which more than 50% of the employees are female and then comparing the list with others showing comparatively large numbers of employees, or comparatively large sums paid for wages, will lead to interesting conclusions on the characteristics of employment in existing industries. These conclusions, considered in connection with the local population and labor supply, should serve as a basis for determining which industries are most desirable in a community.

Application of Fundamental Requirements

Familiar examples can be cited to confirm conclusions from these census studies. Products of mass production and products in which the value of material is relatively high do not appear in the list showing large numbers of employees and high costs of fuel and power per unit of value added by manufacture. Automobiles, airplanes, precision machinery, and jewelry are industries comparatively free from other restrictions on location but dependent on a supply of skilled labor. Woodworking, canning, food products, soap, and cheap novelties are industries requiring a comparatively high number of employees. Boatbuilding, railway car building, styled clothing, foundries, leather, and musical instruments are industries with comparatively high wages. Some of the industries in which both the number of employees and the wages paid are comparatively high are buttons, textiles, clothing, drugs, and medicines.

A comparatively high cost of fuel and power is indicated for the manufacture of electrochemical and electrometallurgical products, ceramic products, steel products, refined sugar, chemicals, vegetable oils, textile finishing, paper, and ice. The last item is included to illustrate an exception. The location of an ice plant is determined more by accessibility to the market, on account of expensive handling and loss during shipment, than by the availability of cheap power.

Ceramic and leather products are the most important industries showing a combination of heavy pay rolls and high cost of fuel and power per unit of value added by manufacture. The combination of a comparatively large number of wage earners with a heavy pay roll and high cost of fuel and power is characteristic of the textile industry. The foregoing examples can be multiplied by increasing the scope of the study, but these few will suffice to show the wide variety of industrial activities that share the same fundamental requirements with respect to power, fuel, and labor.

Transportation is a primary requirement for nearly every industry, whether involving raw materials, finished products, communications, or means for taking employees back and forth to work. Transportation costs include, besides the usual freight and passenger charges, the costs of time consumed and of damage to perishable or fragile products, such as ice. The time element, during the nonproductive transportation period, affects the amount of working capital tied up by work in process and by materials and products in transit. Transportation facilities, however, are not limited to railroads, automobiles, airplanes, or other locomotive appliances. They include parking space, landing fields, shelter for passengers, and shipping and receiving facilities. Limited accommodations for parking and poor transportation equipment between passenger terminals and factories are marks of obsolescence that apply to many of the older plants.

Influence of Climate

The effect of climate on the location of industry is often the converse of what might be expected. The most highly developed industrial districts are in the more severe climates, when it might be expected that temperate climates would have attracted population and provided economical conditions under which industry would prosper more than in places subject to severe weather. The conclusion is that life in severe climates makes people more adaptable to industrial work than they would be if they lived in mild or warm climates, which are particularly favorable to agriculture. There are many exceptions to this rule and the influence of fuel and mineral deposits is recognized. Still, the volume and variety of manufacturing in Scandinavia, Northern Europe, New England, and the Great Lakes district, not approached in other more temperate or warmer climates, proves that climatic conditions are not controlling factors in the location of manufacturing plants.

Opportunities for Planning

There is an important relation between city planning and factors controlling the location of various types of industry. By city planning, desirable local conditions can be created where they might not exist otherwise.

The activities leading to the adoption of a city plan, as well as the execution of the plan itself, should have a wholesome effect on industrial prospects. Major considerations, such as power, freight rates, availability of materials and accessibility of markets, wage scales, supply of labor, and even housing and living conditions, may balance about equally when comparing several desirable

places. The advantages of one over the other will then depend upon plant sites, local laws and taxes, local utilities, amusements, and local transportation —to mention only a few of many possible items that are susceptible of intelligent treatment in a comprehensive plan.

Industrial districts can be laid out with railroad sidings and highways arranged so that factory sites of various sizes can be accommodated and so that the individual plants are relieved from building long spur tracks and paved roads, water, gas, and sewerage lines, and electric power lines to connect with the nearest existing system.

It is a mistake to select industrial locations where the cost of land might restrict the size of the site. Room is needed for parking space, future expansion, protection against hazardous storage, and for other reasons which may develop long after the site has been chosen. For example, helicopter landings, as yet unusual, promise to become typical features of future industrial sites. The principal reasons for the use of sites that are too small are high unit cost of land and prohibitive cost of providing transportation and utilities at other sites. City planning can eliminate these major difficulties by the proper location and development of industrial districts, as well as by proper zoning of land conveniently situated for industrial and commercial use.

The disposal of waste from industrial processes has been neglected in the past but such neglect is no longer permissible. There are few sites, however isolated, where it is legitimate to allow an industry to dump offensive waste. It is much better to face the problem wherever new plants are built than to evade it in the hope that somebody else will do something about it later. The pollution of streams and bathing beaches and the contamination of water supplies have created serious problems wherever provision has not been made for the treatment or disposal of objectionable waste. At the same time, regulations which are too stringent cause the industries concerned to favor locations where the cost of compliance will be more reasonable. Therefore, it is no service to a community to formulate restrictions or to enforce penalties which discourage desirable development. Neither is it any service to an industry to allow it to become a nuisance and then to prosecute it for an offense which could have been avoided.

Fair taxation should be inherent in any plan for the most desirable as well as the most profitable use of land. Industries may seek locations outside city limits primarily to avoid city taxes but, at the same time, they get more land without paying too much for the plant site. It should pay the city to let industry have plenty of room. The city's income is not necessarily reduced, in such cases, by an amount corresponding with what the industries could have been taxed if within the city limits. The city gets its income indirectly, because wages paid by the industry are spent in the city and support the expansion of retail business and services, the construction of homes, and the consumption of goods sold within the city. Sound economics would prescribe locations outside the city limits for industries needing large sites or room for expansion, so the city eventually would get the benefit of increased expenditures for wages and materials.

There is a large and important class of industries which seek locations within the city limits. Such industries show a preference for the congested districts accessible to concentrated labor reservoirs, markets, and services, and so they provide tenants for loft buildings, warehouses, and buildings specially constructed to accommodate small manufacturing tenants. Some of these industries continue to be comparatively small, although others expand later and seek larger sites and more commodious facilities in outlying areas.

The so-called incubator building, or manufacturing loft building, is a favorite subject for discussion in this connection. Experience has proved that such buildings are important assets to communities when they are built correctly and in the right location. Failures may be caused by spending too much on these buildings as well as by poor building design and construction and by improper location. It should be assumed that the tenant wants only the essentials for manufacturing convenience and comfort of employees. These loft buildings should be designed with liberal floor loads, with flexible systems of power, water, steam, and gas connections, and with provision for ample entrances and exits and for compliance with insurance regulations. The wiring, piping, and ventilating systems should have a capacity sufficient for air conditioning equipment, which can be installed later as needed. Railroad sidings and shipping platforms for cars and trucks, protected from the weather and served by conveniently placed elevators, are other important requirements. City planning, making it possible to find desirable sites for these buildings and access to them without blocking traffic in adjacent streets, will create inducements for important new industries. More than that: It will improve the appearance and the convenience of the city and increase the value of central property.

Summary

The location of industrial plants is subject to new influences resulting from World War II.

Certain fundamental requirements, including the supply of materials, labor, power, fuel, and transportation, retain their relative importance.

A trend toward decentralization is apparent in the effort to relieve congestion, to serve new and expanding markets, and to utilize new reservoirs of labor and improved transportation facilities.

Local and regional planning should provide for improved and economical sites for both large and small industries.

DISCUSSION

Harold M. Lewis,[4] M. ASCE.—The part of the civil engineer in the location of industry has been, primarily: Supplying some of the accessories to a successful site, such as transportation facilities; laying out site utilities, such as water supply, drainage, streets, and terminals; and designing foundations and other structural elements of the plant itself. The fact that this paper was presented at a joint meeting of the City Planning Division of the American Society of Civil Engineers and the American Institute of Planners indicates that civil engineers are taking an active interest in some of the broader phases of the problem. Instead of simply having an industrial site handed to them, they should play an increasing rôle in helping their clients determine where that site should be.

Mr. Wood has indicated that the location of industry has followed certain laws based on accessibility to raw materials, convenience for manufacturing (power and labor), and accessibility to markets. These essentially physical factors are being supplemented by what might be called social and psychological factors. Sites which might not have been considered under the old standards may become desirable because the workers (labor) find the locality a pleasant place to live in and one which affords higher standards of housing, health, recreation, and education. The owners and executives (business) may find that better municipal government and sound city planning provide savings which more than counterbalance some disadvantages in accessibility of raw materials, power, and markets. In other words, a community that is well planned and administered as a result of good city and regional planning may find certain industries coming to it primarily because of those characteristics.

There will always be certain industries that are naturally better adapted to central urban areas, others that tend to gravitate to suburban areas adjoining large cities, and still others that require enough space and employ a sufficient variety of workers to enable them to go out into new areas and establish communities of their own. The economic and industrial survey undertaken by the Committee on a Regional Plan of New York and Its Environs,[5] classifying the industries in the region along these lines, was a pioneer study of its kind.

In the first, or urban, group were those small-scale industries with a seasonal labor force and therefore a high turnover of employees, or in which the time factor in contacting the consumer or purchaser was important. The group included certain types of men's and women's clothing, high-grade jewelry, photo-engraving, job printing, cosmetics, and perishable foods. In the second, or surburban, group were many of the heavy metals and chemical industries, refineries, printing of periodicals, bookbinding, textile finishing, lumber mills, and women's underwear. In the third group the writer would place large-

[5] "Major Economic Factors in Metropolitan Growth and Arrangement," Regional Survey of New York and Its Environs, Vol. I, 1927, pp. 19–30 and 104–107.

scale munitions manufacture, mining, and the assembly and testing of airplanes. Among the cities that have been built up, or greatly expanded, as a result of the establishment of new industries on new sites are: The mining cities of the west such as Leadville, Colo.; the steel cities such as Gary, Ind.; the automobile cities such as River Rouge, Mich.; the rubber cities such as Akron, Ohio; and the iron and steel cities such as Birmingham, Ala.

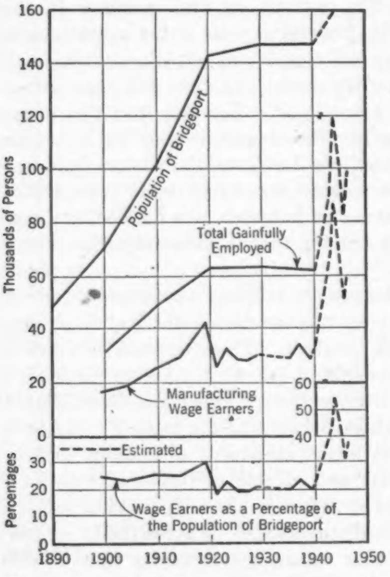

FIG. 2—COMPARATIVE TRENDS IN POPULATION AND WAGE EARNERS IN BRIDGEPORT, CONN., 1899–1946

Mr. Wood referred to the present postwar readjustment period. The writer recently had occasion to study industrial trends in Bridgeport, Conn.—a fairly typical manufacturing center in the 100,000 to 500,000 population range. Like many other cities, it is going through such a period; but, again like many other cities, it had a somewhat similar experience following World War I. The curves in Fig. 2 indicate the similarity and the differences in these two experiences. The manufacturing boom of World War I showed a peak in 1919 in the number of manufacturing wage earners. Then came a sudden drop, with relatively minor changes up to 1939. During the succeeding four years, all four curves showed second wartime jumps, the outstanding feature being the increase in the total number gainfully employed from 62,266 in 1940 to a peak of 119,500 in the fall of 1943, paralleled by similar increases in the number of manufacturing wage earners. The inevitable downward trend came in 1944, but the City of Bridgeport had anticipated this trend. Through its city administration, the Chamber of Commerce, and a representative planning council organized by the Chamber of Commerce in 1943, the problems of both the city and region of which Bridgeport forms a center had been attacked by eleven committees. It was found that, although the city area affords few sites for new large-scale industries, there are ample sites for both industry and port development within the region. These were mapped; their relative advantages and disadvantages were analyzed; and harbor improvements to make them more accessible were proposed.

It is expected that, whereas postwar trends will result in more production per employee, new manufacturing buildings will provide greater floor area per worker, more light and air within the buildings, and more open ground about them. The open space should be used to provide both automobile parking and recreation facilities for employees.

In 1946 a recovery from the low point of 1945 had already occurred and the Bridgeport Chamber of Commerce stated:

"With the experience of World War I to look back on the industrial leaders and business men anticipated a mass exodus of the huge tide of in-migrant workers that flooded this area to reap the harvest of high war-time wages. This exodus did not take place, only a trickle left. * * * With the easing of parts, supplies and raw materials, Bridgeport is looking forward to its greatest peace-time production records."

In this case, advance planning seems likely to stabilize employment at a level considerably above that of the prewar period.

R. F. GOUDEY,[6] M. ASCE.—That industries should be located on the basis of sound engineering evaluations of source of raw materials, availability of labor, location of markets, transportation facilities, and availability of power has been emphasized by Mr. Wood. Rarely are such studies made and it is more common to have industries located by representatives of a local chamber of commerce and by public officials not familiar with the critical problems involved.

In too many instances, industries locate in new territory through decisions based largely on misinformation and even ignorance. Usually when an eastern industry is about to move westward, someone in its organization who is ready for a vacation takes a trip west to make a casual survey; or a written inquiry is forwarded to a local chamber of commerce or a business division of a power utility. In one large metropolitan area, the representative of a prospective industry, if routed through chamber of commerce channels, might have to meet fourteen public officials of the municipality before obtaining correct information on such items as taxes, cost of water, facilities for sewage and waste disposal, power cost, housing facilities, and availability of labor.

On the other hand, if the inquirer entered the area through contact with a large private power utility, he might be induced to locate in the county area instead of the city, in which case he would have to interview twelve or more county officials to obtain information on the points involved in the selection of a new site. In any event, he is kept ignorant of the advantages which other near-by areas might have over the one he first investigated. In many cases the preliminary stages have been passed and a final decision has been made to locate the plant at a given place when, for the first time, engineers for the industry learn that the quality of water is not satisfactory for their purposes, or that they are unable to dispose of liquid waste without polluting the underground water supply, or that the cost of water as indicated by the metered rate schedule did not disclose that there was an additional district tax of 50¢ per $1,000 valuation, or that adequate protection from floods could not be obtained except at exorbitant cost. Such information was not obtained in the preliminary stages because there was no proper coordination of engineering information from the different departments involved in the problem.

Cheap water is essential for cooling water, heat exchange purposes, processing, and fire protection for rayon plants, rubber products plants, woolen mills, paper pulp plants, and tanneries. In cities where domestic water must be

[6] San. Engr., Dept. of Water and Power, Los Angeles, Calif.

imported from long distances, it may be desirable to reclaim sewage for a cheap water supply of ample volume to serve plants having large water requirements. Interesting instances where sewage has been conserved for commercial purposes are as follows:

1. El Tovar, Grand Canyon, Arizona, has reclaimed sewage for boiler, toilet flushing, and engine use since 1925;

2. The Bethlehem Steel Company at Baltimore, Md., uses treated city sewage for cooling water;

3. The Barnsdall Oil Company at Corpus Christi, Tex., uses reclaimed sewage for cooling purposes;

4. The Shell Oil Company at Signal Hill, Calif., at one time used all the treated Signal Hill sewage for industrial purposes;

5. The Kaiser Steel Mill at Fontana, Calif., re-uses all its wastes so that there is little actual waste;

6. In Pasadena, Calif., treated sewage is discharged into the Rio Hondo and is the only supply for certain irrigation ditches in the Riviera District; and

7. In Fresno, Calif., sewage is discharged into aquifers from which irrigation water is developed.

These cases show clearly that, where the original cost of water is high or where it must be transported long distances or be developed at a high cost, reclamation is not only practical but economical.

Many industries attempt to relocate because of trouble experienced with the matter of waste disposal at their old location. Industries have a habit of trying to make little of their waste disposal problems and so make it difficult for consulting engineers to advise them as to a proper location. Although many industries have spent considerable sums in attending to their liquid waste problems, the amount spent by communities has been much greater. There has been considerable duplication of expense. Therefore, these matters should be given consideration during the period when the original location of industries is being considered. In California, the following experience with industrial waste has been particularly troublesome:

(a) In twenty cities there has been trouble with peach waste where lye wastes, spread on the land, resulted in mineral pollution of ground waters;

(b) Fourteen cities have had trouble with tomato waste in which lye waste has been discharged on to the land;

(c) Fourteen cities have had trouble with salt and lye waste from olive packing plants and these wastes have been placed in underground water supplies;

(d) Twelve cities have had trouble with creamery waste, particularly where whey was involved;

(e) Six cities have had trouble with packing pimientos and strong alkali waste with garbage has been placed on to the land;

(f) Five cities have had trouble with slaughterhouse wastes and have had to install grease removal facilities;

(g) Five cities have had difficulty with refineries and separate disposal was necessitated;

(*h*) Five cities have had trouble with winery waste which is now disposed of by land;

(*i*) Four cities have had problems with sugar plant waste, two having put in separate systems and two having ceased operation; and

(*j*) Three cities have had trouble with fish waste and in all instances special works have had to be installed.

The following are typical of the many special problems involved in practically every type of industry:

Anaheim, Calif.—The United States Industrial Alcohol Company discharged molasses waste in the Orange County Outfall Sewer, causing such a terrific production of hydrogen sulfide that the company was forced to disconnect from the sewer and install local treatment works. This situation resulted, however, in pollution of underground water supplies with mineral constituents.

Betteravia, Calif.—Betteravia has its own waste disposal system independent of any municipal system.

Corona, Calif.—The By-Products Exchange Plant at Corona discharged wastes into the Corona Sewer System, resulting in the pollution of several private wells. The company installed a separate system in cooperation with the City of Corona for adequate treatment and proper disposal. There is still some pollution of underground supplies, but no wells so far have been affected.

Guadalupe, Calif.—The creameries in Guadalupe installed a sewer system at their own expense to dispose of the industrial waste without affecting any underground water supplies.

Lemoore, Calif.—The city constructed a biofiltration plant consisting of aeration and with recirculation and a rock filter based on a year's experiment with creamery wastes; but, when the plant was put in operation, it proved to be a complete failure because of the acid lactose splitting organisms which thrived in the aeration tank and its recirculated sludge. Separate disposal had to be provided.

Los Angeles, Calif.—Los Angeles has had trouble with the disposal of alkali, salt brine, chromium, phenol, and solvents which have reached certain strata of local underground water supplies.

Ontario, Calif.—The Citrus By-Products Plant at Ontario installed a separate sewer to seepage beds on land, resulting in the pollution of near-by wells. Suit was brought against the company which was settled outside court; but the city extended City of Ontario water to these water consumers. In the meantime, however, there is continued pollution of the underground water supply.

Santa Ana, Calif.—Two sugar plants of the Hollywood Sugar Company and of the Santa Ana Sugar Company used to have a sewer system carrying the combined wastes to the ocean. These plants discontinued operation for several reasons—one of which was that their sewer facilities were no longer available.

Tulare, Calif.—Tulare built an activated sludge plant with the idea of treating domestic sewage. The chamber of commerce invited a creamery which produced whey waste to Tulare. The volume of waste amounted to 245,000 gal per day and gave an equivalent load of 80,000 people. This demand was

about ten times what the treatment plant could meet and the plant became a complete failure. Separate disposal had to be provided.

Summary.—It is evident that the question of waste disposal should be given far more attention than has been the case in the past. It would greatly assist managers who are considering the problem of relocating industries to deal with a coordinating committee representing all sources of information that management should have in arriving at a final decision as to where industries should finally be located. In some metropolitan areas this committee might require representatives from public and private utilities as well as the heads of city and county departments supplying services to industries. It is strange that large industries appear to avoid the services of consulting engineers in deciding on new locations. The problem is sufficiently involved to warrant such consultation.

CHARLES P. WOOD,[7] ESQ.—Discussion, by amplifying the original paper, has emphasized some features that merit more attention. However, the discussion may be clarified by further definition of the underlying reasons for the location of industries: First, there are entirely new projects in which management is free to choose the best location; second, there are branches of existing industries which serve to increase capacity and to improve distribution facilities without affecting the operations of plants previously built; and, third, there are plants established for the purpose of decentralizing an industry.

Plants in the third class relieve the pressure on the parent plant and also provide the advantages mentioned in the case of branch factories. Distinction should be made between the migration and expansion of industries to take advantage of new opportunities and the decentralization of industries to avoid impairing or exhausting the resources of certain localities.

The New York economic report,[5] mentioned by Mr. Lewis, classifies industries dependent on a metropolitan location and discriminates between them and the industries needing more room than they can find in a great city.

It should be noted that New York (N. Y.) and other large cities are, in effect, industrial incubators for the less thickly populated sections of the United States. Many of the industries that started as small enterprises in the lofty buildings of great cities, which are the only places where they can find suitable rental space and skilled labor, later will expand into their own factories built either in the suburbs or at remote locations.

Reference to employment and industrial activity in Bridgeport, Conn., throughout the period which includes both World War I and World War II, is a good illustration of how planning in advance served to stabilize employment.

Bridgeport is a highly developed manufacturing community with diversified industries and a large, well-housed colony of skilled labor. It is also a convenient distribution point for the great northeastern markets and especially for the New York metropolitan area. For these reasons, it is not comparable with southern or western cities of the same size or larger, which have comparatively few established industries and comparatively small colonies of

[7] Industrial Engr., Lockwood Greene Engrs., Inc., New York, N. Y.

skilled labor. Despite its many advantages, Bridgeport has found it profitable to have its resources studied with a view to revealing opportunities that otherwise might have been neglected. Absence of large sites was not allowed to obscure prospects for the development of smaller sites for industries particularly adaptable to conditions at Bridgeport.

Mr. Goudey's timely comment on the treatment of waste and the reclamation of water directs attention to the increasing importance of the water supply. It is not surprising that this comment should come from the West, where the conservation of water resources is of more consequence than it is in the East. However, the abundance of water east of the Mississippi River is no reason for neglecting the treatment of polluted waste or the conservation of pure water. Polluted streams have become characteristic of industrialized regions, because of lax enforcement or the absence of regulations in the early days of industrial development. Pollution of ground water resulting from spreading industrial waste on the land, also mentioned by Mr. Goudey, shows the necessity for treating dry waste as well as effluents. There are other familiar cases where polluted effluent is collected in pits, whence it gradually seeps into the ground, and where the resultant pollution may not be apparent until there is a need for pure well water in the vicinity.

Reclamation of sewage and other polluted waste water for boiler feed, cooling, and similar purposes will become more important as progress is made with the industrial development of arid sections and as the water supply is depleted elsewhere.

The suggestion that the location or relocation of industries could be facilitated by consulting local coordinating committees fails to take into account that the resulting publicity may nullify the committees' efforts. Competition among industries and localities interested in almost every industrial location prospect makes it necessary to keep the project confidential until a decision has been reached. In such cases, consulting engineers function because they can assemble information impartially without disclosing the identity of their client.

Similarly, the increasing importance of markets as a factor controlling location of industries requires the use of marketing data in appraising the characteristics of an industrial location. In this respect, however, engineers can get assistance from sales and distribution management.

A summary of new plant locations chosen since 1940[8] by six large companies manufacturing different products includes the following observations:

The total number of plants built or locations selected is eighty three, divided thus: Aluminum Company of America, 2; E. I. du Pont de Nemours and Company, 11; General Electric Company, 35; General Motors, 19; Philco, 7; and U. S. Rubber Company, 9. Practically all the new locations are in states already heavily industrialized. Only twenty three are in cities larger than 100,000; the preference for smaller cities and towns being in the ratio of 3 to 1. The division by states, according to the number of plants added since 1940, is as follows:

[8] "Industry Fans Out," *Business Week*, November 23, 1946, p. 31.

New York	13	North Carolina	2
Ohio	12	Tennessee	2
Pennsylvania	8	Virginia	2
Indiana	7	Delaware	1
Massachusetts	7	Georgia	1
Illinois	5	Iowa	1
California	4	Kansas	1
Michigan	4	New Hampshire	1
Kentucky	3	Rhode Island	1
New Jersey	3	Washington	1
Texas	3	West Virginia	1

There is evidence of a tendency toward smaller plants. For example, the General Electric Company's thirty-five new plants are described as engaging from 30 to 1,500 employees each.

The controlling factors mentioned in the selection of these locations are labor, markets, transportation, raw materials, power, and fuel. Reasons given for changes from former locations include a continuing policy of decentralization, decentralization for better control of operations, social and economic benefits to employees, and lower costs.

Paper No. 2307

THE PLANNING OF AERIAL PHOTOGRAPHIC PROJECTS

By F. J. Sette,[1] M. ASCE

With Discussion by Messrs. T. W. Norcross, James M. Cultice, Marshall S. Wright, Robert H. Randall, and F. J. Sette.

Synopsis

Although there is a progressively developing literature in the field of photogrammetry, until the studies herein described were initiated, there was practically no information in regard to planning and estimating the cost of aerial photographic projects. This paper discusses the establishment of a photographic day, zones of similar weather characteristics, and a method of scheduling projects. The reliability of the representative photographic day is discussed. A method of estimating the cost of aerial photography is also presented.

Introduction

The extensive use of aerial vertical photography by the U. S. Department of Agriculture for crop control, soil conservation, flood control, forestry studies, and other important purposes led to an examination of that program with a view to reducing its cost if at all possible. More than 2,900,000 sq miles of the United States have been photographed—approximately 700,000 sq miles of which has been photographed twice because of cultural and other changes on the ground. For certain purposes it may be necessary to rephotograph an area more than once. A decision to rephotograph would be based upon the extent of cultural changes since the date of the original photography, the requirement of greater pictorial detail, or the need for more precise, or larger scale photographs. Aerial photography offers the engineer a useful and economical tool in the planning and execution of engineering projects; in fact, it is a necessary tool which will be increasingly useful in the future.

Unit costs developed in this paper are based upon 1938 prices; upon a photographic scale of 1 to 20,000 (1,667 ft per in.); and the use of a camera with a focal length of $8\frac{1}{4}$ inches. For this scale and camera, the flying altitude is 13,750 ft above the ground.

Note.—Published in March, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Special Assistant to the Director, Bureau of Reconversion Priorities, Civilian Production Administration, Washington, D. C.

Scheduling Operations

Photographic Day.—The number of days in a month that an aerial photographer could reasonably expect to utilize for photographic purposes had to be determined. The Soil Conservation Service (SCS) of the Department of Agriculture had obtained from the United States Weather Bureau a 10-yr record of the number of days for some fifty stations throughout the United States when the sky was cloudless or less than 10% overcast—or, assuming the perfectly clear sky to be unity or 1, when clouds covered 0.1 of its area or less as an average of three observations taken at 7 a.m., noon, and 7 p.m. Flying

[a] First column shows the average number of days per month that the sky is 0.1 or less overcast. The numerals in the other columns show the percentage of the average which may be expected for the stated month. Groups suggesting similar weather patterns may be identified as follows—*, 55% or less; **, 100 to 149%; and †, 150% to 199%—of an average month.

reports from the field seemed to indicate that the number of days having a sky covered with 0.1 or less of clouds could be used as a very close index of the number of photographic days that might be expected. Accordingly, the number of stations was extended to include all stations for which records were available. The years of record varied from 26 to 37, the largest number of stations having a 37-yr record.

When this decision was made, it was also appreciated that an aerial photographer could utilize other days when he often found himself unable to photo-

graph on so-called "clear days" because of adverse local conditions such as haze, fires, heavy winds, or mechanical and other difficulties. Therefore, the designation of a photographic day as that day in which clouds covered 0.1 or less of the total sky served largely as an index.

Regions of Similar Weather Characteristics.—For each weather station, the average number of days per month for the year ($\frac{1}{12}$ average number of days in a year) was divided into the actual average for each month which, multiplied by 100, gave the percentage that each month was of the average for the year. In other words, the values in Table 1 are percentages of the average days in the first column of the table. For example, Table 1 shows that, in an average year, New York, N. Y., has 4.5 days per month when the sky is 0.1 or less overcast—clear days. The average March weather is clearer than that, being 109% of 4.5 days or an average of 4.9 days. Stations with similar characteristics are indicated by appropriate superscripts. The number of stations (144) covering the entire United States made it difficult to ascertain the boundaries between regions. To do so, probability curves were plotted for each station. The curves for some of the stations were of the normal fre-

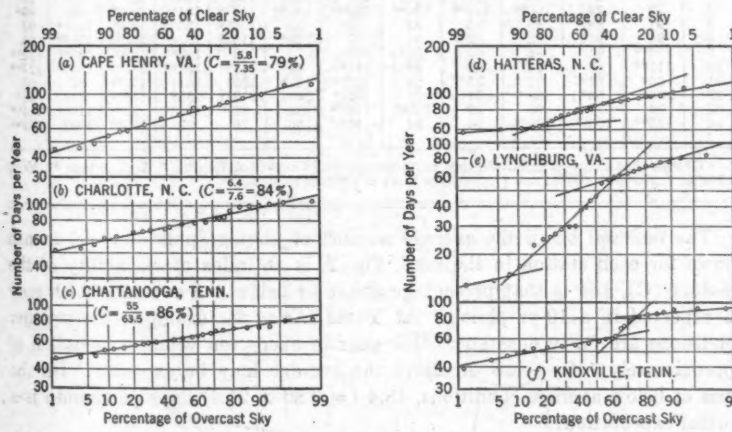

FIG. 1.—DETERMINATION OF BOUNDARIES OF AREAS OF SIMILAR WEATHER CHARACTERISTICS BY PROBABILITY CURVES (C = COEFFICIENT OF VARIATION)

quency distribution type whereas those for other stations were not. It was assumed, therefore, that, for the former stations, the weather pattern was consistent whereas the latter stations were subject to two or more weather patterns. Such irregular areas, therefore, were assumed to be boundary stations. Figs. 1(a), 1(b), and 1(c) illustrate the consistent type of station; and Figs. 1(d), 1(e), and 1(f), the boundary type of station.[2] There seems to be no definite boundary line, but rather a transition zone between the regions. Since there was no need to be precise about region boundaries, these

[2] "Method of Estimating Time Required on Aerial Photographic Projects," by F. J. Sette, *Photogrammetric Engineering*, Vol. IV, No. 1, p. 42.

were drawn through those stations which showed the greatest variation in normal regional distribution.

As a result of these studies, Table 2 and Fig. 2 were prepared. Table 2 offers a quick method of scheduling projects. For example, regions 3 and 4 show very poor conditions for the months of June through September when two or three days per month is the average expectancy of good photographic weather, whereas in November, six to eleven days may be expected. Consequently, considerations of cost should dictate the scheduling of photographic projects in these areas from October through April. Equipment released from these areas could be used in regions 5 and 6 through October.

[a] Groups that suggest similar weather patterns may be identified as follows: *, 55% or less; **, 100% to 149%; †, 150% to 199%; and ††, 200% or more of average month.

The numeral below the average number of photographic days per month shown for each station in the map, Fig. 2, is an index of variability of the weather (C), and is that percentage above or below the average which may be expected in a 10-yr period. At Yuma, Ariz., for example, the weather conditions are fairly constant. One year in every ten years, a deviation of approximately 14% below or above the average may be expected. On the basis of below average conditions, 18.4 ($= 0.86 \times 21.4$) days per month is a normal expectation.

Validity of Index.—Although some preliminary observations had indicated that the number of days 0.1 overcast or less may be equivalent to the number of photographic days that could be expected, it was decided to test this assumption on the large-scale operations of the 1938 aerial photographic program of the Agricultural Adjustment Administration (AAA). Weekly weather reports of daily cloud conditions over the project areas were obtained by arrangement with the Weather Bureau. Four such areas are defined in Table 3(*a*). The study that follows is based largely on weekly reports of operation received from the contractors and from the Weather Bureau observers nearest the project locations. The reports from the crews were really estimates and were considered as such. Also, Weather Bureau stations were often located at a distance from the area being photographed; it was possible for perfect weather

FIG. 2

to exist in the area being photographed while the sky was more or less overcast at the station where the observations were made.

Tables 3(*b*) and 4 should be studied together. The former shows the number of flights made and the available photographic days as reported by

the Weather Bureau; and the latter discloses that only 54.8% of the total flights, accounting for 61.4% of the total photography, occurred on days of 0.1 or less overcast.

Two factors are important in appraising the value of the reported cloudiness: (1) The method of averaging 7 a.m., noon, and 7 p.m. observations, as used by the Weather Bureau; and (2) the location of the Weather Bureau observer, who might have been at considerable distance from the area being photographed. Thus, it is perfectly possible that, at the 7 a.m. observation, it was raining or that the sky was completely overcast, clear by 10 a.m., and 0.2 overcast at 7 p.m. Such a day would be reported as 0.4 overcast although it would be excellent photographic weather. Similarly, the cloud conditions over the area as a whole may have been 0.1 or less overcast and 0.4 overcast where the observer was located. Moreover, with the present availability of highly sensitive photographic film (which is several times "faster" than that produced a few years ago) complete cloudlessness is no longer an absolute requirement; on the contrary, sufficiently high cirrus clouds sometimes have a beneficial effect on the quality of the photographs by softening the light and reducing the intensity of the shadows.

TABLE 4.—NUMBER OF FLIGHTS AND THE AREA COVERED, AS RELATED TO CLOUD CONDITIONS

(As Reported by the Weather Bureau from the Project Area)

Proportion of sky overcast[a]	Number of flights	Square miles covered[b]	Percentage of Total:

Total	2,877	634,458	....	....

[a] Average cloudiness. [b] Reported total coverage. [c] 0.1 of sky, or less, overcast.

A study of the maximum 2-day performance of each contractor, totaling one hundred and one flights, showed an average coverage of 630 sq miles and 5.06 photographic hours per day as compared with 220 sq miles and 2.31 hours for all flights. These hundred and one flights (or 3.5% of all flights) accounted for 63,501 sq miles, or better than 10% of the total coverage. The reported cloud conditions of the 101 days when these records were made showed 84 days, that were 0.1 or less overcast and 11 days that were 0.2 overcast. All factors considered, it seems evident that for all practical purposes the index (namely, the day of 0.1 clouds or less) has substantial validity as a photographic day.

Effect of Sunlight.—Thus far no mention has been made of the effect of season, or of varying hours of sunlight, upon the time available for photography. In general, photography in the northern latitudes ceases about November 15 (when snow may be expected or when the photographic time is too short to continue operations economically), and is rarely resumed before April 1.

In the southern states, between latitudes 27° to 36° north, where only a comparatively few days of snow coverage is normal, the length of photographic daylight is of primary importance. There is no period in these latitudes between the dates of January 21 and November 22 when there is not at least three full hours of sunlight (10:30 a.m. to 1:30 p.m.) and when the sun is not

less than 30° above the horizon—a requirement that is generally specified in order to avoid objectionable shadows. There is a 2-hr period (11:00 a.m. to 1:00 p.m.) between December 4 and January 7 when the sun has a vertical angle of not less than 30° above the horizon. At latitude 30° north, the sun is 30° or more above the horizon for at least 3 hours during the winter months, which is more than the average time of photography (2.27 hours) in Table 3(*c*) for the southern region.

Little is known of the effect of winter sun on the quality of photography; but it is well known that when the sun is low the rays are obscured by considerable haze and other poor atmospheric conditions. The shadows cast by the winter sun are long, and they obscure photographic detail. The best photographic time is the midday period of a clear day following precipitation, and the best season is as nearly June 21 (the summer solstice) as clearing of snow from the ground and the leafing of the trees will permit.

Tables of solar altitudes and Weather Bureau reports should be consulted when planning aerial photographic projects extending into the winter months.

Photographic Coverage

General Considerations.—To prepare a program and to estimate an aerial photographic project properly, it is necessary to know what the plane and the crew can do. The area that a crew can photograph depends on many factors, some of which are: Speed and power of plane, experience and ability of crew, scale of photograph, elevation of plane required to obtain the necessary scale, topography of area (mountainous or flat) and its mean elevation, whether or not the area is marked by the outline of public land surveys of the United States General Land Office, availability of good flight maps, favorable weather conditions, and distances from flying base to area to be photographed.

In general, the faster a plane can climb to its position and the speedier it is, the more time can be spent on photography, and more photographs can thus be obtained in a given length of time. Better advantage can also be taken of favorable weather conditions.

The most important single factor is the ability of the crew. Good pilots for aerial vertical photography are not numerous because of the severe combination of qualities required of them. Only a small percentage of trained pilots seem to have the patience and mapping intuition of line and direction necessary for success in aerial photography. The photographer and pilot must work as one unit, which adds to the difficulty of obtaining many successful combinations. Consequently, the area that can be photographed in a given time depends very largely on the skill of the crew because it involves not only the original photography but also the additional reflying necessary to fill in gaps or to replace unacceptable work.

Areas that are sectionized by the Public Land Survey System are more easily photographed from the air because the pilot can use section lines to guide him. In general, the states that are not sectionized, in addition to the thirteen original states, are West Virginia, Kentucky, Tennessee, Vermont, Maine, and parts of Texas and Louisiana.

Good flight maps enable the members of the crew to plot the flight lines, and to select landmarks as guides in the air. If good maps are available, they should be supplied to the contractors. When rephotography of an area is to be undertaken, probably the best flight maps would be the "photo-index" sheets obtained from previous projects. These should be supplied to the crew.

Flying Time.—Of first consideration is the flying time of a single photographic expedition. Table 3(*c*) indicates that, on the average, it takes 2.04 hours for a plane to leave the ground, fly into photographic position, and return to the ground after completing its mission. For brevity, this interval may be called "en route time." Approximately 2.31 hours are required for photography, making a total of 4.35 hours for the complete flight.

It is rather interesting to note that, in the western division, the en route time required was appreciably above the average (2.36 hours), probably because of the high mean elevation of the terrain photographed and the greater distances between landing fields.

Area Coverage.—Table 3(*d*) indicates the estimated area coverage obtained on the various projects. The effect of power of the plane and the higher productivity obtained when flying over sectionized country are illustrated in the following:

Description	Average horsepower: 180 hp	350 hp
Coverage per flight (sq miles):		
Over sectionized areas	212	248
Over nonsectionized areas	195	164
General average	205	233

In nonsectionized areas a heavy plane seems to be at a greater disadvantage than a lighter plane, although the advantage is reversed in sectionized areas. No information could be obtained to explain the poorer performance of heavier planes in nonsectionized areas.

Coverage Per Exposure.—The cameras in use for vertical aerial photography produce photographs 7 in. by 9 in. and 9 in. by 9 in. in size. The areas of the photographs are therefore 63 sq in. and 81 sq in., respectively, and show a ground area (scale of 1 to 20,000) of 6.28 sq miles and 8.07 sq miles, respectively. If an average overlap and sidelap of 60% and 30%, respectively, are required, and the plane can maintain the necessary elevation, the net progressive area per exposure is 1.75 sq miles for the 7-in. by 9-in. photographs, and 2.24 sq miles for the 9-in. by 9-in. photographs. Apparently, however, the net average per exposure is considerably less as Table 3(*e*) indicates.

The SCS reported that a study of a project of about 68,000 sq miles indicates that each photograph (7 in. by 9 in.) covers a net area of approximately 1.26 sq miles.

Table 3(*e*) shows that there is some difference, even as between divisions, in the coverage that can be expected per exposure. Some divisions have had a higher proportion of 9-in. by 9-in. cameras on their projects, which accounts for the greater coverage per exposure. It appears that 1.25 sq miles and 1.75 sq miles per exposure of 7-in. by 9-in. and 9-in. by 9-in. cameras, respectively, may be used for estimating purposes. The difference between the theoretical

and the actual area per exposure is accounted for largely by the fact that the specifications require the contractor to photograph more than the actual area of the project. Most contracts required that each county be flown as a separate subproject. Certain requirements were met—as, for example, photographing several miles beyond the county boundaries which increases the number of exposures normally necessary for the area of the county. Consequently, the area of photography is greater than the area of the county and can be calculated by plotting flight lines on the map.

Reflights.—Upon completion of the initial photography of a project, the contractor may find that some of the work does not meet the requirements of the specification; that is, there may be gaps, insufficient overlap or sidelap, or other defects. Reflights are then necessary to obtain complete coverage. Upon inspection by the contracting officer, some of the material may also be found unsatisfactory and additional reflights are necessary.

From the available material, the following appears to be the average reflights by AAA divisions:

Division	Percentage of reflights
East Central	20.6
Northeast	29.3
North Central	29.0
Southern	28.7
Western	23.4
Average	26.3

The allowance for reflying is difficult to estimate since it is largely a matter of efficiency on the part of the contractor and of inspection on the part of the contracting officer. Past performance of the contractor and of the contracting officer, where known, should be used in determining the average for the estimate.

Unit Costs

General Considerations.—Determination of unit costs in the field of aerial photography is a hazardous venture. Only the contractor knows the initial and operating costs of his plant and equipment; the performance and efficiency of his planes and personnel; and other pertinent costs such as insurance, taxes, etc. There are numerous competitive differences between contractors such as prevailing scales of pay, quality and speed of planes and equipment, ability to use plant and equipment on other work, and location of main laboratory from project area—all of which make it difficult to estimate the cost of a project with precision. Nevertheless, it is possible to approximate the reasonable cost of a particular project.

Value of Plane and Equipment.—A study of the planes used in the AAA 1938 aerial photographic program considering value, power, and age of planes is summarized in Table 5(*a*). Because the medium and heavy planes are often purchased secondhand and also because very often contractors use these planes on other work, a cost of $7,500 seemed reasonable for the plane. Similarly, studies of camera and other equipment indicated $1,500 as a more than reason-

able estimate. Many of the cameras had been in service since World War I. Assuming a 10-yr period of depreciation for both plane and equipment and 6% interest on the investment, a charge of $100 per month should be made. Hangar rentals in 1937 varied from $30 to $50 a month—$40 per month probably being a fair charge. Obviously, it is not generally feasible to keep

TABLE 5.—COST OF AERIAL PHOTOGRAPHY

No. of planes	Average horse-power	(a) Average Capital Costs			(b) Operating Costs (Dollars per Hour)					
		Age (years)	Probable Cost		Fuel	Over-haul	Insurance		Over-head	Total oper-ating cost
			New, in dollars	Dollars per horse-power			Lia-bility	Com-pensa-tion		
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)	(11)
10	145	1.3	4,950	33.00	2.18	1.09	1.50	1.25	0.90	6.92
20	300	5.8	8,860	29.50	4.50	2.25	2.00	1.25	1.50	11.50
27	435	8.5	13,100	30.10	6.56	3.27	2.50	1.25	2.04	15.62

planes working all year. The charge to projects should be on the basis of 10-month operation per year. The yearly charge for the plane and yearly hangar rental totals $1,680; and, if overhead is assumed at 15%, the total yearly charge is $1,932 or $193 per month on a 10-month operating basis.

Operation and Maintenance of Planes.—From such sparse information as could be assembled it seemed that, assuming gasoline to cost 25¢ per gal and oil to cost 35¢ per quart, a rule-of-the-thumb formula of 1.5¢ per hp-hr could be derived. A similar formula for estimating the cost of overhauling and inspecting equal to 0.75¢ per hp-hr was derived. This value may be used in estimating despite the fact that aerial photographic pilots do much of the work themselves during the large amount of waiting time. Insurance on plane and equipment and public liability is quite high; and, although it is not known how much contractors carry, studies indicate that a reasonable charge is $1.50 per flying hr for light planes, $2 per flying hr for medium planes, and $2.50 per flying hr for heavy planes. In addition, one must add compensation insurance while flying, which varies from state to state. For estimating purposes, $1.25 per flying hr is assumed (Washington, D. C., rate in 1938). The cost of operating a plane is summarized in Table 5(*b*), assuming overhead at 15%. The hourly operating costs shown in this table explain the tendency of contractors to purchase new light planes in recent years.

Salaries of Pilot and Photographer.—The salaries of flyers and aerial photographers are subject to larger fluctuation. Some companies, for example, may pay entirely upon coverage completed and accepted; some may pay a base salary plus so much per square mile of accepted photography; and others may pay on a straight salary basis. The sums to be used in estimating should range between $500 and $600 per crew of two per month. An average of $550 per month may be used for estimating purposes.

Although compensation insurance for employees, while flying, was included in the operating cost of the plane (see Table 5(*b*)), there is an additional charge

for employees while on the ground. This charge is also subject to large variations. Using 1938 rates for Washington, D. C., compensation insurance would amount to $20 a month for the crew. The Social Security insurance rate in 1938 was 4% of the salary, or a total of $22 per crew. Accordingly, $600 a month for the salary of the crew may be used in estimating; and to this sum should be added overhead, assumed at 15%. The total allowance for this item will be $690 per month.

Cost of Flying.—The cost of flying cannot be reduced to a square mile basis until the project area is known and the number of days available determined. For estimating, the time is divided into two parts—waiting time and flying time. The waiting-time cost per month is the sum of salaries for the crew of $690 and the charges for the plane and hangar rental of $193, a total of, say, $885 for estimating purposes. Flying time is computed on a flight basis. In the North Central States, for example, the average time of flight is 4.46 hours, or 4.5 hours for all practical purposes. For a medium-size plane, the cost per flight will be about $51.80 or, say, $52 for estimating purposes.

Because of the vagaries of the weather, the contractor must allow for some contingency. The method suggested in this analysis is to add to the waiting-time cost the percentage of variation shown in Fig. 2 for the area under consideration.

Cost of Photography.—Efficient organization plays a large part in the cost of photography. Volume production is another important element of cost. The following analysis is based on continuous production of large quantities and is not applicable to intermittent or low-volume production.

TABLE 6.—COST OF PHOTOGRAPHIC MATERIAL

Material	Quantity	Man-hours	Dollars per Stated Quantity			
			Labor	Material	Overhead	Total
Film	One roll	4	2.52	27.50	10.00	40.02
Contact Prints, Single Weight:						
Commercial stock	100, 8 in. by 10 in.	4	2.52	2.70	1.74	6.96
Waterproof stock	100, 8 in. by 10 in.	4	2.52	10.00	4.17	16.69
Negatives	100, 20 in. by 24 in.	55	34.70	141.00	58.57	234.27
Contact prints	100, 20 in. by 24 in.	9.5	6.00	19.70	8.57	34.27

A survey by the U. S. Department of Labor of twenty-five firms engaged in aerial photography indicated that, in 1938, the median wage paid to workers was from 52½¢ per hr to 57½¢ per hr. Firms on the East Coast and West Coast paid about 75¢ per hr, in Texas about 40¢ per hr, and in the Middle West about 60¢ per hr. For the purpose of this study, 60¢ is used which, with compensation and Social Security insurances (1938), would amount to 63¢ per hr. Table 6 contains the cost of the usual photographic material, when the camera used takes a 7-in. by 9-in. photograph. Overhead is estimated at 33⅓% of the cost of labor and materials.

A necessary requirement of aerial photography is a photo-index sheet which is a composite photograph of all the pictures taken, after all reflights have been made. Such a sheet makes identification simple and quick when a photo-

graph of a particular area is required. To make such an index, contact prints are stapled on boards in the order and position that the photographs were taken in the air and are then copied. The coverage on one of these sheets, from actual tests, averages 240 sq miles. Assuming 1.25 sq miles per contact print, 192 prints will be required per sheet. Moreover, the contractor will be required to make a contact print for each exposure he makes in the air and, consequently, reflights of 30% must be included. Laboratory wastage of about 5% is an additional necessary allowance. Accordingly, the number of contact prints to be made for each sheet is 262 at $6.96 per hundred—or a total cost of $18.25. Prints may be stapled at about 25 per man-hr at a cost, for 192 prints, of $4.85. Assuming $6.00 for board, staples, and overhead, each board will cost about $29.10 before it is photographed. The negative will cost about $2.35 and the contact print will cost about 35¢—or a total of $31.80 per index sheet.

The usual contract stipulates the delivery, by the contractor, of the aerial photographic negatives, one set of waterproof contact prints, one set each of photo-index negatives and photo-index sheets, and one set of single-weight prints which had been used in making the photo-index sheets. The photographic cost per square mile may be estimated by assuming a 1,000 sq mile area for simplicity of calculation. A roll of film will cover 137.5 sq miles (1.25 sq miles per exposure times 110 exposures per roll). Therefore, 1,000 sq miles will require 7.27 rolls of film, or 9.5 rolls allowing for 30% reflights. The number of waterproof prints required will be $\frac{1,000}{1.25}$ or 800 net. Allowing 5% waste, 840 prints will be printed. Reflying is not included in this item as these prints are made last, after all reflights have been finished. The number of index sheets is obtained by dividing 1,000 sq miles by 240 sq miles or 4.17 sheets. The cost in dollars per 1,000 sq miles ($650) may be itemized as shown in Table 7.

TABLE 7.—COST OF MATERIALS FOR 1,000 SQUARE MILES BY PHOTOGRAPHY

Item	Quantity	Unit cost[a]	Total cost
Rolls of film..........	9.5 each	$40.02	$380.19
Waterproof prints.....	840 each	0.167	140.28
Photo-index sheets....	4.17 each	31.80	129.43
Total cost (dollars)...	1,000 sq miles	0.65	$649.90

[a] Dollars per unit of quantity listed.

In 1938, some contractors were using cameras taking 9-in. by 9-in. photographs, a size now generally required. The cost of photography is somewhat less. This size of film comes in rolls of 150 ft and longer, instead of 75 ft for the 7-in. by 9-in. camera. For 150 ft the man hours required for developing is about 50% more than that shown in Table 6. The material cost is 100% more. Including overhead, the cost per roll is $78.37. Printing productivity for 9-in. by 9-in. contact prints is the same as that shown in Table 6. The material cost is 20% higher—that is, in proportion to the areas of the photographic papers. A 7-in. by 9-in. print is made on an 8-in. by 10-in. paper, whereas a 9-in. by 9-in. print is made on a 10-in. by 10-in. paper.

The number of exposures may be computed by dividing the total length of the film in inches by 10 in. For a 150-ft roll, 180 exposures, each covering

1.75 sq miles, will cover 315 sq miles. Consequently the cost of film per 1,000 sq miles, including 30% reflights, will be \$321.32. Similarly, allowing 5% waste, only 600 waterproof prints will be required per 1,000 sq miles at a cost of \$116.10. The coverage of a photo-index map of 240 sq miles remains unchanged except that, instead of 262 prints of the 7-in. by 9-in. size, 187 of the 9-in. by 9-in. size will be required. The cost per index sheet is \$26.56, computed as shown herein. Consequently, the cost per 1,000 sq miles is \$547.42, or on a square-mile basis, about 10¢ less than the cost of photography using a 7-in. by 9-in. camera (see Table 7).

Other Cost Considerations.—Studies indicated that the size of project was an important element in the total cost. Every effort was made to block out contiguous areas of fairly large sizes for incorporation into single projects. In certain regions, areas averaged from 15,000 sq miles to 20,000 sq miles per project, and in others no more than 5,000 sq miles or 6,000 sq miles were possible. Adequate competition was another important factor. This could be controlled by releasing projects when more than enough equipment seemed to be available. Uniform specifications were absolutely necessary if costs were to be kept down; and this was done as nearly as practicable. Finally, efforts were made to schedule work on a year-round basis for as many planes as possible so as to spread the costs of equipment and overhead over more units of work. For this reason, contracts for aerial photography in the south stipulated that planes could take off on, or about, June 1 but had to be returned by, or before, December 1. This provided additional equipment for projects in areas where summer conditions provided greater utilization. Because of the known effect on costs of these variables, aerial photographic projects were cleared through the various bureaus of the U. S. Department of Agriculture and often with some of the state governments so that needs were all consolidated and programmed. Moreover, when bids were received and evaluated, they were subject to rejection if they exceeded, appreciably, the engineer's estimate of the project. The efficacy of the administrative policy implementing research conclusions was demonstrated by the reduction in costs obtained.

Programming and Estimating Projects

With such information, it is possible to program and estimate aerial photographic projects on, say, a scale of 1 to 20,000. Two examples will be used (both in the Middle West) to show the effect on the costs by reason of weather conditions. Both projects are to begin on June 1 and end before December 1. Project A (17,000 sq miles) is in northern Missouri, extending across the state, and project B (10,400 sq miles) is in southern Indiana. Project A cuts across weather regions 7 and 8, and project B is all in region 7.

Time Required.—By inspection, in Table 2, the average number of days in project A that are 0.1 or less overcast is about 7.5 per month, with a variation of 25%. As the area is about equally divided in regions 7 and 8, the monthly percentages will be averaged in project A. In project B, the probable average number of days per month is about 5.6, with a variation of about 27%. The time available for both projects using one-plane crews is computed as shown

in Table 8. (For method of computing clear days available see Table 1 and supporting text.)

Although the average coverage per flight for the Middle West is 242 sq miles, the heavier plane in sectionized areas can cover 248 sq miles. For estimating purposes assume 240 sq miles per flight. The number of flights, including reflights of 30% for project A will be 92 and for project B, 56. The

[a] Cumulative days available to a one-plane crew. For a two-plane crew, multiply these values by 2.

time required for project A is 6 months and for project B, say, 5 months, two planes and crews being used for each project. The waiting time in project A is about 5½ months, but because of the size of project the delays caused by inspection of material would justify the employment of the crew for the full six months. Extra flights—probably 10% of the total would be equitable—for reconnaissance and getting on and off the projects at the start and finish of the work must be added to the number of flights. Thus, project A would require one hundred and one flights and project B, sixty-two flights. The estimated costs of the projects are as listed in Table 9.

TABLE 9.—COMPARATIVE ESTIMATES OF COSTS

No.	Item	Project A		Project B	
		Cost	Remarks	Cost	Remarks
1	Waiting time	$10,620	Six months[a]	$ 8,850	Five months[a]
2	Contingency	2,660	25% of item 1	2,390	27% of item 1
3	Flying time	5,250	101 flights[b]	3,220	62 flights[b]
4	Photography	11,050	17,000 sq miles[c]	6,760	10,400 sq miles[c]
5	Subtotal	$29,580		$21,220	
6	Profit	4,420	15%	3,180	15%
	Estimated Costs:				
7	Total	$34,000		$24,400	
8	Unit	$2.00	Per square mile	$2.35	Per square mile

[a] Two planes at $885 each. [b] At $52 each. [c] At 65¢ per sq mile, assuming camera takes 7-in. by 9-in. photographs.

Depending on the camera used in 1938, project A may cost from $1.90 to $2.00 per sq mile, whereas project B may cost from $2.25 to $2.35 per sq mile.

Sufficient information has been given to estimate costs for future programs. The average values of plane and equipment will probably not change appreciably. The costs of operating and maintaining a plane and of photographic material can be adjusted in accordance with the prevailing salary and wage rates and the costs of materials. The productivity of labor, discussed in the section, "Cost of Photography," has not been materially affected by new developments and may be used for current estimates. Since the size of the aerial photograph now generally used (1946) is 9 in. by 9 in., the cost of photographic materials should be estimated on that basis. For aerial photography of a different scale (other than 1 to 20,000) or which uses a camera with a longer or shorter focal length than 8¼ in., the foregoing information could be used but this would require considerable manipulation.

Results Obtained

Analyses of a number of projects led to the belief that a properly administered program should result in average costs of from $2 to $2.50 per sq mile. In fact, an established year-round program might well cost less than $2 per sq mile. This is important to consider, especially since aerial photography has such widespread usefulness even outside the field of engineering. The campaign to reduce the cost of aerial photography (the studies for which began late in 1937 and began to be implemented in the spring of 1938) was successful because of the increasing familiarity with the work to be done on the part of both contractors and contracting officers. Instructions were issued to all the technicians in the department acquainting them with the elements of programming and of costs so that the maximum economy could be obtained. The following paragraph is quoted from the instructions:

TABLE 10.—Reduction in Costs of Aerial Photography by Careful Planning and Programming

Description	1926–1937[a]	1938	1939	1940	1941
Area covered, in square miles	970,434	635,562	445,844	376,436	381,083
Total cost, in dollars	4,110,423	1,968,668	926,273	765,281	892,320
Unit cost, in dollars per square mile	4.24	3.09	2.07	2.03	2.34

[a] Dates are inclusive, and all dates are for the calendar year.

> "While quality of performance is most important, the cost of aerial photographic projects must be kept to a minimum. Proper programming is essential to economy of operations. Insofar as possible, programs should be planned on a 12-month basis, taking every possible advantage of the probable weather conditions. Areas should be large enough to permit economy of operation. Changes in specifications should be examined to determine how costs may be effected. And, lastly inspections of materials should be made promptly and fairly to reduce idle time and waste of materials."

The results obtained more than justified the efforts and expenditures in making the studies. The reduction in costs is shown in Table 10 which was prepared from data submitted by the U. S. Department of Agriculture.

Acknowledgment

Although the work was done under the direction of the writer, it could not have been accomplished without the invaluable assistance and cooperation of the technicians in the various divisions of the Agricultural Adjustment Administration, the Soil Conservation Service, the Forest Service, and other bureaus, and of some of the contractors who were generous of their time and ideas. The writer is particularly grateful for the aid which he received from Marshall S. Wright, Office of the Secretary; Louis A. Woodward, SCS; Grover M. Plew and J. Marvin Cultice, AAA, all of the U. S. Department of Agriculture.

Conclusions

The studies reported in this paper need greater testing and refinement, because the usefulness of aerial photography is just beginning to be understood and appreciated. Cultural changes in some parts of the United States were so rapid, even before the beginning of World War II, that it is more economical to refly the areas than to use old photography. For proper planning, many areas will require reflying every 5 years, on an average. When the use of aerial photography becomes widespread (as it may in the not-too-distant future) flying and photographing of from 400,000 to 500,000 sq miles per yr may be a normal operation. When that time comes more precise information may need to be developed.

DISCUSSION

T. W. NORCROSS,[3] M. ASCE.—The U. S. Department of Agriculture (USDA) has been using aerial photographs since approximately 1926. Until the Soil Conservation Service (SCS) started a comparatively large photographic program, little attempt was made to prepare an engineering estimate of the cost of such work. The size of the SCS program, and the personnel available, did not warrant the type of study later made under Mr. Sette's direction, utilizing data collected under the combined programs of all USDA bureaus. The rougher estimates made by the SCS took cognizance of terrain in a manner different from that presented in the paper.

Mr. Sette's approach to this problem is sound and logical. It is based on scale, lens, weather conditions, cost of equipment and materials, cost of operation plus a fair profit, and coverage per photographic exposure. No known tangible item has been omitted. The author concludes correctly that the method needs greater testing and refinement. Certain intangibles not previously included are believed worthy of consideration in refining the method employed in estimating costs.

Table 3(*d*) shows that 634,458 sq miles of photography were used as the basis of computations. This area (or the smaller areas covered in 1939, 1940, and 1941) can be considered as offering an annual photographic program of sufficient size to plan for continuous operation—an attraction to commercial concerns conducive to active competition. A smaller annual program can easily result in the operation of a smaller number of concerns, less competition, and resulting higher unit costs.

Aerial photographs are being sought more and more by a larger number of users as their value is appreciated. Photographic concerns in the United States are no longer dependent almost entirely on the federal government for large contracts and are engaging in photographic operations in foreign countries. Some of these new customers do not operate on the same basis as the federal government and are willing to pay the price asked to secure the desired material. Competition of this kind can reach such proportions that, excluding the increased costs of operations, either the bid price received will be higher than heretofore; or new concerns must be encouraged to restore competition. Increased competition may result in lower bid prices, but it also raises administrative costs of the contract and delays delivery of satisfactory materials.

In the paper, photography of different types of terrain was taken into consideration only to a limited extent—the effect of power of plane and the higher productivity obtained when flying over sectionized and nonsectionized areas were cited. In the data compiled, the preponderance of areas photographed was agricultural. In this type of terrain, land lines are easily recognizable in sectionized country. Using a heavy plane in nonsectionized country causes difficulties. In photographing mountainous timbered areas, even though in sectionized country, a similar lower productivity would be expected; and, in mountainous country, the heavier plane might easily be necessary to obtain the

[3] Chf., Div. of Eng., U. S. Forest Service, U. S. Dept. of Agriculture, Washington, D. C.

necessary flying height. When lack of competition is coupled with difficulty of terrain, particularly mountainous terrain, the bidder probably increases the unit cost out of proportion to the difficulty of operation. He knows that few concerns will have the type of equipment required and he will have a better opportunity to secure a price over and above that which would normally result. Necessary flying altitude and amount of available equipment for working at varying flight heights should be considered in the preparation of estimates. In the past many estimates have been made in conformity with the Sette method, with the result that review of the estimate, in conjunction with terrain conditions and required flight height, shows that, because the unit price was considered too low, it has been altered upward to take these difficulties into account.

Photographs are made for a variety of purposes. Generally those secured by USDA are for general land use studies which require the characteristics outlined by Mr. Sette. For mapping purposes photographs of entirely different characteristics may be, and usually are, required. To undertake all kinds of work, the contractors must be equipped to meet the varying requirements. This condition existed at the time the study was made, and the data in the paper were based on the assumption that equipment was adequate. Also, of the volume of work performed at that time, the largest part was for the USDA. Comparative costs to the USDA and mapping agencies would doubtless show a higher unit cost for others because of the smaller volume of work. During World War II, however, many concerns made all their equipment available to the war effort and must re-equip. Many are uncertain of the kind of equipment to purchase. Unit costs will reflect the cost of this equipment, and only through assurances of a large, well-planned program can a high rate of depreciation be avoided.

JAMES M. CULTICE,[4] ESQ.—Aerial photographic activities were largely suspended for civilian purposes during World War II; and, with the preparation of new bid invitations, the usefulness of such data can again be apparent to contractors and purchasing officials and their engineers. Numerous requests have been received for the clear weather zone map (see Fig. 2).

The validity of the 0.1 cloudiness as an index for available photographic days should be emphasized. The paper indicates 2,973 clear days in contract areas, according to this specification, and 2,877 contract flights within the same period. The difference of 4% is very small and indicates that the probable[5] time necessary to complete an item can be estimated reliably from the standpoint of weather conditions. Although these comparisons are pertinent, it was not intended to convey the impression that flights are made regularly on days of 0.1 cloudiness, and this fact is adequately developed in the paper.

It would be of interest to note the actual award prices for the project areas estimated in Mr. Sette's study. The writer checked the contracts in the southern Indiana section and found a unit price in the successful bid of $2.24 per sq mile on an item of 10,421 sq miles, against an estimated $2.35. In northern Missouri where the weather pattern is more favorable, the contract price of

[4] Chf., Eng. Section, Aerial Photographic Laboratory, Field Service Branch, Production and Marketing Administration, U. S. Dept. of Agriculture, Washington, D. C.

[5] "Days Available for Aerial Photography," by J. M. Cultice, *Photogrammetric Engineering*, Vol. 6, No. 1, p. 32.

$1.70 for an item of 12,203 sq miles was less than Mr. Sette's lower suggested value of $1.90. These prices were both for 1940 coverage and, thus far, rephotography has not been purchased in these areas. The open, well-developed, and well-sectionized country was of course, conducive to flying economies.

Wartime developments in new aerial photographic planes, cameras, and camera equipment, new flight line control instruments, and better and faster films should make the cost of aerial surveys comparable to the cost of those presented in the paper for areas similar in terrain to the agricultural lands for which the estimating study was originally developed. Existing photo indexes will facilitate the planning of flight lines and should aid the pilot to make better use of flight time through easier recognition of ground detail.

The widespread wartime use of aerial photography and the extension of its usefulness in all fields have greatly increased the demand for aerial coverage for all purposes. The resultant advantages of plane placement and the better utilization of weather conditions in smaller localized areas by concurrent projects will increase efficiency and lower costs. Furthermore, the helpfulness of the cost estimating system is equally effective regardless of price levels. Adequate corrections can be easily applied; and new methods, better equipment, and supplies can be evaluated and their effect on the total final estimate can be computed with some measure of real dependency.

Those concerned with the engineering and administrative phases of the acquisition of aerial photography in the United States Department of Agriculture have frequently noted the value of this study in effecting saving for industry and thereby producing saving for the government and others.

MARSHALL S. WRIGHT,[6] ESQ.—Since 1936 the U. S. Department of Agriculture has followed a procedure, whereby all proposed aerial photographic projects are first submitted to the Office of the Secretary for approval before photographic operations are initiated either directly or by contract. During the period from 1938 to December, 1941 (Pearl Harbor), all applications to initiate work had to be accompanied by an "Engineer's Estimate" of cost, in the manner the author has indicated. During World War II the requirement that an "Engineer's Estimate" be submitted to the Secretary's Office along with all applications to initiate aerial photographic operations was discontinued, due mostly to the fact that aerial photographic operations were greatly curtailed at the request of the War and Navy departments. Furthermore, it was practically impossible to prepare cost estimates, because of delays and unforeseen restrictions on normal operations.

A resumption of aerial photographic activities of the magnitude in effect during the period from 1936 to 1941, whereby practically two thirds of the area of the United States was photographed to rigid federal specifications by commercial contractors, would necessitate the continuance of a thorough check of estimated costs as balanced against contract prices to assure the government a commensurate return on its investment; and, what is equally important, would require a constant study to assure that the most efficient methods are employed. This would also necessitate, on the part of the contracting officer, a thorough

[6] Technical Asst. to the Chf., Office of Plant and Operations, U. S. Dept. of Agriculture, Washington, D. C.

knowledge of all improvements in photographic and flying equipment, field and laboratory technique, and an intimate knowledge of the facilities of all contractors.

In the inauguration of the cost-analysis method outlined by the author, possibly the two greatest concrete benefits that were derived were (1) the preparation and subsequent placing in the hands of every potential commercial contractor the indicated map (Fig. 2) of the United States showing, by regions, areas of comparable weather condition expectancies; and (2) as a consequence of benefit (1) the over-all planning of seasonal work to permit a contractor to be awarded areas in the northern part of the United States during the summer months. The map (benefit (1)), the cost of which probably could not be justified by any one single contractor, was a major contribution to the entire aerial photographic industry. Admittedly, it did "do something about the weather"; and, most directly, it was probably the greatest contributing factor toward an indicated reduction of approximately $1.00 per sq mile (compare 1938 with 1939 in Table 10).

Because of benefit (2), the contractor was enabled to discontinue this work in the fall, and move to the southern states and continue photographic operations in other contracted areas. The result was evident in lower bid prices because the contractor could utilize his personnel and equipment on a year-long basis.

One phase that the author has not mentioned is that the Congress of the United States included in the Agricultural Appropriation Act for 1938 the following provisions which permit the sale, to the public, of photographic reproductions:

> "The Secretary may furnish reproductions of such aerial or other photographs, mosaics, and maps as have been obtained in connection with the authorized work of the Department to farmers and governmental agencies at the estimated cost of furnishing such reproductions, and to persons other than farmers at such prices (not less than estimated cost of furnishing such reproductions) as the Secretary may determine, the money received from such sales to be deposited in the Treasury to the credit of the appropriations charged with the cost of making such reproductions. This section shall not affect the power of the Secretary to make other disposition of such or similar materials under any other provisions of existing law."

As evidence of the great usefulness of aerial photography in the solution of all land-use problems, the Department has sold approximately $850,000 worth of aerial photographic reproductions to states, public utility corporations, and individuals, excluding the great use for them by other federal agencies.

ROBERT H. RANDALL,[7] M. ASCE.—Both the user and the producer of aerial photography will profit by this paper. The studies described were undertaken at a time when the aerial photographic program of the United States Department of Agriculture (USDA) was in its early stages. The procedures that developed from them unquestionably saved considerable money in the first year's operation. Commercial organizations working on contracts with the USDA also undoubtedly profited by these studies. Originally undertaken

[7] Chf. Examiner, Surveying and Mapping, U. S. Bureau of the Budget, Washington D. C.

for the use of the USDA in administering its own photographic program, the results of this pioneer work continue to be of use not only to the USDA but to all users of aerial photography in the federal government and to all concerns supplying aerial photographs.

The studies reported in this paper constituted a program of research which had never been attempted on such a scale, by aerial photographers, individually or collectively. Reduced to usable and convenient form, they furnished statistics on weather conditions by which, for the first time, the USDA could plan its photographic requirements in different areas in such a way as to take advantage of the best weather conditions. This development was in itself an economy to the government. Furthermore, the photographic contractors were enabled to forecast conditions under which they would be required to operate, thus lowering their bid prices. During the first year that this analysis of weather conditions was available to the contractors, it is estimated that the USDA saved about $500,000.

In addition to the direct economies to the government and to the contractors by the availability of information on weather conditions, the studies described in this paper produced a second material, although less direct, benefit: The USDA was able to inaugurate a practice of making detailed estimates for each photographic job requested by any of its bureaus or agencies. This procedure of preparing estimates, and of checking the bids received against them, constituted an improvement in administrative practice, which, although no longer followed by the USDA in the degree of refinement that was observed in the earlier days of the photographic program, is still followed in general not only by the USDA but also by other federal departments and establishments.

It is impossible, of course, to determine the extent to which this administrative practice of USDA influenced other federal agencies outside the department. It is a fact, nevertheless, that all agencies procuring aerial photographs for the purpose of making maps or charts now recognize the common-sense value of careful advance estimating. In 1941, when these agencies (under the suggestion of the Bureau of the Budget in the Executive Office of the President) developed a uniform system for accounting and reporting their performance and costs, they included advance estimating for aerial photographic projects. In this system the planning of aerial photography can be separated into five steps: (1) Determination of limits of project; (2) consultation of records, to ascertain what maps and photographs are already available; (3) determination of scale or flying height; (4) preparation of estimates of time and cost; and (5) administrative and technical clearance to conduct the work—that is, to determine the availability of funds, obtain final authorization for expenditures, etc.

Although the aerial photographic requirements of the USDA and other federal agencies were many, at the time that Mr. Sette's studies were made, the aerial photographic interests of the United States are now even greater. During World War II the federal government photographed some 15,000,000 sq miles in various parts of the world; and, with this and other available cartographic material, compiled and published aeronautical charts covering all the land areas of the planet. Besides aeronautical charts, the armed forces also produced topographic maps on various scales in many parts of the world. To

revise and improve these as the national interest may indicate, and to keep them up to date, implies a continued national interest in aerial photography in respect to not only the continental United States but the remainder of the world as well. The sensible procedures described in this paper should continue to contribute to the efficiency and economy with which this work may be done.

F. J. SETTE,[3] M. ASCE.—In asserting that the size of the annual photographic program is conducive to active competition and to lower prices, Mr. Norcross is quite correct, because it permits contractors to plan for continuous operation. It should be realized, however, that the size of the program by itself will not result in lower prices unless projects are scheduled in accordance with equipment available and the prevailing climatic conditions. The greater use of aerial photography for topographic mapping purposes and the need for rephotography because of cultural changes may well require a substantial, annual, aerial photographic program. This being so, planning, coordination, and integration, as now performed in the United States Department of Agriculture (USDA) for its own bureaus and agencies, should also be performed at a higher level, presumably in the Executive Office of the President (Bureau of the Budget) for the various departments of the federal government.

Large commercial concerns have been developing markets in foreign countries for some time, even before the war; and to the extent that they are successful and stay out of the domestic market, competition may be reduced. No American concern can safely stay out of the domestic market entirely.

In difficult terrain such as mountainous timbered areas, aerial photography may be considered more costly because of operational requirements. For example, the use of heavy planes is costly, narrowing the area of competition so that competitors may take advantage of this special circumstance. If an estimator knows the location of commercial concerns with reference to project areas, and the type of equipment at their disposal, he can determine a reasonable allowance for these circumstances.

Although the federal government is the largest user of aerial photography, the increasing use by others of the government's aerial photography, as reported by Mr. Wright, is gratifying. The writer feels that World War II interfered with the full utilization of the government's available aerial photography, by private interests. There should be an even greater demand in the future, especially if the photography is kept current with cultural changes. Mr. Wright states that one of the benefits outlined in the paper was that of enabling the contractor to utilize his personnel and equipment throughout the year by permitting him to move south in the fall. In the aerial photographic program of the summer of 1937, it apparently was the disappointing performance of a score of crews in the south that led the writer to an analysis of the monthly weather conditions. After 1937, large-scale immobilization of plane crews in the southern states in the summer and fall was no longer permitted.

Mr. Randall reports that the procedure of preparing estimates and of checking the bids against them is still followed, in general, not only by the

[3] Deputy Director, Bureau of Constr. and Field Operations, Civilian Production Administration, Office of Temporary Controls, Washington, D. C.

USDA but also by other federal departments and establishments. If this procedure is continued in the future and if programs of various departments of the government are coordinated and integrated, extensive economies can be made by commercial concerns in planning their operations and in utilizing their equipment. Such economies, in turn, can be passed on to the government in the form of reduced bids.

The writer is particularly pleased that Mr. Cultice was able to give actual contract prices for aerial photography to compare with estimates developed in the two examples shown in the paper. Project A located in northern Missouri was estimated to cost from $1.90 to $2.00 per sq mile on the basis of 1938 prices. Mr. Cultice states that the contract price in 1940 for aerial photography in northern Missouri was $1.70 per sq mile. On September 19, 1946, bids were opened by the USDA, for aerial photography involving 13,484 sq miles in northwestern Missouri, southeastern Nebraska, and south-central Iowa. The low bid averaged $2.38 per sq mile. Project B was estimated to cost from $2.25 to $2.35 per sq mile. Mr. Cultice reports a contract price of $2.24 per sq mile in 1940. In 1946, the low bid for 8,430 sq miles (mostly in Indiana) was $2.42. One of the parcels in this area of 4,647 sq miles was bid at $2.35 per sq mile. On September 19, 1946, bids for a total coverage of 39,086 sq miles were requested, the low bid for which averaged $2.40 per sq mile. The project areas were located in Minnesota, Wisconsin, Iowa, Missouri, Nebraska, Illinois, Indiana, and Pennsylvania.

On December 30, 1946, bids were requested for a coverage of 17,178 sq miles in South Carolina, Georgia, and Florida; and the low bid averaged $2.53 per sq mile. For the September and December bid openings, the average of all the low bids was $2.44 per sq mile for a total coverage of 56,264 sq miles. Considering the scatter of the projects and the increases in cost of labor, materials, and supplies, the 1946 bids certainly compare favorably with the 1941 contract prices, which averaged $2.34 per sq mile for a coverage of 381,083 sq miles. It seems apparent that the gains made in the past are being maintained. Should wages and salaries keep increasing and the prices of supplies and materials keep pace, government technicians must give greater attention to each element of cost that enters into the contractor's bid in order to keep the costs of aerial photography as low as possible.

The writer is grateful to Messrs. Norcross, Cultice, Wright, and Randall for their contributions to his paper and for their favorable comments. The paper contained a number of assumptions, the validity of which could be upheld only by adequate cost records in the possession of commercial aerial photographers. Since the assumptions have not been challenged, the writer must conclude that these may not be too far "out of line" with actual costs. Contract awards for successive years, 1939 through 1941, and bids submitted in 1946, lend further support to the general reliability of the various assumptions.

CRITICAL STRESSES IN A CIRCULAR RING

BY E. A. RIPPERGER,[1] ESQ., AND N. DAVIDS,[2] ESQ.

WITH DISCUSSION BY MESSRS. ROBERT R. PHILIPPE AND FRANK M. MELLINGER, E. P. POPOV, AND E. A. RIPPERGER AND N. DAVIDS.

SYNOPSIS

Many times, in investigations of the physical properties of foundation rock samples, tensile strength tests are required. Usually, the sample consists of one or more short cylindrical prisms of the type taken by core drilling, and then the conventional tension test (in which axial forces are applied to pull the specimen apart) is absolutely inadequate. As a suitable test for use under such circumstances and with such material the Soils Laboratory, U. S. Engineer Office, Pittsburgh, Pa. (later, the Soils Engineering Section, Cincinnati, Ohio, Testing Laboratory), devised and investigated the "ring test" described in this paper. As the name implies, specimens for this test are rings formed by cutting disks about 1 in. thick from cylindrical cores and by drilling a small hole in the centers of the disks. These rings are then placed in a standard testing machine and loaded in compression until failure occurs. The results of the tests have been interpreted in the light of certain unpublished data which Max Frocht[3] obtained using photoelastic methods.

INTRODUCTION

As part of an investigation of the feasibility of using the "ring test" in obtaining a measure of the tensile strength of concrete, the writers, in 1942–1943, made a mathematical investigation (the results of which are presented herein) of the type and distribution of the stresses normal to the section in the plane of the concentrated load—the so-called "critical section." Numerical values of these stresses were then computed for rings with diameter ratios ranging from 0.0 to 0.5. The last case (diameter ratio 0.5) has been analyzed by S. Timoshenko,[4,5] but by a somewhat different method.

NOTE.—Published in February, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[4] "On the Distribution of Stresses in a Circular Ring Compressed by Two Forces Acting Along a Diameter," by S. Timoshenko, *The London, Edinburgh and Dublin Philosophical Magazine and Journal of Science*, Vol. 44, No. 259, July, 1922, p. 1014.

[5] "Theory of Elasticity," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York and London, 1st Ed., 1934, pp. 114–116 and 119.

The exact general solution for the stresses in a ring with any type of loading was first obtained by A. Timpe[6] in 1905, and in 1924 was fully discussed by L. N. G. Filon.[7,8] In Mr. Filon's presentation the stress distributions are given in the form of infinite series whose coefficients are functions of the Fourier expansion coefficients which represent the stresses of the applied boundary forces. A difficulty in the present problem is the lack of a convergent Fourier development for the boundary stresses, since these become infinite under the loads. Nevertheless, the coefficients taken from this divergent series may legitimately be used to form a convergent series representing the stress distribution in the interior of the ring.

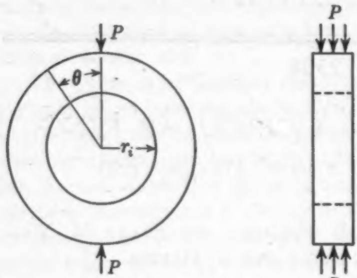

Fig. 1.—The Loaded Ring

Notation

The letter symbols in this paper are defined where they first appear, in the text or by line diagrams, and are assembled for convenience of reference in the Appendix.

Analysis of the Stresses

An arbitrary, symmetrical, normal loading of the outer boundary of the circular ring (see Fig. 1) may be described by the boundary conditions: For $r = r_o$—

$$\sigma_r = \frac{a_o}{2} + \sum_{n=1,2,3,\ldots}^{\infty} a_n \cos(n\,\theta) \quad \text{(1a)}$$

for $r = r_i$—

$$\sigma_r = 0 \quad \text{(1b)}$$

and, for $r = r_i$ and $r = r_o$—

$$\tau_{r\theta} = 0 \quad \text{(1c)}$$

in which r_i is the inner radius of ring; r_o is the outer radius of ring; r and θ are plane polar coordinates; σ_r denotes the stress normal to the boundary (radial stress); and $\tau_{r\theta}$ is the shearing (tangential) stress. The compressive loading shown in Fig. 1 must be considered negative. Eq. 1a is the Fourier expansion for the stress distribution of the load, in which[9,10]

$$a_o = \frac{1}{\pi}\int_{-\pi}^{\pi} \sigma_r \, d\theta \quad \text{(2a)}$$

[9] "Fourier Series and Boundary Value Problems," by R. V. Churchill, McGraw-Hill Book Co., Inc., New York and London, 1st Ed., 1941.

[10] "An Elementary Treatise on Fourier's Series and Spherical, Cylindrical, and Ellipsoidal Harmonics," by William E. Byerly, Ginn & Co., Boston, Mass., 1893

and

$$a_n = \frac{1}{\pi}\int_{-\pi}^{\pi} \sigma_r \cos n\,\theta\, d\theta \quad \text{(2b)}$$

R. V. Churchill[9] has published a mathematical proof of these relations as well as a general treatment of the Fourier series. The presence of concentrated, normal, line loads of magnitude P at $\theta = 0$ and $\theta = \pi$, in Eqs. 2, is characterized by the boundary stress functions: For $\theta = 0$ and $\theta = \pi$—

$$\sigma_r = \infty \quad \text{(3a)}$$

and, for $\theta \neq 0$ and $\theta \neq \pi$—

$$\sigma_r = 0 \quad \text{(3b)}$$

such that, for $-\frac{\pi}{2} \leqq \theta \leqq 0$—

$$r_o \int_{-0.5\pi}^{\theta} \sigma_r\, d\theta = 0 \quad \text{(4a)}$$

and, for $0 < \theta \leqq \frac{\pi}{2}$—

$$r_o \int_{-0.5\pi}^{\theta} \sigma_r\, d\theta = P \quad \text{(4b)}$$

The Fourier coefficients a_n of σ_r as defined by Eqs. 2 are found by integrating these equations by parts, using Eqs. 3 and 4, after substituting $\theta = 2\,\phi$, because of the symmetry:

$$a_n = \frac{2\,P}{\pi\, r_o};\quad n = 0, 2, 4, \cdots \quad \text{(5a)}$$

and

$$a_n = 0;\quad n = 1, 3, 5, \cdots \quad \text{(5b)}$$

However, the Fourier series formed with these coefficients is divergent, since the coefficients a_n do not tend to become zero as n approaches infinity.

The general stress potential $\phi(r,\theta)$ for a circular ring under symmetrical loading may be written in the form:[7,8,11]

$$\phi = r_o^2\left[A_o\left(\frac{r}{r_o}\right)^2 + B_o \log\left(\frac{r}{r_o}\right)\right]\frac{a_o}{2} + r_o^2\sum_{n=2}^{\infty}\left[A_n\left(\frac{r}{r_o}\right)^{n+2} + B_n\left(\frac{r}{r_o}\right)^n + C_n\left(\frac{r_i}{r}\right)^n + D_n\left(\frac{r_i}{r}\right)^{n-2}\right] n\, a_n \cos(n\,\theta) \quad \text{(6)}$$

The arbitrary constants A, B, C, and D appearing in this expression are evaluated by determining the stresses from the relations:[12]

$$\sigma_r = \frac{1}{r}\frac{\partial\phi}{\partial r} + \frac{1}{r^2}\frac{\partial^2\phi}{\partial\theta^2} \quad \text{(7a)}$$

$$\sigma_\theta = \frac{\partial^2\phi}{\partial^2 r} \quad \text{(7b)}$$

[11] "Theory of Elasticity," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York and London 1st Ed., 1934, p. 114.

[12] *Ibid.*, p. 53.

and

$$\tau_{r\theta} = -\frac{\partial}{\partial r}\left(\frac{1}{r}\frac{\partial \phi}{\partial \theta}\right) \ldots\ldots\ldots\ldots\ldots\ldots\ldots (7c)$$

—applying the boundary conditions Eqs. 1, solving the resultant simultaneous equations, and substituting the diameter ratio, $\frac{r_i}{r_o} = \bar{r}$. The constants thus derived are:

$$A_o = \frac{1}{2\,(1 - \bar{r}^2)} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (8a)$$

and

$$B_o = -\frac{\bar{r}^2}{1 - \bar{r}^2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (8b)$$

Also,

$$A_n = \frac{1}{2\,R_n}\left(\frac{1 - \bar{r}^{2n}}{n} - \frac{1 - \bar{r}^{2n-2}}{n+1}\right) \ldots\ldots\ldots\ldots (9a)$$

$$B_n = \frac{1}{2\,R_n}\left(\frac{1 - \bar{r}^{2n}}{n} - \frac{1 - \bar{r}^{2n+2}}{n-1}\right) \ldots\ldots\ldots\ldots (9b)$$

$$C_n = \frac{\bar{r}^n}{2\,R_n}\left(-\frac{1 - \bar{r}^{2n}}{n} + \frac{1 - \bar{r}^{2n-2}}{n+1}\,\bar{r}^2\right) \ldots\ldots\ldots\ldots (9c)$$

$$D_n = \frac{\bar{r}^n}{2\,R_n}\left(-\frac{1 - \bar{r}^{2n}}{n}\,\bar{r}^2 + \frac{1 - \bar{r}^{2n+2}}{n-1}\right) \ldots\ldots\ldots\ldots (9d)$$

In Eqs. 8 and 9,

$$R_n = (1 - \bar{r}^{2n})^2 - n^2\bar{r}^{2n-2}\,(1 - \bar{r}^2)^2 \ldots\ldots\ldots\ldots (10)$$

The series, Eq. 6, and hence the expressions for the stresses, Eqs. 7, require explicitly the knowledge of the Fourier coefficients a_n of the boundary stresses. Substituting Eqs. 5 in Eq. 6, and differentiating Eqs. 7, the following expression is derived for the stress σ_θ normal to the critical section $\theta = 0$:

$$\sigma_\theta = \left.\frac{\partial^2 \phi}{\partial r^2}\right]_{\theta=0} = \frac{P\,K}{\pi\,r_o} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

in which

$$K = 2\,(A_o + 4\,B_2) - B_o\left(\frac{r_o}{r}\right)^2 + \sum_{n=2,4,\ldots}^{\infty}\left[P_n\left(\frac{r}{r_o}\right)^n + Q_n\left(\frac{r_i}{r}\right)^{n+2}\right] \ldots (12)$$

In Eq. 12, the coefficients P_n and Q_n are defined as:

$$P_n = 2\,n\,(n+1)\,(n+2)\,A_n + 2\,(n+1)\,(n+2)^2\,B_{n+2};\ n = 2, 4, \cdots \ldots (13a)$$

and

$$Q_n = \left(\frac{2}{\bar{r}^2}\right)[n^2\,(n+1)\,C_n + n\,(n+1)\,(n+2)\,D_{n+2}];\ n = 2, 4, \cdots \ldots (13b)$$

The constants $A_n, \cdots, D_n$ are defined by Eqs. 9. The power series, Eq. 12, however, converges for all values of r such that $r_i < r < r_o$ because P_n and Q_n

remain less than some fixed upper limit b as n approaches infinity; hence,

$$\sum \left[P_n \left(\frac{r}{r_o}\right)^n + Q_n \left(\frac{r_i}{r}\right)^{n+2} \right] \leqq b \sum \left(\frac{r}{r_o}\right)^n + b \sum \left(\frac{r_i}{r}\right)^{n+2} \quad \ldots .(14)$$

Since the right-hand member of Eq. 14 represents a geometric series with a ratio less than unity, it converges, as does the left-hand member by the comparison test. (For a discussion of the properties of an infinite series refer to the work of I. S. Sokolnikoff and E. S. Sokolnikoff.[13])

Even though Eq. 14 was derived from a nonconverging Fourier development, it represents, correctly, the stress in the interior of the ring because the "singular" stress function σ_r, as given by Eqs. 3, can be approximated by an arbitrarily close continuous distribution $\sigma^k{}_r$ (and hence a distribution whose Fourier expansion converges), with Fourier coefficients $a^k{}_n$. (For example,

$$\sigma^k{}_r = \sum_n \frac{2\,P}{\pi} \frac{\sin \frac{n}{k}}{\frac{n}{k}} \cos (n\,\theta); \quad n = 2, 4, \cdots \ldots\ldots\ldots\ldots (15)$$

which approaches σ_r as k approaches ∞, and as $a^k{}_n$ approaches $\frac{2\,P}{\pi}$.) The representation in the interior (Eqs. 10 and 11) for this distribution (denoted by $\sigma^k{}_\theta$) will be legitimate—that is, symbolically,

$$\sigma^k{}_\theta\,(r) = F[a^k{}_n] \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (16)$$

in which the brackets denote simply that the stress varies in some explicit manner with $a^k{}_n$. In any closed subinterval $(r_i + \epsilon) \leqq r \leqq (r_o - \epsilon)$, for arbitrarily small ϵ, the power series is uniformly convergent and hence varies

continuously with its coefficients,[13] in other words, as $a^k{}_n$ approaches a_n—

$$\underset{k\to\infty}{\text{Limit}}\ \sigma^k{}_\theta = \underset{k\to\infty}{\text{limit}}\ F\,[a^k{}_n] = F\,[\text{limit}\ a^k{}_n] = F\,[a_n] = \sigma_\theta \ldots\ldots (17)$$

which is a restatement of Eqs. 11 and 12.

The condition that r shall remain in the interior of the ring is an essential requirement in the foregoing proof. If $r = r_o$ is substituted in Eq. 12, the

[13] "Higher Mathematics for Engineers and Physicists," by Ivan S. Sokolnikoff and Elizabeth S. Sokolnikoff, McGraw-Hill Book Co., Inc., New York and London, 2d Ed., 1941.

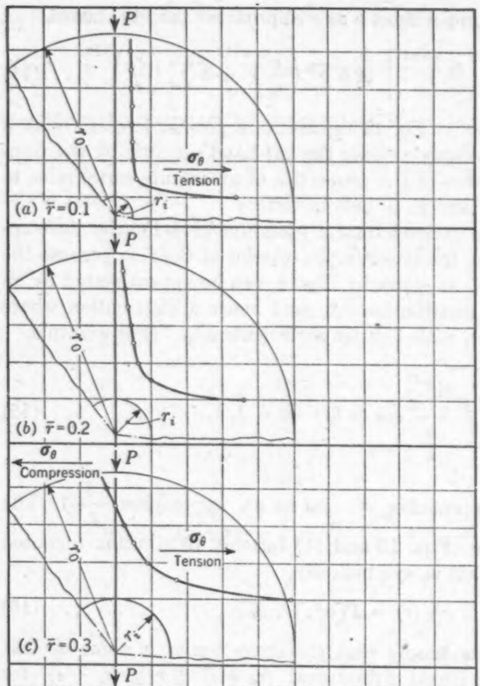

FIG. 2.—STRESSES NORMAL TO SECTIONS AT $\theta = 0$ AND $\theta = \pi$

series remains convergent, nevertheless. The value so obtained, however, is not the actual stress under the load (this stress is infinite, as discussed subsequently herein, under "Discussion of Wedge Action"[14]) but should be interpreted as the limiting value for $r = r_o - \epsilon$ as ϵ tends to become zero.

Numerical values or curves of the critical stress $\sigma_\theta]_{\theta=0}$ are most conveniently expressed in terms of the "concentration factor" K, defined by Eq. 12, from which the critical stress is obtained by using Eq. 11. Curves of K expressed as a function of r for various values of r_i/r_o have been plotted in Fig. 2. The segments of a loaded ring on which the stress distributions are shown for each of the five values of $\bar{r} = r_i/r_o$ are intended to show precisely how the stress varies along the critical plane, the edge of which appears as the vertical axis of the plot. The typical ring diagram in Fig. 3 depicts the infinitesimal "stress rectangle" showing the directions of the principal stresses. The numerical values of K in Table 1 were computed to five places, carefully checked by duplication and by using various relations, and then rounded to four

[14] "Theory of Elasticity," by S. Timoshenko, McGraw-Hill Book Co., Inc., New York and London, 1st Ed., 1934, p. 96.

places. In order to use the tables, or the curves, to obtain the stress at a distance r from the center of a given ring, it is necessary first to select the proper value of K in Table 1, and then to multiply by a constant as given by Eq. 11.

Thus, as an example, suppose the ring test is applied to a concrete specimen 2 in. thick having the outer radius $r_o = 10$ in. and the inner radius $r_i = 1$ in. If the applied load is 1,000 lb, what is the value of the stress σ_θ along the critical section 4 in. from the center? In this example, $\bar{r} = 0.1$ and $r/r_o = 0.4$, and Table 1 then gives $K = -0.99$ approximately. Since the load per unit thickness, P, equals -500 lb, Eq. 11 gives $\sigma_\theta = \dfrac{-500 \times -0.99}{3.14 \times 10} = 16$ lb per sq in.

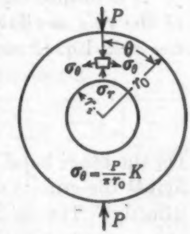

Fig. 3

Examination of the curves of Fig. 2 or of the data in Table 1 shows that the maximum tensile stress in the critical section occurs at the inner boundary $r = r_i$. This fact is most interesting because at this point failure is to be expected in brittle materials such as rocks or concrete, which are strong in compression and relatively weak in tension. Consequently, Fig. 4, showing the concentration factor K at the point $r = r_i$ as a function of $\bar{r}$, has been prepared to permit finding K for values of $\bar{r}$ other than multiples of 0.1. By reading this factor from the curve it is then possible to compute the "failure" stress of rings with any ratio of diameters between 0.0 and 0.5 by substituting the ultimate failure load per unit thickness, for P in Eq. 11. Thus, in the foregoing example, K for $r = r_i$ is -6.4; and, if failure of the specimen occurs at 6,000 lb, the failure stress in tension is $\sigma_\theta = \dfrac{3{,}000 \times -6.4}{3.14 \times 10} = 610$ lb per sq in.

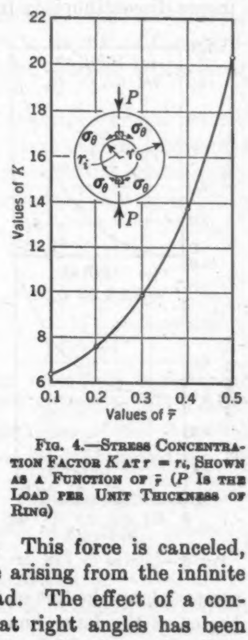

Fig. 4.—Stress Concentration Factor K at $r = r_i$, Shown as a Function of $\bar{r}$ (P Is the Load per Unit Thickness of Ring)

Discussion of Wedge Action

It is certainly apparent from inspection of the stress distribution curves of Fig. 2 that the resultant force over the critical section is not zero as should be required for equilibrium. As a matter of fact, the resultant force is P/π for each diameter ratio. This can be proved from the relation,

$$F = \int_{r_i}^{r_o} \sigma_\theta \, dr = \frac{\partial \phi}{\partial r}\bigg]_{r_i}^{r_o} = \frac{P}{\pi} \quad \ldots\ldots (18)$$

in which ϕ is the stress potential given by Eq. 6. This force is canceled, however, by an equal and opposite tangential force arising from the infinite stress, previously mentioned, directly under the load. The effect of a concentrated load in producing a concentrated force at right angles has been discussed by various writers[14] and is usually referred to as "wedge action."

Also, as the diameter ratio $\bar{r}$ $(= r_i/r_o)$ of the ring increases, the stress distribution more nearly approximates that expected from the linear bending theory of curved bars. On the other hand, for the smaller values of r_i, the stress is practically uniform over the cross section except for the singularity at the load and the high local stress concentration at the inner boundary.

It is of interest to consider the limiting case in which the inner radius, r_i, of the ring is allowed to approach zero, giving in effect a circular disk. If $r = r_i$ in Eq. 12 and then if r_i approaches zero:

$$\underset{r_i \to 0}{\text{Limit}}\ \sigma_\theta \Big]_{r = r_i} = \frac{6\,P}{\pi\, r_o} \quad \ldots\ldots\ldots\ldots (19)$$

On the other hand, if $r_i = 0$ is used directly in Eq. 12, the stress distribution across the critical section of a circular disk under diametral loads is obtained directly. The result is a uniform tension with a magnitude of

$$\sigma_\theta = \frac{P}{\pi\, r_o} \quad \ldots\ldots\ldots\ldots (20)$$

This result agrees with previous studies of this problem; and, if an infinitesimally small hole is made at the center of a circular disk of radius r_o under concentrated diametral loads, the stress at the hole normal to the load axis passes discontinuously from the value $\dfrac{P}{\pi\, r_o}$ to $\dfrac{6\,P}{\pi\, r_o}$.

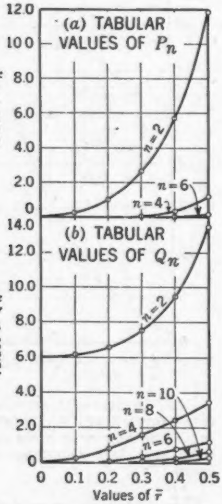

FIG. 5.—CURVES OF EQS. 12

Fig. 5 shows the coefficients P_n and Q_n, Eq. 12, plotted as functions of $\bar{r}$ and r. These curves illustrate the rapidity with which these functions converge and also provide a convenient method for extending the stress computations to intermediate values of $\bar{r}$. For more accurate work, the values in Table 2 may be used. These values were computed only to five places.

The singularity under the load quite naturally raises the question why, in spite of the infinite value of the stress at that point, a finite stress at $r = r_i$ should cause failure. One explanation that is advanced is that a slight plastic deformation occurs under the load which causes such a redistribution of load that the infinite stress over an infinitesimal area is changed to a finite stress over a finite area. If the material is as strong in compression as, say, concrete, such a redistribution would not materially affect the stress at an appreciable distance from the load. In actual tests, almost invariably, the failure begins at $r = r_i$ in the plane of the load and progresses along the line of the load to the outer boundary. To show that failure begins at the inner boundary a number of tests were stopped and the load was removed in time to halt the progression of failure, leaving the ring

cracked from the inner boundary to a point near the outer boundary but still in one piece.

The ring test should be used with caution for concrete specimens because of the tendency of concrete to creep under tensile stress. Creep or plastic flow in the region of the high tensile stress concentration at the inner boundary may cause an appreciable redistribution of stress which, in turn, will make these methods of interpreting results erroneous. If the test is used for concrete specimens, the inner diameter should be large relative to the size of the aggregate, to reduce the effects of the local conditions of the concrete at the inner boundary.

The plane disk may have an advantage in that the stress on the section through the plane of the load is uniform. Nevertheless, the plane disk is not satisfactory as a test specimen because there is no point in the critical plane where one or the other of the principal stresses becomes zero, as is desirable in pure tension tests.

APPENDIX. NOTATION

The following symbols, used in the paper, conform essentially to American Standard Letter Symbols for Mechanics, Structural Engineering and Testing Materials (ASA—Z10a—1932) prepared by a Committee of the American Standards Association, with Society representation, and approved by the Association in 1932:

A = an arbitrary mathematical coefficient, with appropriate subscript, as required (also B, C, and D);
a = a coefficient in the Fourier series; a_o and a_n in Eqs. 2;
b = a fixed upper limit for the coefficients P_n and Q_n in Eq. 12 (see Eq. 14);
F = resultant force;
K = a concentration factor;

k = a parameter, or index, in Eq. 15;
n = a number;
P = a concentrated ultimate failure load, per unit of ring thickness;
P_n = coefficient in Eq. 12;
Q_n = coefficient in Eq. 12;
R = a substitution constant (see Eq. 10);
r = radius; a polar coordinate:
  r_i = inner radius of ring;
  r_o = outer radius of ring;
  $\bar{r} = r_i/r_o$ = diameter ratio;
ϵ = increment of radius;
θ = angular distance; a polar coordinate;
σ = unit stress:
  σ_r = radial stress;
  σ_θ = tangential stress;
τ = shear stress; $\tau_{r\theta}$ = tangential shear stress; and
ϕ = a function of r and θ (see Eq. 6); stress potential.

DISCUSSION

Robert R. Philippe[15] and Frank M. Mellinger,[16] Assoc. Members, ASCE.—The development, by Messrs. Ripperger and Davids, of L. N. G. Filon's formal solution to evaluate the critical stresses in circular rings is an excellent contribution, particularly in the testing of brittle materials. The original application of the "ring test" is attributed to Max M. Frocht of the Carnegie Institute of Technology, Pittsburgh, Pa., who had used this type of test to measure the tensile strength of bakelite. Inasmuch as the shape of specimen required is easily cut and drilled from cylindrical cores, the test was adapted to the testing of concrete and foundation rock in connection with the design of concrete dams. More recently the test has been applied with promising results to the evaluation and correlation of aggregate quarry cores. However, this discussion will be limited to the application of the ring test in determining the physical properties of the more massive types of foundation rocks.

If the tensile strength of a brittle material is determined by a ring test and its compressive strength is measured by an unconfined compression test, these two points will serve to define O. Mohr's[17] envelope of rupture for perfectly brittle material (Fig. 6). This envelope can be expressed as Coulomb's equation

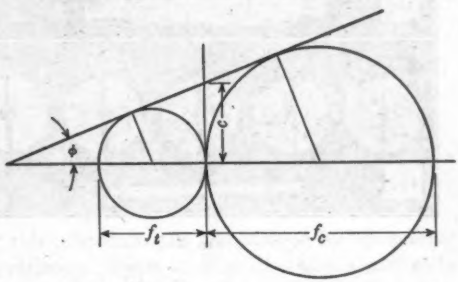

Fig. 6.—Mohr's Envelope of Rupture

$$\tau = c + p \tan \phi \qquad (21)$$

in which τ is the unit shearing strength; c is the apparent unit cohesion; p is the unit normal load; and ϕ is the angle of internal friction.

By examination, the following relationship of ϕ and c results in terms of the tensile strength f_t and unconfined compressive strength f_c.

$$c = \frac{f_t}{2 \cos \phi} (1 + \sin \phi) \qquad (22a)$$

and

$$\phi = \text{arc} \sin \frac{f_c - f_t}{f_c + f_t} \qquad (22b)$$

The application of the ring test for measuring the tensile strength of rock does make use of the assumption (upon which the authors' computations are based) that the tested material is truly elastic. Within the limitations of this as-

[16] Senior Engr., Ohio River Div. Laboratories, Mariemont, Ohio.

[17] "Abkandlungen aus dem Gebiete der Technischen Mechanik," by O. Mohr, W. Ernst, Berlin, 1914.

sumption a ring specimen prepared and tested as described in this paper will yield the tensile strength of a brittle material by applying an adaptation of Eq. 20:

$$f_t = \sigma_\theta = \frac{P}{\pi\, r_0} K \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (23)$$

Photographs of nominal rock specimens 3 in. and 6 in. in diameter which have been so tested are shown in Fig. 7. The regularity of the vertical break; the uniformity of results from two specimens, each cut from the ends of a compres-

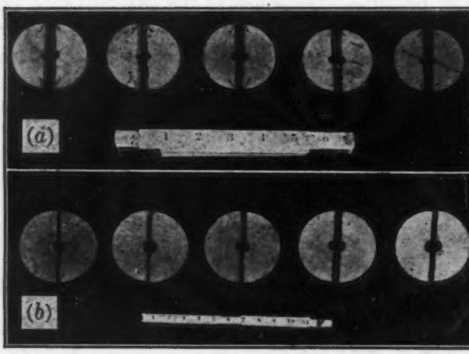

FIG. 7

FIG. 8

sion specimen; the sensitive result; and the plausibility of over-all results—at least make this test useful for comparative purposes.

The compressive strength f_c is measured by a simple, unconfined, compressive test on the rock. A specimen is prepared by cutting a rock core into a length equal to about twice the diameter, then lapping the end surfaces until they are truly perpendicular to the axis of the core. Extreme care in preparation is needed for good results, an outstanding example of which is shown in Fig. 8. The sharpness of the break shown on this photograph suggests another means of measuring the angle of internal friction. The angles of rupture (θ) according to J. B. Johnson[18] should bear the following relationship to the angle of internal friction (ϕ):

$$\phi = 2\,(\theta - 45°) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (24)$$

Generally the angles found in this manner are from 2° to 5° greater than those found by the measurement of f_t and f_c. In the case of the Sutton sandstone, illustrated in Fig. 8, the angle of fracture varied between 68° and 70°. By Eq. 24 the angle of internal friction is computed to be between 46° and 50°, as against the value of 46° determined by the measurement of f_t and f_c.

Table 3 lists some dam sites at which foundation investigations have yielded 3-in. and 6-in. rock cores that have been tested by the measurement of f_t using

[18] "The Materials of Construction," by J. B. Johnson, John Wiley & Sons, Inc., New York, N. Y., 1898, p. 25.

the ring test and f_c. The results are encouraging in so far as they are consistent with the classification and the relative appearance of these rocks. In addition there is a degree of correlation between the type of rock, its void ratio, and its physical properties as revealed by this method.

[a] Ratio of the volume of voids to the volume of the solids.

Further means of checking this procedure can be obtained by conducting triaxial tests on cylindrical specimens. Steps in that direction are already being taken by the staff of the Ohio River Division Laboratories. However, the triaxial test requires apparatus and technique far too complicated for normal use; it is anticipated that its greatest value will be in obtaining measurements of stress and strain on the more critical specimens revealed by the ring and compression test results.

The need for a dam in some general locality is not often fixed by the quality of its foundation. The increasing size of dams, the complication of types of concrete sections, and the price competition of earth dams are making it more necessary to take advantage of all there is to know of the physical properties of the materials of construction. It is believed that the ring test for tensile strength determinations will be a very useful means of judging these properties.

E. P. POPOV,[19] JUN. ASCE.—The problem of determining the critical stresses in a circular ring, subjected to two concentrated opposing radial forces on the outer boundary, is not a new one. The solution is of practical importance in certain bearing and machine design problems as well as in the case cited by Messrs. Ripperger and Davids.

Since the series used by the authors to obtain a solution is shown to be nonconvergent in expressing the radial boundary stresses under the concentrated loads, the procedure may appear questionable. The use of this nonconvergent

[19] Asst. Prof., Civ. Eng., Univ. of California, Berkeley, Calif.

series can be avoided entirely by a method first suggested by S. Timoshenko.[4,20] Such a method was further recommended by L. N. G. Filon.[7] The Timoshenko method utilizes a known finite solution for two equal and opposite concentrated radial forces applied on the outer boundary of a solid cylinder. Then a concentric hole, equal to the bore of the hollow cylinder, is cut out of such a solid cylinder. Normal and shearing forces exist as distributed forces around the edge of the hole to maintain the state of stress in the remaining hollow cylinder equivalent to that in the original solid one. These edge forces can be expressed by convergent series. Application of equal and opposite forces around the edge of the hole can then be used for the determination of the constants of integration in the stress function[21] in terms of these boundary stresses. The resulting stresses are superposed on the stresses obtained from the finite solution of a solid cylinder to obtain true stress in a hollow cylinder. Displacements can be treated in a similar manner.

The special case of this problem by the foregoing method for $\bar{r} = 0.5$, as noted, was solved by Professor Timoshenko,[4,20] and extended further by his students. The case of $\bar{r} = \frac{1}{3}$ was solved by V. Billevicz,[22] and a general solution for any value of $\bar{r}$ was obtained by J. Maulbetsch, as reported by C. W. Nelson.[23]

The foregoing method involves the use of certain series. The radial, tangential, and shear stresses for a solid circular cylinder in the series form are shown[23] to be:

$$\sigma_r = \frac{2P}{\pi r_o}\left[-\tfrac{1}{2} + \cos 2\theta - \left(2\frac{r^2}{r_o^2} - \frac{r^4}{r_o^4}\right)\cos 4\theta + \left(3\frac{r^4}{r_o^4} - 2\frac{r^6}{r_o^6}\right)\cos 6\theta \cdots\right] \ldots\ldots\ldots\ldots\ldots\ldots (25a)$$

$$\sigma_\theta = \frac{2P}{\pi r_o}\left[-\tfrac{1}{2} + \left(2\frac{r^2}{r_o^2} - 1\right)\cos 2\theta - \left(3\frac{r^4}{r_o^4} - 2\frac{r^2}{r_o^2}\right)\cos 4\theta \cdots\right] \ldots (25b)$$

and

$$\tau_{r\theta} = -\frac{2P}{\pi r_o}\left[\left(1 - \frac{r^2}{r_o^2}\right)\sin 2\theta - 2\left(\frac{r^2}{r_o^2} - \frac{r^4}{r_o^4}\right)\sin 4\theta + 3\left(\frac{r^4}{r_o^4} - \frac{r^6}{r_o^6}\right)\sin 6\theta \cdots\right] \ldots\ldots\ldots\ldots\ldots\ldots (25c)$$

[23] "Stresses and Displacements in a Hollow Circular Cylinder," by C. W. Nelson, thesis presented to the Univ. of Michigan at Ann Arbor in 1939 in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

These series are convergent and with a desired value of radius r can be used as the boundary stresses at the bore. In these series the angle θ is measured from a horizontal axis to the right of the origin. The loads are applied vertically.

For the derivation of Eqs. 25, and of other formulas pertaining to the analytical solution of the hollow circular cylinder, the readers are referred to Mr. Nelson's dissertation,[23] in which the problem is fully treated. However, for the purposes of comparison with the paper by Messrs. Ripperger and Davids, certain critical values compiled by Mr. Nelson are quoted. Perhaps the most significant points of stress on the hollow cylinder are those marked 1, 2, 3, and 4 in Fig. 9. The stress concentration factors for the tangential stresses corresponding to these points are shown in Table 4 for the different diameter ratios. The factors of stress concentration for the maximum tensile stresses are given through and beyond the diameter ratios presented by the authors in Table 1. Table 4 also shows some other values for additional points that may be of interest. The comparable points of stress are in complete agreement with the results obtained by Messrs. Ripperger and Davids, which is reassuring. In connection with Table 4, it may be worthy to note that, in these elastic analyses, only small deformations are considered, and thus a solution for a case such as $\bar{r} = 0.9$ should be questioned.

0.1	10.108	− 6.385	− 0.143	−0.816

The solution devoelped by the authors, as well as the one used for obtaining the results shown herein, treats the problem of a hollow cylinder as a two-dimensional problem. In practice, including the case of foundation rock samples, the cylinder is of finite length, compressed between the flat surfaces of two larger bodies. The latter is not a two-dimensional problem. Actually the load distribution along the length of the load is not uniform.

Theoretically, considering the pressures between two bodies in contact, Mr. Nelson[23] shows that the load distribution along the length of the cylinder is approximately uniform except near the ends of the areas of contact, provided the width of actual contact is small compared to the length of the

cylinder.[24] Since such requirements are usually met, these solutions are adequate.

The theoretical results are further verified by photoelastic tests briefly reported by O. J. Horger.[25] More details pertaining to these tests may be of interest and some are cited,[23] for comparison, in Table 5. The agreement between the theoretical and experimental results is seen to be excellent.

The writer is happy to offer these comments from a source not generally available as a verification and extension of the results presented by the authors.

E. A. RIPPERGER,[26] ESQ., AND N. DAVIDS,[27] ESQ.—Messrs. Philippe and Mellinger have described one practical application involving the use of the theoretical calculations contained in this paper, and, as Mr. Popov has suggested, there are no doubt many others. The wide variations in the nature of the stress distribution at the so-called critical section, as illustrated in Fig. 2, make it necessary, however, to use a great deal of caution in applying these theoretical results to the calculation of failure stresses for even relatively brittle materials. To illustrate and emphasize this point the data in Table 6 have been compiled. These computed failure stresses for concrete rings having the dimensions shown were calculated through the use of Eq. 11.

Specimens were moist cured for 28 days before testing and the maximum size of the aggregate was approximately $\frac{3}{4}$ in. The apparent increase in tensile strength as the value of $\acute{r}$ decreases is believed to be due chiefly to the decrease in linearity of the stress distribution at the critical section as $\acute{r}$ becomes small. A small plastic yielding of the concrete at the critical point enables the ring with $\acute{r} = 0.1$ to withstand a much larger increase in the load (P) required to cause failure, than a similar deformation would cause in a ring with, say, $\acute{r} = 0.3$. It will also be noted that variations of calculated strength from speci-

men to specimen are greater for $r = 0.1$ than they are for larger values of r. This may be attributed to the fact that, for the case where $r = 0.1$, the hole in the ring represents a discontinuity of the same order of magnitude as the discontinuities introduced by the larger aggregate particles.

Mr. Popov implies that the use of coefficients taken from the nonconvergent boundary stress series in the development of a convergent series to represent interior stresses is a questionable procedure which should have been avoided by the use of Professor Timoshenko's method. Although it is certainly true that nonconvergent series must be used with much caution in mathematical processes, the procedure followed in this paper is shown to be quite correct (see the discussion of that point and the continuity proof, Eqs. 14, 15, 16, and 17) and at least a part of any value this paper may have lies in that demonstration. Despite the general mistrust of nonconvergent series by mathematicians, several problems in mathematical physics have been correctly solved by such series.[28] The ring problem is another example.

The question as to whether or not a loaded circular ring actually represents a case of plane stress does not arise in theoretical treatment of the problem, for it is assumed that the load is distributed in such a way as to give a plane-stress condition. The question does arise, however, when any practical application of the calculated results is contemplated, and Mr. Popov is to be commended for having posed the question and then answered it.

The authors are indebted to Mr. Popov for having brought to their attention some excellent work done on this problem, of which they were unaware at the time of their own investigation.

EXPRESS HIGHWAY PLANNING IN METROPOLITAN AREAS

By Joseph Barnett,[1] M. ASCE

With Discussion by Messrs. Harry W. Lochner, Fred Lavis, Homer M. Hadley, Donald M. Baker, W. J. Van London, Merrill D. Knight, Jr., R. H. Baldock, Jacob Feld, Harold M. Lewis, Theodore T. McCrosky, Spencer A. Snook, Lawrence S. Waterbury, Bernard L. Weiner, George H. Herrold, Ralph R. Leffler, M. Hirschthal, and Joseph Barnett.

Synopsis

Perhaps, the need for free-flowing highway facilities to relieve traffic congestion in cities is evident, but attention is focused on this need by the superior facilities available on arterial routes in rural areas as compared with those in urban areas. The factors that influence the locations of arterial routes in cities and their effect on the city plan are discussed. The need for obtaining factual data is emphasized and the pattern of arterial routes developed in representative cities is shown. Brief comment is included on the subjects of by-passes versus radial routes, the need for flexibility, the use of existing streets, and the terminal problem. Relative merits of different types of expressways are presented. The need for, and description of, preliminary engineering reports to unite the numerous interested agencies are detailed, and an economic analysis of each project is suggested.

Introduction

Modern development of highway transportation has resulted in large differences between rural and urban roads, expecially in regard to the capacity of such roads to serve the traffic using them. Many cities are approached by numerous good roads of adequate capacity in rural and suburban areas; but in cities themselves, where the traffic reaches its highest volumes and where, therefore, there is the greatest justification for facilities permitting uninterrupted flow, the stops necessitated by street intersections increase in frequency, the average speed of travel decreases, and inconvenience and cost of motor

Note.—Published in March, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Chf., Urban Road Div., U. S. Public Roads Administration, Federal Works Agency, Washington, D. C.

vehicle operation rise sharply. The streets affected have undergone a progressive change in function from predominantly serving land to similarly predominantly serving new and mounting arterial traffic flows. Such improvements as have been made have generally been designed to combine in one facility the service of both classes of traffic, the local and the arterial. As yet there have been few instances in which the desirable separate provision for arterial traffic has been attempted.

With the increase in motor vehicle travel, it was inevitable that this unbalanced provision of highway facilities in urban and rural areas would contribute to the decentralization of cities. Suburban housing developments naturally were near main radial routes out of the cities. The typical distribution of city population is created by many factors, and it is not the writer's intention to delve into them except to emphasize that the improvement of radial routes in the adjacent suburban and rural areas, without comparable improvements within the cities, was one of these factors. Most cities present the pattern of a central business or commercial district, an adjacent ring of dilapidated old buildings, generally old residences (either converted to commercial use or allowed to run down to substandard housing), a surrounding area of medium-grade or high-class housing of more than average density, and a creeping or fingerlike development—new, heterogeneous, and uncontrolled—along the radial routes leading out of the city.

In most instances the radial routes present a picture that is far from pretty. Unrestricted development along the roadsides has made entrances to cities via highways as unattractive as entrances via railroads. Instead of the industrial development that borders the railroads, the highways are fringed by a conglomeration of roadside businesses which, with their varied and blatant signs, vie with one another for the attention of travelers, detract from the sightliness of the city's gateway, and constitute a positive detriment to efficient highway transportation. To the credit of the railroads it may be stated that, except for grade crossings, which are gradually being improved in operation or eliminated, the roadbeds are as useful today for the movement of trains as when they were built. Contrariwise, on the average highway approaching a city, each new roadside business contributes its measure of interference, and the accumulation of such interferences steadily decreases the capacity of the road and its effectiveness in serving moving vehicles. A creeping obsolescence develops which is no fault of the highway engineer; it is rather the fault of antiquated laws and the pressure of real estate interests which make it difficult and, in some cases, impracticable to protect the traffic facility from roadside interference.

By-Passes

By-passes have frequently been constructed around cities on the theory that the adequacy of existing city streets would be improved by rerouting the cars of travelers who do not wish to stop in the city. Another justification for such by-passes, frequently cited, is the removal of heavy commerical vehicles from the main street, along which the through route usually is located. This expedient might offer not only the advantage of traffic relief but also the elimination of the noise and odor common to such commercial carriers. In

many cases by-passes have proved to be useful adjuncts; and, indeed, they should be considered for many municipalities where traffic data indicate that the need exists and where physical conditions permit. On the other hand, the fallacy of planning by-passes as a general solution of the city traffic problem has been glaringly revealed by the state-wide planning surveys, and other studies, which have shown that the bulk of the traffic approaching the larger cities is destined for points within the city itself and, for that reason, cannot be by-passed. Commonly, less than 10% of the traffic approaching cities of more than 300,000 population is destined for points beyond the urban area. By-passable traffic is about 20% in cities with populations of from 10,000 to 300,000, and only in communities of 2,500 or less does the by-passable traffic normally reach 50% of the total traffic.

Radial Highway Arteries Are the Greatest Need

Numerous fact-finding agencies have brought many highway transportation problems into focus. As a result, it has become increasingly clear that so much of the total traffic is urban in character that the need for allocation of funds for the improvement of highway facilities in metropolitan areas can no longer be ignored or relegated to a position of secondary importance. It has become clear, also, that traffic congestion in cities will be solved to the greatest extent feasible by the construction of facilities that permit the uninterrupted flow of traffic into and through the cities. The appalling number of traffic accidents is continually in the minds of highway planners; and, since most accidents occur at intersections in cities and a frequent type involves pedestrians, it is inevitable that the accident rate will be reduced by providing express highways on which crossings at grade are eliminated and pedestrians are not in close proximity to moving vehicles. As a consequence, highway planners have been giving preferential attention to plans for express highway projects that will provide solutions to the serious problems of city traffic congestion.

The mounting interest in urban arterial roads has been due to three general factors—(1) Availability of factual data; (2) necessity for accumulation of plans; and (3) the consciousness that planning for congestion relief has been inadequate.

(*1*) *Factual Data.*—Factual data regarding the movement and the origin and destination of motor vehicles in and approaching cities have been collected by various organizations such as state highway departments, other state agencies, county and city engineering organizations, planning commissions, and consultants. As a rule, these data leave much to be desired. Many cities have fairly good flow maps of traffic. Many cities have origin and destination data taken at an external cordon of stations on the main radial approach roads. Few cities have comprehensive origin and destination data that cover important intracity travel. However, regardless of the variation in the quantity or kind, such data almost always indicate that the most useful arterial road would be located radially with respect to the central business district. Since adequate traffic data reveal many more important needs, administrators supplied with such data have the comforting realization that they can proceed with plans with reasonable assurance that their judgment is based on, and backed by, facts.

Of all the varied data bearing on the planning of expressways in cities those showing the origin and destination of all traffic—through, suburban, and intracity—are most important in determining preliminary location of the expressway itself and in determining both the locations of access connections and the volumes of interchange traffic for which the expressways should be designed. The methods heretofore used in making comprehensive origin-destination studies are costly, laborious, and time consuming; and it is small wonder that few cities have undertaken to obtain data by such methods. The Public Roads Administration, Federal Works Agency, with the assistance and advice of experts of the Bureau of the Census, U. S. Department of Commerce, has developed a method for obtaining origin-destination data which promises to reduce cost, labor, and time sharply and at the same time enables the planner to arrive at more complete, accurate, and useful data. The method, roughly, follows the small-sample interview method used by public opinion polls except that the questions deal with travel facts such as "Where did you go yesterday, how, and for what purpose?" The questions are asked of occupants of a small percentage of selected sample dwellings in an area such as a census tract or part of tract, and the data obtained are expanded in proportion to the total dwellings of that area. Such questioning can be made by paid interviewers as rapidly as needed. The answers are transferred to coded punch cards from which the numerous factual data are summarized. A check on accuracy can be made by measuring traffic volumes at certain control points, such as river crossings and major intersections. As a result of the splendid cooperation of the officials of the cities and of the state highway departments, this method has been used, or is being used, in about thirty-eight metropolitan areas, and the number of cities is growing rapidly. It is felt that the "bugs" in the method have been eliminated.

Sometimes origin-destination data of traffic approaching a metropolitan area at a cordon of stations will be sufficient for locating an expressway. Such data will include by-passable traffic and traffic having a destination, or making a stop, in the city but the important intracity travel is missed. Origin-destination data at each station of a cordon are obtained by interviewing the drivers of a small percentage of vehicles leaving the city and expanding the results to the total traffic volume measured at the same time.

(2) *Shelf of Plans.*—No small measure of interest in urban arterials is due to the necessity for providing a shelf of plans for the construction of needed public works so that the construction industry could be prepared to provide jobs as soon as necessary. Quite naturally, industries are geared to city areas, and whenever there is unemployment, the necessity for jobs will be most severe in cities.

(3) *Relief of Congestion.*—The most important factor creating interest in urban arterial highways is the realization that only a small "dent" has been made in the solution of the traffic problems in cities of the United States. It is a law of nature (and in many cases a fortunate one) that people tend to forget past troubles. In many cities traffic conditions improved during the imposition of wartime driving limitations—to some extent because of the reduction in the number of vehicles. To a great extent, road users have forgotten the pre-

war miseries of congestion and will not be content to return to them. Highway engineers realize that there has been a huge unsatisfied travel demand; and they realize that it is imperative to meet that demand by planning the construction of free-flowing facilities that will solve the problem of congestion in urban areas. Widening, traffic-light control, one-way streets, rerouting, no parking in rush hours, and many other palliatives have been of great help, and will continue to be used; but the urban traffic problem will not be solved without generous provision for free-flowing facilities that will permit the uninterrupted flow of vehicles between points near origins and destinations.

Pattern of Arterial Routes

Discussions with state, county, and city officials regarding needed arterial highway facilities in urban areas inevitably invoke the statement that the particular city in question is different—it has special problems and cannot be considered a normal city. These statements generally are believed to be true; yet, when a comprehensive system of arterial routes in a city is laid out for long-term development, that city assumes a pattern which is unmistakably like those for almost all other cities of the same size. Adequate traffic data and the judgment of competent highway engineers inevitably lead to the conclusion that, to serve traffic best, arterial routes should be located so that the through routes outside the city are connected with the central business district. Practical considerations, such as the high cost of property in the central business district, require that the lines be relocated a little, perhaps several blocks, to the fringe areas that are so common in many cities. In the fringe areas, buildings have been allowed to deteriorate because no agency existed to control city development. These areas could not compete with the less expensive land surrounding them when additional housing was being constructed because their proximity to business made the land potentially valuable, although the time for conversion to business had not yet arrived. The houses in these areas could be rented as dwellings to low-income groups or to some types of businesses, and so could pay the carrying charges while the owners hoped that commercial expansion would absorb them. There usually has been no incentive to maintain the houses in good condition.

When the routes leading to the central business district are connected along these fringes, the pattern takes shape. In the larger cities, the procedure consists of the construction of a close-in circumferential route from which arterial roads to the outskirts of the city, and beyond, radiate in several directions. The pattern may twist, bulge, or be cut off on one or more sides; the inner circumferential route may be round, square, or elongated; the radial routes may be somewhat circuitous; and a large body of water or other topographic feature may block radial roads in some directions—nevertheless, the pattern is apparent. Fig. 1 shows the arterial highways, both existing and planned, in Cleveland, Ohio, one of the larger cities of the United States. The shaded area indicates the central business district.

In large metropolitan areas another characteristic part of the pattern is the outer circumferential route and sometimes an intermediate circumferential route. These routes are useful and, in some cities, very necessary facilities for

traffic between the outskirts or suburban areas and between points near different radial routes. They are not first-order priority projects, however, although sometimes considered first because of the relative ease with which the right of way can be acquired.

The pattern of arterial routes just outlined, even though forced by the circumstance of available right of way, is close to ideal in many respects. One factor that must be emphasized in developing a system of arterial routes is flexibility—flexibility in choice of routes presented to a driver and flexibility in fitting future construction to future needs. When the central business district is surrounded by an inner circumferential route, a driver has wide latitude in

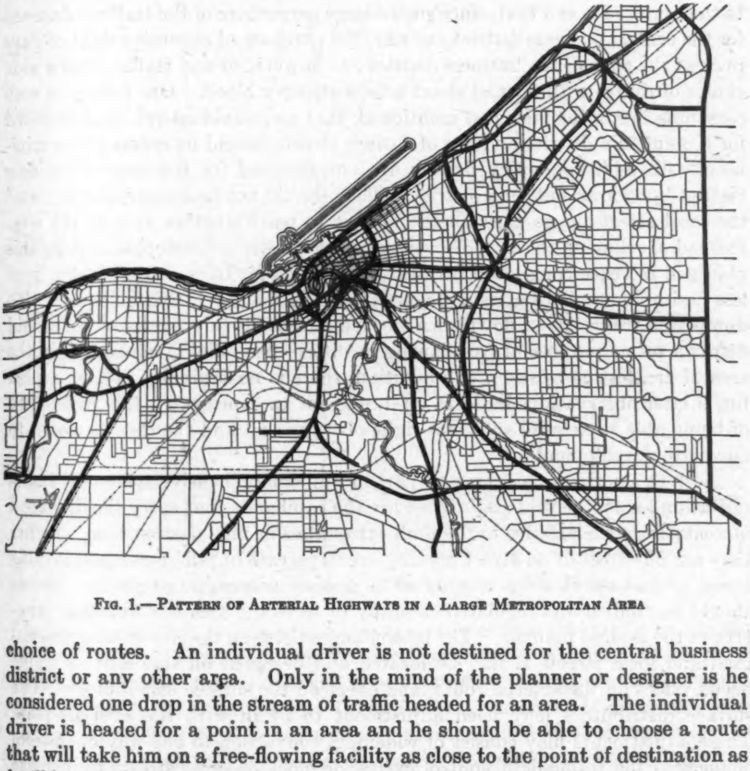

FIG. 1.—PATTERN OF ARTERIAL HIGHWAYS IN A LARGE METROPOLITAN AREA

choice of routes. An individual driver is not destined for the central business district or any other area. Only in the mind of the planner or designer is he considered one drop in the stream of traffic headed for an area. The individual driver is headed for a point in an area and he should be able to choose a route that will take him on a free-flowing facility as close to the point of destination as feasible. A flexible system of expressways will reduce his time of travel to a minimum and permit travel with ease and safety—the fundamental reasons for making the improvements and providing the service the road user expects. In addition, if the driver arrives as close to his destination as feasible on a free-flowing artery, he is not obligated to travel local streets any more than absolutely necessary, thus relieving congestion in the heart of the city where relief is needed most.

Use of Existing Streets

The thoughts just expressed are the essence of the opposition to quite a different line of thinking by some planners. It has been proposed that arterial routes need not be developed as free-flowing facilities throughout their length, but rather that a type of design should be used to insure free movement on the radial routes entering a city where the expense of development is not significant. Such roads should be connected to one street, and preferably two or more existing surface streets, widened if feasible, through the central business district. On behalf of this plan, it is argued that the chosen route would not have to be on the edge of the central business district, but could be brought directly to the center of it and that, since such a large percentage of the traffic is destined for the central business district anyway, the purchase of expensive right of ways in or at the edge of the business district can be avoided and traffic given a wide choice of routes with normal street access at every block. One fallacy in such reasoning lies in the fact, just mentioned, that an individual vehicle is destined for a point in a district and use of surface streets should be reduced to a minimum. In addition, many drivers are not destined for the central business district but for an outlying district. They should not be encouraged to travel the local streets to go through the city or to reach another area in the city. Instead of relieving the area of most severe congestion, development along this plan will increase congestion because free-flowing facilities attract traffic from less desirable parallel routes and generate traffic that never existed before. To dump this traffic on to downtown surface streets already overcrowded would defeat a prime purpose of free-flowing facilities—the relief of congestion in the area of greatest congestion. In addition, there is no flexibility in such a plan for, if later observations indicate vital need for an expressway, the probability of being able to acquire sufficient right of way is nil and the door is closed to adequate development.

Surface streets are a necessary part of any comprehensive system of transportation for motor vehicles. They are the capillaries that carry the life blood of a city from the arteries to the limb extremities or final destinations, whether they are off-street or on-street parking areas, private or public garages, loading areas, or just street stops to drop off or pick up passengers or goods. Streets should be studied and regulated carefully to serve the area and abutting property in the desired manner. The interchanges between the free-flowing arterial road and local streets should be located and designed on the basis of traffic needs, effect on the arterial route, and effect on the surface distributors. The surface distributors may need adjustment to fit in with the over-all plan. These adjustments may consist of widening, conversion to one-way operation, changes in the traffic-light control cycles, or blocking cross streets to increase storage capacity—or any or all of these. Experience indicates that a complete plan is much more than "bulling" through a free-flowing type of arterial highway.

Stage Construction

A complete system of free-flowing arterial highways cannot be built overnight or even in a few years. The cost per mile of such facilities is so great that

a program of construction usually will have to be spread over several years to finance the improvement. To this end, routes to be improved should be divided into project sections that can be completed and connected to existing facilities to bring an immediate return in the form of road-user benefits on the investment made. Projects also can be constructed in progressive stages so that they can be used as facilities far superior to existing ones but not yet up to the ultimate design. For example, where cross streets do not carry large volumes of traffic, a section of expressway ultimately to be depressed can be constructed at grade. Other sections can be constructed with traffic on minor cross streets forbidden from crossing but permitted to make right turns to and

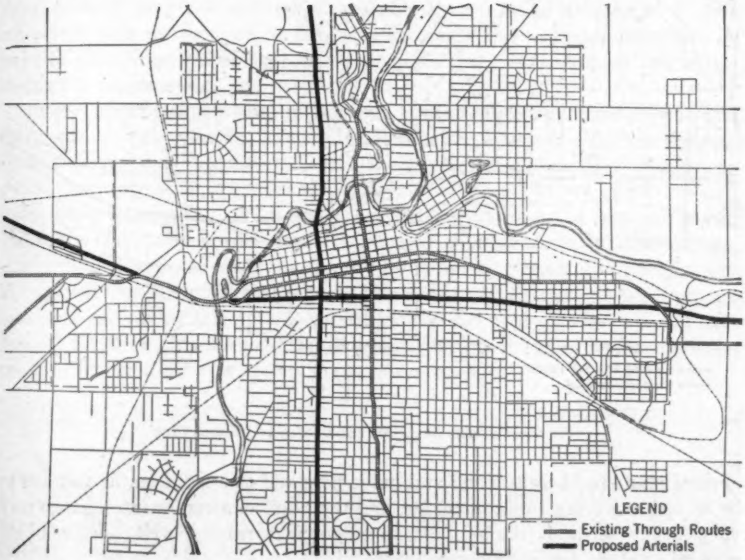

FIG. 2.—PATTERN OF ARTERIAL ROUTES IN A CITY OF MEDIUM SIZE

from the expressway. Only on important cross streets would traffic be allowed to cross. Parallel frontage roads sometimes can be provided to serve as terminals for minor cross streets and as protection for through traffic even where through traffic lanes are subject to traffic-signal control at important cross streets. A facility that permits almost uninterrupted flow of traffic can be provided by separating the grades at heavily traveled cross streets, allowing less important ones to cross at grade, and terminating all minor cross streets. Additional grade separations can be constructed as required. Where frontage roads are to be provided or existing streets serve as frontage roads, these roads may be used as an interim stage for through traffic until it becomes feasible to construct the through traffic artery. If the right of way for the ultimate development is available, numerous methods of stage construction can be employed.

Long-range predictions of future traffic requirements probably cannot be made with a high degree of precision. It becomes incumbent to develop, as well as possible, a broad general plan by which it will be possible to make such changes as may be found necessary to serve future traffic. The lines of a good

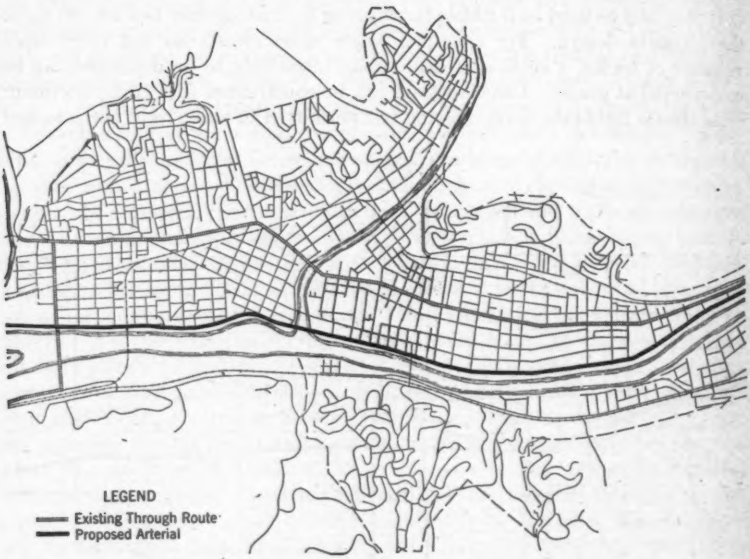

FIG. 3.—PATTERN OF AN ARTERIAL ROAD IN A SMALL CITY

general plan are likely to bend and bulge here and there, the traffic volumes to be served may vary to some degree, and the requirements for interchange may vary in number and volume; but the salient features of a well-conceived bold plan will not change appreciably.

The pattern of arterial routes just described, in which radial routes approach and are carried as close to the central business district as feasible, forming an inner ring, does not seem to materialize in cities of less than about 200,000. In such communities, two arterial roads at approximately right angles appear to be all that can be justified (see Fig. 2). This is a natural development since, generally, there are fewer radial routes and the central business district is smaller than in larger cities. With only two arterial roads in the smaller cities, the travel distance on surface streets to reach a destination may not be any greater than in larger cities with several arterial routes and an inner ring. In yet smaller cities, particularly where development is strung out along a railroad, a river, or an existing highway, one arterial road into and through the city generally is all that can be justified. The pattern in one such city is shown in Fig. 3. These are borderline cases and the origin and destination of local and through traffic should be examined to determine whether or not a by-pass is desirable.

Types of Expressways

Many types of streets and highways can be considered free-flowing facilities, and there are just as many conflicting opinions regarding the desirability of each type. The engineer can only discuss their merits and deficiencies.

Streets or highways at grade can be constructed with several well-known expedients so that traffic moves well on them with only moderate interruption. The mere designation of a street as a preference street by "stop" signs on all cross streets will aid materially. At heavily traveled cross streets, however, signs indicating preference are inadequate. Traffic-signal control, or officer control, during hours of peak load or all day, is necessary. Isolated traffic-signal controls may not aid free movement; they may be detriments to free movement, but are required to minimize accidents and to regulate traffic. A series of signals progressively controlling traffic may be considered an aid in freeing the movement of vehicles.

Interference from the sides of the road is not reduced by these expedients; only conflicts with cross traffic at intersections are affected. To free through traffic from roadside interference, it has been common, where width permits, to provide separate side roads for abutting property and to segregate through traffic between islands or barrier strips separating it from the frontage roads. These are the "boulevards" found on major thoroughfares in many cities. They can be developed for high capacity by permitting crossings at grade only at important cross streets and terminating minor cross streets at the frontage roads. A facility of this type is shown in Fig. 4. Still greater capacity and freedom for through traffic can be developed by providing a divider between opposing traffic and by occasional grade separations.

Fig. 4.—An Expressway at Grade

A surface expressway, although it is a tremendous improvement over any thoroughfare with all streets crossing at grade and is capable of handling large volumes of through traffic, is not truly a free-flowing facility. Traffic-signal controls are required for the occasional street crossing at grade and for the more

frequent pedestrian crossings at grade. Structures that require pedestrians to walk up or down to bridges or underpasses are not used except under severe compulsion, can become nuisances, and often do not justify their cost. Pedestrian facilities will be used without strict control only when entrance to them is easier than crossing the expressway at grade—such as a footbridge at the general level of adjoining streets crossing over a depressed expressway.

The expressway type that has proved the most desirable in developed urban areas is that in which the express facility is at or below the general level of the surrounding area, no direct access with abutting property is provided, and all crossings at grade are eliminated. An example is shown in Fig. 5. In addition

FIG. 5.—A DEPRESSED EXPRESSWAY

to providing free movement for all through traffic, the depressed type of expressway does not present a visual physical barrier between the areas adjacent to the expressway, and it is flexible as regards future requirements of cross traffic in that additional structures across the expressway can be provided readily, with little or no interference with through traffic during construction.

CONTROL OF ACCESS

The control or limitation of access is necessary to the proper functioning of a free-flowing expressway. Sometimes (particularly on new facilities) this can be obtained when purchasing the right of way, provided the laws of the state permit. Controlling the right of access is not a simple matter. The rights of citizens to enter a public highway are rooted deep in fundamental common law

and are not easily withdrawn.[3] The surest safeguards appear to be the purchase of these rights from the owners of adjacent property and the provision of frontage roads along both sides of the expressway to serve abutting property. Sometimes these lanes are newly constructed. Frequently, one or both are existing streets. Where the line of the expressway is generally parallel to an existing thoroughfare in a grid pattern of streets so typical of cities in the United States, it is preferable to acquire right of way between the streets rather than to widen one of them. Maintenance of, and changes in, public utilities in cities—particularly underground lines—are costly and annoying. Changes in utilities parallel to the expressway can be reduced to a minimum by locating the expressway between existing streets, which continue to act as frontage roads and as media for utilities. The maintenance of traffic in cities during construction also is important. By locating the proposed expressway between existing streets, the latter can function as before with interference resulting from construction operations limited largely to work on cross streets.

Elevated Structures

The elevated structure type of expressway (see Fig. 6) is the most costly of all, as regards construction. There is a prevailing impression that such expressways save right-of-way costs, and particularly that they can be located on existing streets without the acquisition of additional right of ways. This impression is correct to a limited extent only. Elevated structures can be constructed on right of ways barely wide enough for the structure proper, but this rarely is desirable. Existing streets have distinct functions in serving abutting property and in accommodating moving traffic, even though limited in capacity by the cross streets. Consequently, the placing of columns in the street for the support of an elevated structure seriously restricts the usefulness of the street. The structure itself blocks off light, creates a potential nuisance area below, and seriously damages property on both sides. It should be realized that, where elevated structures can be justified, the expected traffic volume usually is high enough to justify a four-lane or a six-lane facility which requires a width nearly that of the average city street.

Undesirable features of an elevated structure are avoided to some extent by increasing the width of right of way to accommodate surface frontage roads clear of the structure supports, thus releasing the area under the structure for parking or other businesses. The increased width generally is needed, in any case, at intervals, to provide space for ramps. The use of an area under an elevated structure for business purposes, say, retail or warehousing ventures, is desirable in that revenue is forthcoming and the policing and maintenance of the area is transferred to the owners of the establishments although the added fire hazard must be considered. By the time that the various refinements are worked out and a sufficient width is obtained to minimize the damage to abutting property, the required right of way probably is sufficient for the development of a depressed expressway.

There are two major advantages to elevated expressways aside from pro-

[3] "Public Control of Highway Access and Roadside Development," by David R. Levin, Public Roads Administration, Washington, D. C., 1943.

viding space below the structure for some useful purpose: (*a*) Advantage to local cross traffic; and (*b*) maintenance of utilities.

(*a*) Nearly all streets can cross under the expressway without interference with through traffic—indeed, with less interference than existed prior to construction since the major traffic stream will use the overhead structure. An occasional street will be blocked off by a ramp.

(*b*) Utilities crossing the expressway are practically undisturbed by elevated structures. In some cities changes to utilities may be a major item of cost.

Sometimes topography will make elevated structures a necessity regardless of other considerations. If topography is rolling, a desirable control gradient

Fig. 6.—An Expressway on an Elevated Structure

of 3% or less may be feasible only where the expressway is in a depressed section crossing high ground and on an elevated structure crossing low ground. Low gradients are desirable, particularly for trucks which may slow down and reduce the capacity of the facility on even moderate gradients. On long steep, or even moderate, gradients, trucks are reduced to crawl speeds, seriously impeding following vehicles. This condition has been alleviated on existing two-lane roads by providing an additional distinctive lane for slow-moving vehicles upgrade. Truck drivers show a high degree of compliance. Where long gradients cannot be avoided on urban expressways, the use of such added lanes should be considered to avoid a reduction in capacity of the upgrade pavement.

Principles of Design

The design of an expressway, of each interchange and of each focal area such as a terminal, should be examined in the light of the principles that follow: (*a*)

The facility must fit traffic needs; (*b*) traffic operation on the completed facility must be free flowing and safe; (*c*) the path of the individual driver (at least that in a major traffic movement) should be as direct and simple as feasible and the required actions on his part be natural; (*d*) the operation should be flexible so that a driver will have a wide choice of destinations; (*e*) the facility should be flexible so that it can fit into any reasonable future change in the traffic pattern and so that it can be connected to important traffic facilities that may be provided in the future; (*f*) the facility should be integrated with the city plan; (*g*) there should be a wide distribution to the street system; (*h*) stage construction and development of short usable sections should be practicable; (*i*) it should be possible to maintain traffic adequately; (*j*) disruption of existing transit facilities, railroads, and utilities should be kept to a minimum; (*k*) important structures such as major bridges and buildings should be left intact; (*l*) the design should envision connecting the free-flowing facility to similar facilities beyond the immediate area of the problem; (*m*) the cost must not be out of line with the service rendered; (*n*) maintenance of the facility will be nominal; and (*o*) the completed facility should be pleasing in appearance.

The critical examination of interchanges is suggested because they are much more important in expressways in urban areas than in any other highway facility. Interchanges that are improperly located and designed can aggravate rather than relieve traffic congestion on city streets; they can affect their desired pattern adversely and can back up traffic on the expressway. The foregoing principles are not listed in the order of importance but to group those that are related to each other. For any one problem not all the listed principles may be applicable.

Terminal Facilities

Terminal facilities for both passenger and commercial vehicles are available in many cities in varying degrees and for widely varying charges. There are numerous ramifications of the important terminal problem; but its solution should go hand in hand with the development of expressways. Expressways in cities generate a considerable volume of traffic which tends to aggravate congestion in terminal areas if steps are not taken to provide for it. To solve the terminal problem, it is desirable that all interested agencies, particularly local public and private agencies, attack it broadly in the form of zoning control and the development of off-street parking and loading facilities by private and public interests. In many cities existing parking lots cannot be depended upon for future use. Their land value is so high that improvement by construction of commercial buildings should be expected as the city expands. An interesting development in some cities is the multiple use of such buildings for stores where retail frontage is valuable, for parking on the lower floors easily accessible to the streets by ramps, and for commercial businesses on the upper floors to which elevator service is convenient.

The problem of truck loading will be solved only by a bold approach. There appears to be no less justification for loading trucks inside business establishments than for loading freight cars on private sidings. The truck terminal, whether developed privately or as a union terminal, lessens street congestion

in that it decreases the truck mileage in congested areas and may reduce the size of trucks operating therein. However, major improvement will require loading-dock space inside the building line of the ultimate destination of the goods carried. In some locations, the result of limiting or eliminating first-floor street frontage will not be an undue hardship; and, at other locations, passages to the rear of the property or ramps to upper floor docks will be justified. Zoning to require, or at least to encourage, development of dock space inside the building line appears justified.

Planning Agencies

Orderly procedure in express highway planning may change for different cities because of variations in the distribution of planning functions. The planning of express highways logically can be considered the function of the state highway department, the city engineer, the county engineer, the city plan commission, or the highway committee of the chamber of commerce—or any or all of these. Some cities have presented a spectacle of so much planning that what should have been a healthy rivalry resulted in a jam which prevented progress. In such cases the efforts of a coordinator become necessary to induce the various agencies to bury minority differences and to agree on a plan acceptable to all. These problems are the concern of all and it is gratifying to note, in many cities, a healthy cooperation between the several agencies interested in the cities' welfare.

Major highways in cities are the main arteries of transportation for people and goods; and, if they enable vehicles to travel only at low average speeds, the city suffers in both increased cost and time for all functions depending on transportation. If the major highways are developed as free-flowing expressways, the tempo of transportation in the city can be increased with favorable results for all. The writer cannot agree with visionary enthusiasts who believe that freeing transportation will of itself rehabilitate a city, although it can be of material aid. The forces of decentralization are too great to be stopped entirely, but the proper location and development of expressways can assist in the establishment of self-contained stable neighborhoods and in the stabilization of trade and values in the principal or central business district.

The self-contained neighborhood appears to be one objective on which most city planners agree. A neighborhood should be roughly from a half mile square to one mile square, and should contain, in addition to housing, all the essentials of living, such as schools, places of worship, community and recreation facilities, and the everyday stores—the butcher, the baker, and the modern version of the candlestick maker, the five-and-ten-cent store. The central business district would retain the larger establishments such as the department stores, clothing establishments, commercial and industrial offices, and banks. Properly located expressways can serve the triple function of acting as dividers between neighborhoods or between a neighborhood and an area of a different type, as transportation mediums for highway traffic between neighborhoods and the central business district, and as transportation arteries for through highway traffic. When travel to the central business district takes but a short time and the road users have convenient terminal locations for parking, loading,

and unloading, the tendency for the larger establishments to move from the central area to the neighborhoods is likely to be retarded and the central business district stabilized. A detailed discussion of city planning as a whole is beyond the scope of this paper; but the highway engineer must appreciate that, in the location and design of urban arterial facilities, he is participating in city planning. Accordingly, it is essential that he cooperate intimately with all other agencies interested in the planning, development, operation, control, and general welfare of the city.

Preliminary Engineering Report

One of the most useful mediums to unite all interested agencies in the consummation and approval of a plan for an expressway is the preliminary engineering report. Such a report may cover one or several projects. A properly prepared report has several useful functions. First and foremost, it serves the designer himself by permitting him to examine the proposed solution objectively and to assure himself that the proposed facility will solve the transportation problem, that it fits in with the numerous related projects, that the design is feasible, and that the broad picture is complete. A designer may be so engrossed in detail that he loses the over-all picture—loose ends are not garnered and impracticable features creep in.

The preliminary engineering report helps to acquaint all agencies with the problem and its solution, to develop constructive criticism, to unearth errors in so far as it is possible to do so, to fit the project into the over-all city plan, and to focus the attention of fiscal authorities on funds needed for advancing the project from preliminary engineering status to right-of-way acquisition and final construction.

The cost of a preliminary engineering report almost always is manifoldly justified. Free-flowing express facilities through cities are complicated. Right of way is costly, numerous utilities are affected, and alternate locations or even slight adjustments in the line and the access connections might have serious consequences. Unlike those for rural highways, the construction plans for urban expressways may be materially affected by such adjustments and changes in the plans are costly and time consuming. It is desirable, therefore, that the salient geometric features of the design, arrangement of roads, alinement, width, accesses, walls, bridges, and other design features and standards be "tied down" before construction plans are begun. The preliminary engineering report can be used for such purpose. When the approval of all interested agencies is at hand, the detailed design can proceed with assurance that no radical changes will be made.

Preliminary engineering reports vary considerably with each project or group of projects and with different administrators. In some cases a line has previously been established definitely, and the report may show the results of location surveys and plans in considerable detail. In other cases the preliminary engineering report may present no more details than the general location and justification usually found in a city planning report. In such cases the report should be considered one of a series, the later reports going into greater detail before construction plans progress very far. In general a preliminary

engineering report should include five broad phases: (I) Transportation, (II) Design loads, (III) Solution, (IV) Estimate of cost, and (V) Justification.

(*I*) *The Transportation Problem.*—The report should indicate the general transportation problem to be solved. To this end it should show the traffic and transportation situation. Where does traffic originate and where it it destined? What traffic flow exists as a result of traffic pressures and what traffic flow would exist under unrestricted conditions? What delays are encountered? How does traffic, as it flows, affect other functions of the city? How are industry, trade, and commerce influenced? How is mass transportation concerned and to what extent will the proposed facility serve it? How are pedestrians affected? What is done with vehicles when they reach their downtown destinations? All such questions should be answered in the preliminary engineering report. Existing conditions should be depicted by topographic maps and aerial views, both oblique and mosaic. Maps and graphs showing land use, social trends, and other data are useful in showing the problems that transportation in the city is facing. Land value and improvement maps are invaluable in analyzing the probable cost of right of ways in choosing locations. Utilities should be indicated, particularly those underground.

(*II*) *Design Loads.*—The report should indicate the traffic volumes for which the expressway is to be designed—either in that part of the report dealing with the problem or in that part showing the proposed solution; but traffic volumes should be shown somewhere. The design traffic volumes are the "loads" to be accommodated. There is no more logic in designing a highway facility without these loads than there is in designing a bridge structure without knowing the weights and distribution of the wheel loads it is to carry. All too frequently, the available traffic data are not sufficient to determine the probable traffic volumes that will move on the expressway and the probable number of vehicles that will make the several turns at each point of interchange. In such cases the data should first be obtained; but, where this is not feasible, the probable volumes should be determined by judgment (using the best data available) and thus recorded as a part of the preliminary design data. This procedure is superior to one in which only the number of traffic lanes is decided by the judgment of the same engineers.

(*III*) *Solution.*—The report should give the proposed solution, including a preliminary design plan and profile, which may be drawn to a scale of about 1 in. = 400 ft. They should show the edges of all pavements, including frontage roads, access connections, and adjacent streets. Structures and walls should be indicated. Landmarks and adjacent areas affected by the construction also should be shown. The alternate locations studied in arriving at the final location, as well as the alternate designs tried at each intersection, should be marked and an account given of the reasons for choosing the proposed design. The reports will pass through many hands, and a presentation of alternate ideas will help reviewing and affiliated agencies to avoid repetition of the same process of trial and elimination.

A preliminary engineering report should be prepared in a manner clearly understandable by the many officials and other individuals who are not engi-

neers and to whom a blueprint is a mysterious document. Some parts of the design, particularly directional types of interchanges, are difficult to visualize in three dimensions. Such locations should be shown in perspective delineations which give clear pictures of what is intended. In some cases, models are made although they generally are expensive, require a long time to construct, and frequently do not show as large an area as one or more perspective delineations. These are made in an amazingly short time by men who generally are not engineers but who have the peculiar "knack" or gift required for that type of work. Aerial pictures, with the proposed facility drawn in, also have been advantageous. General pictures of what is intended are very useful when it becomes necessary to acquaint the public at large with the project. Newspapers welcome material of this character.

(*IV*) *Estimate of Cost.*—The preliminary engineering report should include a reasonably accurate estimate of the cost. Such cost should be broken down into the usual subdivisions of right of way, construction, engineering, and contingencies. In addition, it should be broken down further into sections which, preferably, would be usable upon completion. Expressways in cities take time to design, finance, and construct, and the administrator should have the cost estimate in such flexible form that it can be fitted into an ever-changing fiscal program. To this end the report should show the manner in which sections of the expressway can be constructed in stages and the cost of each stage.

(*V*) *Justification.*—The preliminary engineering report should describe fully the reasons justifying the expenditures proposed for the construction of the project—in particular the transportation problem, which it is intended to solve by the expressway, and how the solution will be accomplished. Frequently, reports discuss congestion and interference with industrial or commercial functions, and sometimes accident frequency, and follow such discussion by a description of the relief that will be afforded by the new facility and how it will be obtained. The effect of the expressway on the city plan and on the development and stabilization of important areas might well be included. These are worthwhile reasons for prosecuting the project, and the benefits sometimes are sufficiently evident to be enough justification; but, for a realistic businesslike approach, the report should include an economic analysis of the project.

An important part of an economic analysis is the balance sheet, showing on the one hand the annual cost and on the other the annual benefits. Since this paper deals with expressways, a treatment of benefits due to direct land service use can be omitted without appreciable error, in order to deal entirely with benefits to road users. The cost of an expressway in a city is a capital expenditure and should be sanctioned only after an analysis has been made to determine what benefits will accrue to road users. Road-user benefits are not the only returns, as has been noted. Intangible benefits, such as ease and comfort of driving and facility and convenience of travel, and indirect benefits, such as effects on city stabilization or development, may outweigh benefits to road users in some cases; but an economic analysis that compares road-user benefits with annual costs should be made. This relationship is the guide that administrators need in determining economic feasibility of a project or in com-

paring alternate solutions to a transportation problem, for it indicates in businessmen's terms the road service to be provided by the proposed expenditure of funds.

The annual cost of a project may be assumed to be the sum of the annual cost of financing plus the annual cost of maintenance and operation. The subject of finance is beyond the scope of this paper, but it is well to state that the annual cost of financing is the same for any one rate of interest and any one period of time of amortization, regardless of the method of financing adopted. The annual road-user benefits are the saving in the cost of vehicle operation, the saving in time, and the saving resulting from accident reduction. Of course, there are some differences in observations (and in their interpretation) for the cost of vehicle operation on various types of highway facilities. There are differences of opinion regarding the factors to be used in calculating the value of saving in time although there is general agreement that time is valuable even for pleasure-bent passenger vehicles. If factors are inaccurate to a great degree, the resulting analysis can be misleading; but, if available factors are reasonably accurate, the economic justification for a project should be developed and included in the preliminary engineering report. Such analyses are particularly useful in comparing two or more solutions for the same problem or in assigning priority ratings to several projects.

Considering the large number of vehicles involved, the savings in vehicle-operation costs effected by the elimination of "stop-and-go" driving and other speed changes, and the time saved in traveling steadily even if not at high speed, expressways in cities show high returns on the investment, well beyond comparable returns on most other types of highway and street improvements. The demonstration of this fact to the driving public will give administrative officials the courage to satisfy demands for expressways. Such demands are certain to increase in volume and intensity as the inevitable congestion in cities returns; as those responsible for the welfare of a city look for every aid in its rehabilitation, stabilization, or further progress; and as the driving public becomes acquainted with the many desirable features of travel on free-flowing protected highway facilities.

DISCUSSION

HARRY W. LOCHNER,[3] M. ASCE.—In the development of an expressway plan for the average city, a sound and realistic viewpoint must be maintained. The plan should embody the ultimate improvement of the system with provision for building usable units as funds become available. Mr. Barnett mentions the past inadequacy of appropriations to develop the rural highway system. In most cases the development of a highway plan for urban areas involves the same problems.

The Federal Highway Act of 1944 authorized $1,500,000,000 for highway improvements during the first three years after the end of World War II. Compared to previous federal highway appropriations, that sum appears very large, but in reality it is small compared to the need in urban highway improvement. Federal funds for urban areas are allocated on a population basis, to be matched equally by local funds for construction, and on a one-third and two-thirds basis for right of way—the larger sum to be advanced by the state or local agencies.

As an example—the Federal Interstate Highway System, as proposed under the Act, calls for five interstate highways entering Louisville, Ky., a city of approximately 300,000. When federal funds have been matched by local appropriations, a three-year program involving the expenditure of approximately $3,500,000 will be possible. That sum is to be considered in relation to the average cost of expressways estimated at from $1,000,000 to $2,000,000 or to $2,500,000 per mile, in a city such as Louisville. Funds might be utilized in developing a short section of one route completely, or, more desirably, in developing a longer section partly with progressive improvement as additional funds become available. Such progressive construction gives motorists who are unacquainted with expressways the opportunity of appreciating their value.

Mr. Barnett has demonstrated the ease with which numerous methods of stage construction can be employed if the right of way for the development is available. Land acquisition is one of the important aspects of expressway development. Unfortunately, in most cases it is the most difficult to attain, and its realization is dependent to a large measure on the adequacy of the preliminary engineering report.

In the past, most states have required local agencies to obtain the right of way for highway improvements. It appears that in several states local agencies will still be required to obtain the right of way, with one-third aid from the federal government. In those cases, particularly, the plan must be sold to legislators to assure the appropriation of the relatively large amount of money required to secure the needed lands. One of the major functions of the preliminary engineering report is that of selling the plan—not only to the officials but to the public as well.

In most large cities where the cost of expressways is relatively high, the projects can be justified only by designing the route as an artery for all forms

[3] Mgr. (H. W. Lochner & Co.), Chicago, Ill.

of transportation. Each artery should be planned to accommodate mass-transportation vehicles as well as private vehicles. The saving in time for the large number of mass-transportation riders which can be effected on expressways of itself will justify a very high proportion of the improvement cost.

One of the intangible benefits to be derived from sound planning of expressways is the opportunity of developing adjacent public recreational facilities. In many instances fractional pieces of properties will remain after acquisition of land for highway right of way. This land can be secured for public use at a very small additional cost. Located along the expressway (which could be landscaped), such pieces of property can be improved as small parks or playgrounds for the benefit of the adjoining neighborhoods.

In planning expressways, traffic information is but one of the tools utilized. By the proper analysis of the data, factual information can be developed to substantiate the selected location. Traffic information is of major value in determining both volumes of traffic that will use the several access points and their probable required capacities. It is also particularly important in designing terminal facilities to accommodate traffic desiring to go to and from the downtown area. No traffic survey technique has been developed which gives complete accuracy and the fineness of information that might be desired. The results of every type of origin and destination traffic survey require careful analysis and application. Mr. Barnett mentions the "interview type" of origin-destination survey. Complete results of that type of survey are available for the City of Savannah (Ga.) which show that approximately 80% of the "to-work" traffic going to either industry or office was reported, together with a lesser percentage of the "to-shop" and "to-recreation" traffic. Fortunately the traffic to and from work consists of the larger part of traffic movement within cities, has the highest economic value, and accounts for most of the peak-hour traffic for which the expressway is designed.

Expressway planning, if it is to be of long-range benefit, must envisage the changes and expansion of the urban area. Mr. Barnett mentions the fringe of depreciated residental properties around downtown areas. In numerous instances those areas will be redeveloped for industrial purposes. In such cases an expressway might be located as a buffer between the industrial areas and the residential properties.

Expressways will play a major rôle in causing development and undevelopment. Access will be provided to new industrial, commercial, and residential areas. Each must fit into the most advantageous over-all plan of development. Each will influence estimated expressway traffic flows. Therefore, planning must of necessity be conceived on a broad basis and must be sufficiently flexible to accommodate future changes.

With the exception of New York City (N. Y.) and a few other isolated cities, motorists have not had the opportunity of using expressways. Therefore, it is difficult for them to comprehend the nature of such an improvement and its benefits. In Chicago (Ill.) the Outer Drive—13 miles in length—built in the park along the Lake Shore, follows general expressway standards. Even with the example, laymen in Chicago have difficulty in visualizing an expressway built through the developed areas of the city. In planning a system of

expressways in the average city it is desirable, therefore, to make every effort to improve even a small area. Such an illustration will generate the public enthusiasm and desire for the completion of the entire system.

FRED LAVIS,[4] M. ASCE.—The subject of this paper is timely and indicates the general nature of some of the problems. The paper, however, would be more useful if it were more specific.

To state (as the author does under the heading, "Introduction") that "* * * the roadbeds [of railroads] are as useful today for the movement of trains as when they were built" is a half truth which ignores the fact that roadbeds of railways, subgrade, ballast, ties, rails, and fastenings have been and are being continuously improved. They have little semblance to the roadbeds of even 25 years ago. The Pennsylvania Tunnel extension into New York, N. Y., was completed only about 35 years ago.

One may question the statement of the author that the elevated structure type of expressway is the most costly of all as regards construction and also the vague references to the value of operating cost of low rates of gradient. There should be some indication that a large volume of literature on the subject of trunk-line parkways, express highways, and freeways is available. Although it may be impractical to include a complete bibliography, it should be mentioned that there is much specific information on the subject. The following three papers by the writer are cited, for example: "The Money Value of a Car Minute,"[5] "Highways as Elements of Transportation,"[6] and "Safety and Speeds as Affecting Highway Design."[7]

Elaborate studies were made in Caracas, Venezuela, about 1940 or 1941, and the "Diagonales" were projected and partly built in the congested area of Buenos Aires, Argentina, before that.

The paper by Mr. Barnett is too vague and general to be of use to younger engineers, and it contains little that is new to engineers of knowledge and experience in this particular field. As a matter of fact, problems of this kind require the application of the greatest engineering experience and knowledge, and business judgment, to each specific case.

HOMER M. HADLEY,[8] ASSOC. M. ASCE.—This is a truly admirable paper: Clear, lucid, and comprehensive. It covers the subject adequately in all major aspects without becoming involved in minor detail and trivialities, and the presentation is made so effectively and with such logic and reason that the stated best method of dealing with urban traffic congestion cannot fail to find acceptance in the minds of the great majority of readers.

In the development of detailed plans, arrangements for entering and leaving expressways and limited access highways offer the most troublesome problems. With two adjacent fast-moving streams of traffic in the same horizontal plane going in opposite directions, left-hand turns are neither permissible nor possible,

[8] Cons. Engr., Seattle, Wash.

and elaborate cloverleafs and grade separations may be necessary to deal with access and egress. This problem is not absent in elevated structures whose traffic, if all at one level, presents the same conflicts that ground traffic does.

In considering a specific case of this kind it appeared to the writer that these difficulties would largely disappear if a two-level structure were used with traffic separated—say, northbound on the upper level and southbound on the lower level. Under these conditions, access and egress are possible on either side; and, although special framing of the structure and special column positioning would be required at such places, these adjustments could readily be made. Moreover, a two-level structure actually would save right of way; for example, with a six-lane structure under the Design Standards for the National System of Interstate Highways,[9] a minimum width face to face of 83 ft of railings is required, whereas for a three-lane structure this dimension is 43 ft. A saving of a 40-ft right-of-way strip effects a very real saving in cost where land values are high.

How adversely such a two-level elevated structure would affect the use of a street beneath depends not a little upon the positions of columns. If they can be kept clear of the curb lines, the street traffic will not be affected at all; and, although the structure above would cause a certain loss of light, this loss would be far less than that beneath a structure of nearly double the width. If additional provision is made for a reasonable space between the viaduct structure and adjacent buildings and if the structure is given proper architectural treatment, the unfavorable effects would be slight indeed. Of course, there is the further consideration, stated by the author, that topography may make an elevated structure a necessity. When that is the case, the structure unquestionably can be made pleasing in appearance and any unfavorable aspects can be held to minor scale. When the Lake Washington Pontoon Bridge at Seattle, Wash., was first announced, its opponents declared not only that the beauty of the lake would be destroyed but that the value of the abutting property along the lake shores would also be destroyed. Nothing of the sort followed the construction of the bridge. The sole objectionable feature appears to be the noise caused by heavy trucks ascending the 5% grades on the elevated approaches. Passenger cars cause no annoyance whatsoever. In general, the bridge traffic is nonexistent, so far as ground level is concerned. True, this would not be the effect on tall buildings adjoining a viaduct. The traffic then would be at the level of upper floors. However, whether this coincidence would be objectionable or not depends on occupancy. In many cases it would be a matter of entire indifference.

The author makes no mention of vehicular tunnels in his paper. Obviously, they may be unavoidable at times and then they unquestionably are most acceptable. However, if their terminal points can be joined by other construction without too much loss of distance or grade, they appear to the writer to be the least desirable and most costly connections that can be considered. The author's views regarding vehicular tunnels from ½ mile to 1½ miles long are requested.

[9] "Design Standards for the National System of Interstate Highways," A. A. S. H. O., adopted August 1, 1945.

DONALD M. BAKER,[10] M. ASCE.—Express highways are the third factor in the development of trafficways in metropolitan areas. Streets in these areas were not a great problem until the introduction of the motor vehicle. They served adjacent property and were financed and maintained by local taxes. Early motor vehicle traffic, traveling at speeds several times those of horse-drawn vehicles, required better roadway surfacing, which was paid for by local taxes or assessments, and in some instances by local bond issues.

Increasing speeds and traffic density during the decade 1920–1930 led to the development of arterial highways, created by the opening, widening, straightening, and paving of certain principal streets upon which a large part of such traffic concentrated. These arterials served primarily the motor vehicles using them, rather than abutting and adjacent land; but they were financed in most instances by assessments upon this land, on the theory that the land was benefited by the improvement to an extent which was at least equal to, and usually in excess of, the cost of the improvement. This theory proved to be sound in a few instances, but in widespread use was found to be a mistake, since the improvements benefited motor vehicle users far more than property owners, and the burden upon the latter was in many instances unsupportable.

Express highways should be planned and designed as mass transportation facilities to serve the people of a community; and to accommodate not only privately owned vehicles, but also public carriers, usually buses, although some situations will be found where they can accommodate rail facilities without too great an additional cost.

Until well into the 1920–1930 decade, mass transportation in urban and suburban areas was provided by rail lines. In most places these were located on the streets; but in the largest communities, where the capacity of surface lines was inadequate, they were constructed "offsurface." Offsurface rail facilities have greater passenger-carrying capacity per mile of track than do express highways per lane, and can serve more passengers per dollar invested in them than can express highways; but certain conditions have developed which, except under particular circumstances, make widespread extension of such lines very difficult of achievement.

The riding public does not appear to be willing to pay fares that will provide adequate service and yield operating expenses and debt service for offsurface rail facilities; this condition makes their financing primarily an obligation of the community itself. Demands upon public credit for the provision of other needed facilities, such as streets, schools, water and sewerage systems, parks and playgrounds, public buildings, etc., and the taxes necessary to pay for these facilities make the prospect of successful passage of public bond issues to pay for offsurface rail lines very discouraging.

Another drawback to their development arises from the decentralization of population in metropolitan areas, and the increasing ownership and utilization of motor vehicles. In the twenty-five years from 1916 to 1940, motor vehicle registration in the United States increased from 35 per 1,000 population to 236 per 1,000, or nearly seven times. With the revival of motor vehicle production,

[10] Partner, Ruscardon Engrs., Los Angeles, Calif.

registration can shortly be expected to reach a density of one motor vehicle per family.

Prior to 1920, new population followed the extension of rail lines into undeveloped areas surrounding the cities, and settled in close proximity to these lines. People soon found, however, that by owning an automobile they could live anywhere within the area and travel back and forth to their place of employment, or make other travel movements without dependence upon the rail system. Ownership of automobiles was difficult in localities of high population density; and, since most people desired to possess one, this encouraged them to move to areas of lesser density. Congestion due to the increasing number of motor vehicles made travel by rail slower and increased operating costs, with the resulting decrease in service and also in patronage. This spiral has continued to the present time.

The construction of rural and intercity highways was initially financed by local taxation, and later by bond issues, until the motor vehicle fuel and use taxes were developed. These taxes were initially collected and administered by state authorities, whose jurisdiction seldom extended into the corporate limits of cities; and more recently they have also been collected by the federal government for allocation to states. From the outset they have been devoted almost entirely to the construction and maintenance of roadways and highways outside of urban and suburban areas, although a high proportion was collected from motor vehicle owners and users operating largely within these areas. Beginning with the depression (1930–1940), improvement of streets and highways in heavily populated areas by bond issues and assessments upon the adjacent property proved to be infeasible; local pressure on state authorities forced the allocation of some of the proceeds of fuel and use taxes to cities and counties, although the amount so provided was seldom sufficient to more than care for maintenance and a nominal amount of arterial development.

At present, the network of rural and intercity highways is far more adequate to meet the needs of the traffic using them than are the highways and streets in metropolitan areas, with by far the greater vehicle mileage, at least in states with a high ratio of urban to rural population, occurring in cities and metropolitan areas. Tremendous financial losses resulting from deaths and accidents, delays due to traffic congestion, and losses of property values, occur in these areas. Gasoline rationing during World War II reduced the acuteness of the situation somewhat; but, even with the reduction in the number of motor vehicles since 1941, the elimination of gasoline rationing and the subsequent greatly increased use of automobiles are bringing about a serious situation. When renewed production of motor cars has brought registration back to prewar figures, this situation promises to be extremely critical.

Until recent years, the major interest of state and federal highway authorities, in so far as it applied to cities and metropolitan areas, appears to have been in providing facilities for by-passing traffic originating outside of these areas around their congested portions. Recently, however, there has developed a recognition of the needs of such areas for facilities which will reduce congestion within their boundaries.

The author is correct in his statement that the greatest need for express highway facilities is along routes radiating outward from the central business districts of metropolitan areas. A large volume of traffic does occur in a circumferential direction; but congestion comparable to that occurring on radial routes seldom occurs, since a far greater number of circumferential trafficways are usually available. Increasing congestion on radial routes as they approach central districts is due not only to the fewer number of trafficways existing as the central district is approached, but also to the steady contribution of traffic along these routes as they approach the central district which increases its total volume, and to the increasing interference by cross traffic at the more frequent number of intersections. In studies made as consultant to the Los Angeles Transportation Engineering Board in 1938–1939, the writer found that during the 12-hour period, 7:00 a.m. to 7:00 p.m., 35.7% of the total number of motor vehicles entering the central district of Los Angeles (Calif.) originated within a 2.5-mile radius of the central district, 53.1% originated within a 5-mile radius, and 63.7% within a 7.5-mile radius. Only 14.5% of those entering were registered from locations outside the metropolitan area.

The large use of motor vehicles, as a means of travel to the central district, is shown by the fact that 22.9% of the vehicles registered within the Los Angeles metropolitan area entered the central district during the aforementioned 12-hr period. Total persons entering the district during the 12-hr period by means of private automobiles equaled 15.6%, and by public transportation 10.7%, or a total of 26.3%, of the population of the Los Angeles metropolitan district. This may be compared with a figure found by the writer to be equal to 30% of the population of the metropolitan district entering the central district of Los Angeles in the year 1931. These percentages are consistent with the results of cordon counts around the central districts of ten large cities made during the late 1920's and the early 1930's, all such counts indicating that a number of persons equaling from 25% to 30% of the population of metropolitan areas enter the central district of such areas daily by various modes of transportation.

The need of by-passing traffic around central districts to relieve congestion in the approaches to and also within these districts, which was stressed by the author, is likewise acute. The suggested inner and outer by-passes are frequently desirable as an aid in the reduction of congestion in approaches to the district. In the foregoing studies, made in 1938–1939, it was found that from 25% to 40% of the vehicles entering the central district of Los Angeles were destined to points beyond it, and passed through it rather than followed existing but more circuitious by-pass routes. The elimination of this large number of vehicles from the streets within the area and from those approaching it would have done much to relieve congestion.

During the economic depression of the 1930's, many studies were made of traffic habits and characteristics within metropolitan areas, and many plans for relief of congestion were formulated. Most of these are still merely lines on paper and printed pages of text in reports. Difficulties in activating such

plans always lie in finding ways and means of financing the improvements which they recommend. It is the writer's considered opinion that plans for express highways, or in fact for any other improvements, are too often wasted effort unless they include, in addition to the physical plan, a feasible one for financing the improvements recommended.

The "pay as you go" plan which contemplated the use of proceeds of fuel and use taxes derived from motor vehicles for financing highways was far sounder than that of using proceeds of 40-year bond issues to build roads and highways which had a 20-year life, or of assessing adjacent property to pay improvement costs; but city and regional planning, and highway engineering have made great advances since World War I. New highways can now be planned and constructed with the assurance that, given adequate maintenance, they will not be worn out or obsolete for at least half a century. Moreover, the "pay as you go" plan, even if fuel and use taxes are substantially increased, will not provide funds for express highway facilities now needed in metropolitan areas at a rate sufficient to catch up with increasing needs. These needs have been unsatisfied and accumulating, not since the date of Pearl Harbor, but since the beginning of the economic depression in 1929, and are increasing at an almost geometric rate.

Financial losses, due to inadequate travel facilities in metropolitan districts and the resulting congestion, are of vast proportions. In 1933, in a report made to the Central Business District Association of Los Angeles upon a rail rapid transit system for the Los Angeles area, the writer estimated that monetary losses in time to drivers of automobiles, and operating losses to public carriers, because of congestion and traffic delays in traveling to and from the central business district of Los Angeles, amounted to $15,000,000 annually. These were intangible losses. More tangible ones, due to reduction in property values, lost sales in retail stores in the area, traffic deaths and accidents, were not included in this estimate.

If adequate relief is to be achieved, expenditures of a very large order must be made, and made within the next few years, rather than over the next several decades. Because fuel and use taxes, even in increased sums, will be inadequate, the alternative would appear to be the issuance of bonds and the use of the increased tax revenue for debt service on the bonds.

Present interest rates are extremely low, and will be held so until the federal debt is greatly reduced. At current rates an annual revenue of one dollar over a period of from 40 to 50 years will pay interest and repay principal on from $25 to $30 in bonds, and allow an adequate sum for maintenance and operation of express highway facilities.

The cost of increased fuel taxes to a motor vehicle owner would be nominal. The average passenger automobile uses from 500 gal to 700 gal of gasoline per year. An increased gasoline tax of 2¢ per gal would cost the average owner from $10 to $14 per year, and would support from $250 to $420 in bonds for express highway purposes in metropolitan districts. Although savings in gasoline and tire mileage, and in the wear and tear on motor vehicles, may not entirely offset these costs, other and additional savings of a more intangible

character, such as reduction in deaths and accidents, stabilization of property values, and reduction in travel time, will undoubtedly do more than offset the increase. The adoption of such a policy in the next decade, together with allocations from present state and federal revenues should fairly well satisfy the most pressing traffic needs of the metropolitan areas of the United States.

It is but fair and proper that motor vehicle owners outside of metropolitan areas contribute to the cost of express highway systems within these areas. In the past a substantial proportion of outside highways has been constructed and maintained by contributions from vehicle users operating within metropolitan areas. These contributions have been far out of proportion to the use made of outside highways by the urban and suburban contributors. Outside vehicle users will probably make as much use of metropolitan express highways as do the metropolitan users of the outside highways built through their financial aid.

If planners and highway engineers will give the same attention to financing improvements that they do to planning and designing them, the people will probably be able to enjoy them within a reasonably adequate time.

W. J. Van London,[11] Esq.—The purpose of urban expressways is to provide fast and safe mass transportation for people and commodities within and across metropolitan areas. Mr. Barnett has presented a comprehensive discussion of this subject. Such transportation facilities are as much the responsibility of the state and federal governments as are any other arterial highways. The Post-War Highway Bill stipulates that a certain amount of the funds provided by the bill must be used in the development of expressways in urban areas. In Texas the amount is about $27,000,000 when matched equally with state funds—this provision being mandatory.

The Texas Highway Department is responsible for design and construction of urban expressways. All costs are paid from state and federal highway funds except the cost of right of way, which is paid by the respective cities. The general design is that adopted by the American Association of State Highway Officials and is the highest design standard ever adopted by that organization.

The thought seems to prevail that expressway highways are for the purpose of handling through highway traffic. This is far from true. A national survey of all towns in the United States with a population of more than 10,000 shows that only 10% of the traffic on highway routes in cities is through traffic. The remaining 90% is local to what might be termed the metropolitan area. The percentage of through and local traffic varies with the size of the city and the nature of city's enterprises. An interview survey made in 1939 of 35,000 vehicles conducted simultaneously on ten highways leading out of Houston disclosed that only 6% of all traffic was through highway traffic. An analysis of the first expressway proposed for Houston indicates that of 45,000 vehicles per day anticipated in 1948 about 1,000, or 2.2%, will be through highway traffic. Therefore, it appears that urban expressways are what the name implies—transportation facilities for urban traffic.

[11] Engr.-Mgr., Houston Urban Expressways, Texas Highway Dept., Houston, Tex.

It is apparent that so-called by-pass or belt highways cannot be justified for through highway traffic alone. Also, the more directly routed expressways will more effectively handle the small volume of through highway traffic than would a by-pass highway.

Urban expressways do not generally follow existing heavily traveled streets or highway routes, principally because of high right-of-way cost through the developed areas adjacent to these improved streets. Also, these streets usually lead through the congested business area which it has been found best to by-pass a few blocks to avoid congesting business streets with traffic passing from one side of the metropolitan area to the other. This type of traffic is about one third of the total.

In general, the expressway projects will begin at a connection with one or more state highways at the edge of the urban area and pass near, or through, the central business area to a similar connection at the opposite edge of the urban area. From the beginning to a point near the business area they will generally consist of four or six divided freeway lanes, with property service roads as required. All railroads will be passed under or over. Minor streets will be closed and major streets will pass under or over, with adequate access roads to provide for interchange of traffic. Design speed on the freeway lanes is 50 miles per hr. Near the central business area the traffic will be spread to several existing streets which will be used for a distribution system. Probably two of these streets leading directly to the expressway section beyond the business area will be developed as one-way streets.

The value of freeways is often questioned, the contention being that proper traffic light control at street intersection is almost as good as a grade separation. A perfect light-controlled intersection will handle 42% of the traffic that a grade separation will handle, which is probably a sufficient answer to the question.

The construction cost of the expressways contemplated will range from \$750,000 to \$1,000,000 per mile. The right of way will cost from \$50,000 to \$100,000 per mile. Immediately the question arises—are the expressways worth the money? The only justification for a public improvement of this nature is its economic value. A time-travel analysis on an existing route and one proposed project in Houston which will carry 25,000 vehicles per day shows a time saving of 12 min between two common points. Assuming 15 miles per gal for gasoline consumption and a cost of 20¢ per gal, the fuel cost is 1¢ per min at 45 miles per hr—the anticipated expressway speed. Computing 365 days at 25,000 vehicles gives 9,125,000 vehicles per yr. A saving of 12¢ per vehicle would be \$1,095,000. The section of expressway analyzed will cost between four and five million dollars. The saving in fuel cost alone will pay for the improvement in less than 5 years. If other cost factors are considered, such as drivers' and passengers' time, reduced wear on equipment, ownership cost, wages to operators of commercial vehicles, earning value of commercial vehicles, etc., and an estimate of 3¢ per min is applied, the saving to the public would pay for the improvement in less than 2 years.

The planning of an urban expressway system, the over-all design, and the detail design features to provide fast, safe, and economical mass transportation

for persons and commodities require very careful consideration of many factors. The first step in expressway development is to determine where and what the traffic is now, and where and what it will probably be 25 years hence. A route is then selected and a more detailed study made as to the present and probable future development of the affected areas. From these studies the location of street-grade separations, traffic interchanges, the number of traffic lanes required, etc., are determined. Little time and effort is required to make this statement but many months of tabulation and study of reports and data obtained from the various utility companies and bus companies; census bureau reports; city planning commission reports; chamber of commerce reports; past, present, and probable future population; and business and industrial trends; etc., as well as actual traffic counts and interviews are necessary to determine the "load for which the expressway structure should be designed." From these data, traffic flow maps are developed to determine where and what kind of traffic facilities are required. The proposed expressways which are expected to be completed by 1949 are designed to handle 1957 traffic loads.

The structural design features will also be based on the load to be carried. Bridge designs provide for the maximum anticipated loads. Earth and pavement structures will be designed for the maximum anticipated loads with a safety factor of about 1.5. The maximum permanent bearing value of the respective soils will be developed and the maximum anticipated traffic loads will be properly distributed over the soil foundation structures through various pavement structures. The types and designs of pavement structures will be governed largely by economic considerations. The cost of the earth structures, and of pavement structures, will be much higher than that for the usual structures of this kind; however, they will more nearly approach permanency and the cost will be justified by their long and uninterrupted service to large volumes of traffic.

To a considerable extent the foregoing is a specific application of the general principles set forth in this paper. The traffic analyses and the economic evaluation of specific cases in Houston afford conclusive evidence of the soundness of Mr. Barnett's presentation of these matters.

Merrill D. Knight, Jr.,[13] Assoc. M. ASCE.—A natural and rational approach to the problem of express highway planning is presented in this paper. One element in the location and the design of expressways not sufficiently covered is their relation to land use. Too often in the past the zoning plan for a community has not been given the consideration which its importance in the over-all development would seem to justify.

Although origin and destination surveys have become recognized as prime tools in expressway design, these reflect only an existing condition and must be correlated with present and future land use before the analysis will achieve its greatest value in the planning process. In the Savannah, Ga., study, origin and destination surveys were used with due consideration for industrial expansion. However, the procedure still requires some refinements. It is sug-

[13] Highway Engr., Public Roads Administration, Washington, D. C.

gested that further investigations are desirable to determine if specific land uses, when located in respect to other specific land uses, may be used as guides to changes which may be anticipated in traffic flow as the metropolitan area develops.

In the use of zoning maps in a location study, it is believed inadvisable to give too much importance to the consideration of expressways as barriers between zones of incompatible uses. Such a factor as an influence in design has been suggested by a number of engineers, notably, by Jac L. Gubbels.[13] Although expressways may assist in stabilizing values through the segregation of areas with comparable restrictions, this is certainly not their primary function. The primary function of moving traffic between areas of major generators immediately suggests that there should be a very real relationship between the highway plan and the land-use plan. To present a complete analysis of this relationship would require setting values on classified land uses as potential traffic generators.

Probably the greatest obstacle to such an analysis lies in the basis on which many zoning ordinances have been created. A typical city will undertake zoning primarily to protect property values. The first map to be drawn will be one showing existing uses. If retail businesses are widely scattered, the value of adjoining properties has already been depreciated for residential purposes. To avoid hardships resulting in the creation of districts containing too many nonconforming uses, the tendency is to allow larger areas with fewer restrictions. This variation from the optimum allocation of land to classified uses admittedly interposes difficulties in estimating future traffic to be generated by areas presumably planned for specified uses. Such difficulties would be inherent in any city plan possessing sufficient flexibility to permit future growth. To make a plan effective all components should be developed toward a common objective.

Frank H. Malley[14] states that "* * * as cities grow the downtown area remains relatively constant in size as compared with the urban area." He believes that "* * * the proper location and design of Urban Freeways is the greatest single element in the cure of cities' ills and in the directing of their proper and adequate future growth." The determination of the pattern for future urban growth constitutes the most complex phase of selecting locations for proposed expressways.

The Regional Planning Board for the County of Los Angeles (Calif.) in a discussion of the "Master Plan for Highways, 1941"[15] explored, on an over-all basis, the highway requirements as related to the various land uses within the entire area. To do this a pattern of land use was developed, toward which it was believed the ultimate growth of the region should be directed. However, the pattern fixed as a goal for Los Angeles was based on a desire to avoid an overcentralization which has already become a fact in other large metropolitan areas. Hence, it cannot be used as a pattern for many other places. In the

[13] "Planning for City Highway Traffic," by Jac L. Gubbels, *Better Roads*, October, 1945, p. 29.

[14] "Location and Function of Urban Freeways," by Frank H. Malley, Postwar Patterns of City Growth, Am. Transit Assn., p. 18.

[15] "Master Plan for Highways, 1941," Regional Planning Board, County of Los Angeles, Los Angeles, Calif., 1941.

1941 plan, Los Angeles expressways were proposed to serve more as intercommunity highways than as a means of moving people from outlying areas to one or two congested centers. Other cities can benefit from a study of the Los Angeles approach, even though it is not entirely applicable to their problems.

Keeping in mind the necessity for the transportation of workers between their homes and places of employment, it is important to stress that, in assembling basic data, an analysis of land use, both existing and potential, when properly correlated with origin and destination surveys, can be of the highest value in selecting the route which will best meet present and prospective needs. To increase the significance of such analyses, however, further study is required before making any attempt to assign empirical values to specific land uses as traffic generators.

R. H. Baldock,[16] Esq.—A remarkably clear explanation of the present need for urban traffic facilities permitting uninterrupted flow and a proper relating of these facilities to local service streets and terminal facilities are given in this paper. Mr. Barnett mentions the ever-increasing realization that intelligent planning must rely on factual information in regard to the needs and desires of the populace. These factual bases can best be obtained through the medium of comprehensive origin and destination studies, the techniques of which are outlined briefly. Indeed, the data assembled can be used in an infinite number of ways to solve the many and varied traffic problems in a metropolitan city. Mr. Barnett makes an interesting statement to the effect that the development of a pattern of arterial routes results in a remarkably uniform solution for cities of comparable size.

The writer is in full accord with the thoughts expressed in the paper. However, he takes the occasion to stress the following conditions:

1. The current pressing need for adequate terminal facilities to provide storage for varying periods of time, particularly in and near the central business district.

2. The need for improved and adequate mass transportation facilities to attract a greater proportion of people.

3. The job of selling a bold and forthright plan of express highways and terminal facilities to the local citizenry through detailing and publicizing the economic benefits that will accrue.

The writer has stressed the matter of terminal facilities not because this phase should necessarily carry a disproportionate weight in an over-all program but rather because deliberations and planning with respect to express highways have far outstripped planning for terminal facilities. Notwithstanding the fact that there is still much to be done in the matter of planning arterial expressways, it would seem that more detailed study should be accorded the problem of terminal facilities to bring it abreast, so to speak, of progress in the matter of arterial development. The construction of expressways will divert and consolidate a large part of traffic on parallel streets between major points of origin

[16] State Highway Engr., Salem, Ore.

and destination. In addition, it will generate a new and additional increment of traffic by the very reason of the improved facility. This latter increment of traffic will operate to complicate the present acute parking situation even further.

Moreover, an extended period of time will be required to build all the express highways and circumferential routes in a given metropolitan area and the present critical parking problem cannot wait. The terminal parking problem needs to be solved as part of the completed plan as far as feasible. It is further obvious that private enterprise cannot very well conduct the requisite preliminary studies for an intelligent appraisal of the parking problem.

In general, parking locations should be widely dispersed in and around the business district to prevent congestion on adjacent streets and to serve the public better. It may be found necessary for the city to acquire property for development of off-street parking facilities through the power of condemnation, if necessary, and to operate such facilities through leases to private individuals. Real estate values, and the economic requisite of realizing a fair return on the investment, may necessitate building a one-story or two-story structure to increase the parking space. The upper floor or floors can be made accessible by ramps and, where topography permits, by entrances from two different streets at different levels. In other cases, it may be desirable either to build or to give a long-period lease for the erection of a modern office building—the interior of which is utilized either through ramps or through elevators for the parking of motor vehicles. Soundproof and fireproof construction can be used; and, if the architecture is attractive, the utilization of the core of the building for car storage should not detract from the value of the office space around the exterior of the building. To accomplish these improvements, it may be necessary, by state legislation and city ordinances, to establish a parking authority and to provide funds for the capital investment and the acquisition of sites to be amortized through rentals over a period of years.

Mr. Barnett's statement that the truck-loading problem will be solved only through a bold approach is correct. Truck-terminal and loading-dock space inside the building line of the ultimate destination of goods will eliminate first-floor street frontage for truck unloading—an important observation. The incorporation in city ordinances of off-street parking and loading facilities as a condition precedent to new building construction is still in the pioneering stage; however, such a measure appears to be the only permanent solution of this aggravating problem.

Turning to mass transportation and its bearing on the problem, Mr. Barnett states (under the heading, "Planning Agencies"):

> "If the major highways are developed as free-flowing expressways, the tempo of transportation in the city can be increased with favorable results for all. The writer cannot agree with visionary enthusiasts who believe that freeing transportation will of itself rehabilitate a city, although it can be of material aid. The forces of decentralization are too great to be stopped entirely, but the proper location and development of expressways can assist in the establishment of self-contained stable neighborhoods and in the stabilization of trade and values in the principal or central business district."

The increase in the use of automobiles by people working or trading in the central business district cannot proceed to the point where every movement takes place through the use of a personal conveyance. It may be impossible to build the requisite expressways, and certainly it is impossible to construct the required terminal facilities to care for a greatly expanded use of private automobiles—nor is such use economical.

There appears to be a demand for greater use of mass-transportation facilities. The building of expressways and properly located bus terminals will facilitate this trend; and it will give to the user greater safety and almost equivalent speed and comfort of movement. Express and skip-stop bus service can be inaugurated on expressways from suburban districts into the heart of the city. The modern city planner should give careful consideration to this phase of transportation inasmuch as it appears to offer an excellent solution to the pressing problem of traffic congestion in regard to both movement and vehicle storage. If a proper solution is reached, many citizens using their own personal automobiles between the suburbs and the central business district will travel by mass transportation, for convenience and economy. It may, of course, be necessary to use the automobiles from the home to a suburban bus terminal. The lower land values, in such cases, should make possible car storage at reasonable rates.

In the selection of the type of mass-transportation vehicle, the street car running on rails cannot be used because of its inability to conform to the patterns of the traffic stream. Likewise, although the trolley bus is more flexible than the street car, its range of movement is definitely limited, and at times it becomes an obstruction to the free flow of traffic. The expense of erecting and maintaining the overhead wiring system is material and this type of construction detracts from the beauty of a well-designed expressway. With adequately powered motor buses, discomfort can be materially lessened while the freedom of movement makes for ideal operation in a stream of other motor vehicles.

Turning to the job of "selling" the local citizenry on the economic and social benefits accruing from building express highways and providing for adequate terminal facilities, Mr. Barnett has stated that the preliminary engineering report should describe fully the reasons for the expenditures proposed. Although many of the benefits accruing to the public by reason of the building of adequate express highways and terminal facilities are intangible and difficult to evaluate, in most instances it is possible to show that the yearly monetary benefits are much greater than the annual cost of amortizing and maintaining the facilities.

The annual road-user benefits, represented by the saving in cost of motor vehicle operation, the saving in time, and the saving by accident reduction, can be determined. When expressways have been planned carefully, based on origin and destination studies, the amount of these benefits accruing to a large volume of traffic is surprising.

As Mr. Barnett has stated, the direct road-user benefits are not the only returns. Intangible benefits which reduce driving strain in many cases far

outweigh in the public mind the monetary values which accrue. An economic analysis properly presented to progressive civic groups, indicating the direct returns on the investment as well as the many indirect benefits which materialize, should sell such a program even to the more skeptical. In the matter of "selling" the program to a civic group, it is probable that engineers working on the technical phases are somewhat reticent to dramatize supporting data, and thereby fall somewhat short of making a case that will appeal to, and interest, a lay group.

JACOB FELD,[17] M. ASCE.—By assembling and organizing the pertinent data as well as the differences of opinion covering all phases of the problems involved in the planning of express highways through congested areas, the author has prepared a valuable contribution. There is considerable published literature on individual phases of the problem and even more on the designs prepared for special locations. However, a paper of this type which looks upon the problem as a whole, without any special reference to a definite locality, provides a framework for the use of the designer working on any phase of this problem.

Proper planning and execution of express highways will reduce congested traffic and expedite the flow of vehicles through urban areas. However, it would be uneconomical to attempt a complete elimination of congestion in large cities. As a matter of fact, the very basis of city existence is congestion and an efficient city cannot exist without large concentrations of vehicles. The popular expression for an inefficient city, where concentration has been reduced to the point of elimination of congestion, is "an overgrown village." People expect congestion when they enter cities and to some extent would be disappointed if they found none—for instance, the tendency of crowds to congregate on certain streets in every city, most of the sight-seers having no particular business in those streets.

An attempt to design through arteries for every possible concentration of traffic (such as that occurring for a few hours each week end during vacation months in a comparatively few roads leading to every large city) would be a tremendous waste of the facilities for practically 99% of the time. Fig. 7 shows the traffic congestion along the West Side Highway in Manhattan (New York, N. Y.) during the afternoon of Navy Day in 1945. Practically the same degree of congestion exists for about two hours on this highway every Sunday afternoon when the weather is favorable. Possibly a doubling of the capacity might eliminate this congestion for these short periods but it would not be economical to provide such additional facilities.

One method to reduce incidental peak concentrations would be to revise the method of marking through routes. From personal experience, it has also seemed to the writer that it is a mistake to mark certain streets going through a city with a definite route number—especially where a number of routes converge into a city center and then diverge on the opposite side of the center. It would help traffic if the general direction routing was provided for the motorist

[17] Cons. Engr., New York, N. Y.

rather than a definite route number. For instance, a number of streets leading from the outskirts on the west side of the city could be marked east traffic and a very simple sign in the form of an "E" with an arrow could be easily identified. Traffic would then split through a number of streets rather than concentrate on a single route. Such marking would be advisable even where a through artery is provided to take the overflow during the congested periods.

Fig. 7

The writer has found that much better time and less nerve-wracking driving results from by-passing marked routes. For instance, in the City of Waterbury (Conn.), all routes intersect at the center of the city. The provision of a "throughway" for all traffic, converging on the center from practically eight different directions would be uneconomical. A circular or square connecting highway through the outskirts of the city would help the city congestion very little (as the author states), because most of the traffic is going to different parts of the city. However, provision of a throughway going east and west and one going north and south, of minor traffic capacity, with roughly parallel streets marked with direction would solve the problem. This solution is similar to a design of a main pipe line with parallel by-passes for surplus or surge flow. A similar analogy can be found in multiple electrical connections in a grid system.

Urban traffic concentrations have been studied by traffic divisions of the New York City Police Department for many years. Much information can be obtained on peculiarities of traffic congestion from those sources. For instance, in 1936 the writer was organizing construction of a part of the Sixth Avenue

Subway in Manhattan, and among other things desired to find which days would have the least traffic concentration. The street had to be closed for short periods at a time and to avoid too much interference with the local business people it was thought advisable to plan the work so as to close the street on the lightest traffic days. Of course, streets are very often closed for repaving and for other construction, and traffic somehow finds its way around and takes care of itself. On the other hand, the experience of the police indicated that in retail areas like that part of Sixth Avenue, vehicular traffic was heaviest on Fridays.

The question was important enough to warrant the expenditure of some time, and traffic counts were made from April to December, 1936. Actual count of the number of vehicles passing the northerly intersection of 41st Street and the northerly intersection of 45th Street, on Sixth Avenue, were made for a period of 5 min each hour from 8 a.m. to 6 p.m. on six successive days (except Sunday) starting on the fifteenth of each month. Fig. 8 shows the variation of traffic averages for various months. At the time of the count, the

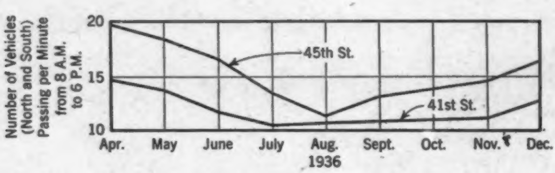

Fig. 8.—Traffic Count on Sixth Avenue, Manhattan

roadway width of Sixth Avenue was 60 ft with an elevated structure in the middle of the street. The clear distance between elevated columns was 22 ft with unused trolley tracks in this part. Each side road was 17 ft in clear width. Theoretically, parking was prohibited, but actually delivery trucks and some private cars were almost always at each curb at each block. The results of the traffic count were used to schedule the main closure of the streets for the summer months when traffic concentration was least and also to avoid closing the streets on Fridays as much as possible, even though the increase in traffic counts for Fridays was not very much above the other days of the week.

This example is cited to emphasize the difference in traffic concentration when commercial traffic is being considered rather than pleasure vehicles. The fact that truck concentration is not at a peak during week ends is often forgotten because of individual experiences of being tied up in vehicular traffic on Sundays.

There are two schools of thought on the location of interchanges between an express highway and intersecting main streets. One group feels that the interchanges should lead directly into the main street, to avoid addition of traffic in adjacent and usual residential areas. The opposing thought is to connect the interchange into subsidiary streets to allow the traffic leading or entering the expressway to filter through supplementary streets and thereby reduce

congestion on the main streets, which usually already carry considerable traffic. The decision is difficult to make, especially where the main street is bounded on each side by residential land use and often by heavily concentrated populations. The meandering of traffic entering or leaving expressway streets serving apartment houses adds seriously to the traffic accident toll. From the safety point of view, it might be better to force all traffic on to business streets even though some congestion results.

The author must be complimented for the very clear manner in which he has analyzed this entire problem and for the open-minded discussion of different solutions for each phase. The design and construction of express highways is becoming a considerable part of the engineering and construction fields. The crystallization of thought and opinion at this time is therefore most useful.

Harold M. Lewis,[18] M. ASCE.—The need of coordinating main arterial highways with general city plans, and of planning suitable off-street terminals for passenger cars and trucks in urban centers, is clearly demonstrated by this important paper. The writer has found that many highway engineers are interested in city planning, but more of them should be; in turn, city planners should give more attention to the economic justification of the highways they propose. A master plan for major urban thoroughfares should do more than create a pattern of loops and radials; these latter should be designed to meet local demands in location, character, and capacity.

The initial development of expressways in the United States started with parkways designed to carry heavy passenger-car traffic through suburban areas. In a few cases such special routes may extend far enough to become interurban; but, essentially, the parkway has remained a feature of metropolitan development. Postwar highway plans, such as those in New York and California, will place more emphasis on interurban expressways for all types of traffic—passenger cars, buses, and trucks.

Most expressway problems still requiring engineering research arise in urban centers, where, as Mr. Barnett states, the proper location and design of "ons" and "offs" are important. These can be closer together on the edges of the business district than in suburban areas where their location is fixed primarily by that of major intersecting highways along the express route. An excellent example of the downtown loop, typical in a pattern for large cities, will be provided in Los Angeles, Calif., under its expressway program—partly completed, with other sections under construction, but mostly still in the planning stage.

At a "transportation clinic" held at Los Angeles in December, 1945, the writer presented an analysis of the relative proportions of through (by-pass) traffic that might use these loop expressways as compared with traffic that would use them for entering (or leaving) the central business district. It was recommended that entrances and exits be provided at twelve points. Fig. 9 indicates that the heaviest by-pass traffic would be along the north and south

[18] Cons. Engr., New York, N. Y.

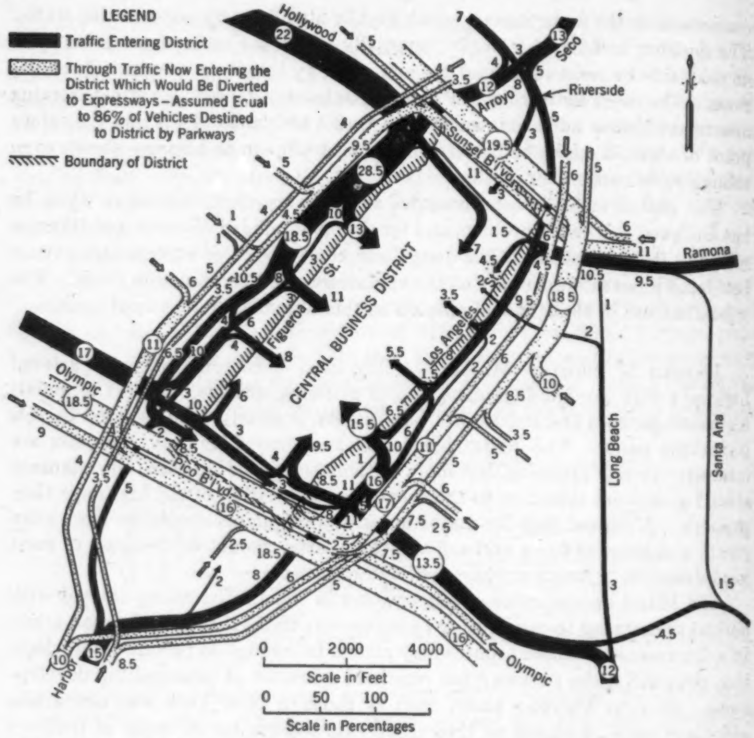

FIG. 9.—ESTIMATED DISTRIBUTION OF PASSENGER VEHICLES ENTERING AND BY-PASSING THE CENTRAL BUSINESS DISTRICT SHOWN AS PERCENTAGES OF TOTAL ENTERING BY PARKWAYS WITH PRESENT DISTRIBUTION OF POPULATION

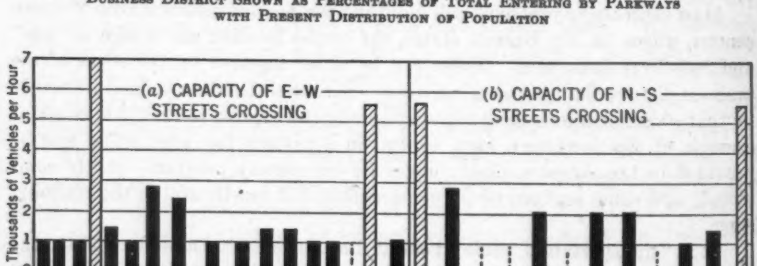

FIG. 10

sides of the loop and that the easterly section, known as the "East Bypass," would carry more through traffic than the westerly section, a part of the "Harbor Parkway." Of the through traffic now entering the district, the part destined to be diverted to expressways was assumed equal to 86% of all the vehicles entering the district from parkways. This assumption and the distribution of vehicles among the quadrants of the area were based on origin and cordon counts made in 1939. For the location of "on and off" points it was assumed that equal traffic would move in reverse directions.

It was proposed that the East Bypass be used for all types of traffic—passenger cars, buses, and trucks—but that other sections of the loop be limited to passenger cars and buses.

Fig. 10 indicates the increase that the loop expressways would provide in the capacity for traffic moving across or along the edges of the central business district. The solid bars show the hourly load that could be carried over existing, continuous streets crossing this district at their points of minimum capacity. The hatched bars show the additional capacity that would be provided by the expressways. Assuming that the Olympic Parkway (the southern section of the loop) were to be built with eight traffic lanes and the other elements of the loop had six traffic lanes, the number of lanes available for through east-west movement would be increased by 39% and their capacity by 63%. The number of lanes available for through north-south movement (now limited by the fact that four existing streets extend only part way through the district, however) would be increased by 60% and their capacity by 100%.

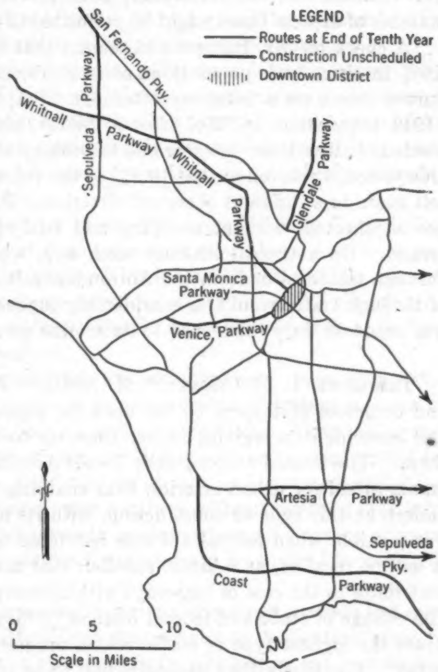

FIG. 11.—EXPRESSWAY PROGRAM OF THE CITY OF LOS ANGELES

In addition to about ten miles of existing routes, the complete system of expressways for Los Angeles city and county involves 358 route miles and a total cost of $582,000,000; of this, about 220 miles costing $400,000,000 will be within the city. Of the proposed system, 287 miles have been scheduled under a ten-year program; the remainder are unscheduled. The total of

existing and proposed routes, differentiating between those scheduled and unscheduled, is shown in Fig. 11.

The panel of consultants taking part in the "clinic" agreed that about 54 miles of the expressway system should have set aside, as a part of the cross section of the routes, separate rights of way for mass transportation vehicles. The writer proposed that a little more than one third of the 297 miles existing and scheduled should have roadways available to passenger cars, trucks, and buses, and that an approximately equal mileage should be reserved for passenger vehicles. Of the remainder, both private passenger cars and a limited number of express buses might be permitted to use the roadways.

A check on Mr. Barnett's statement that the "By-passable traffic is about 20% in cities with populations of from 10,000 to 300,000" is provided by a survey made on a Saturday afternoon in April, 1946, at Glens Falls, N. Y. (1940 population 18,720). For a 2-hour period license numbers were recorded of all vehicles entering and leaving by the four main highways. Within this period it was found that 19.8% of the vehicles checked crossed the city and left again in a different observed direction. About half of this through traffic passed through without stopping and half stopped for a business or other errand. On a typical summer week end, when Glens Falls is traversed by through traffic to or from the Adirondacks, it is expected that the proportion of through traffic would be considerably higher and a second and longer count was made on July thirteenth to determine what the result would be.

THEODORE T. McCROSKY,[19] M. ASCE.—This paper contains a very able and complete statement of the need for express arteries through large cities and metropolitan regions, rather than up to their boundaries or by-passing them. The United States Public Roads Administration is empowered to make grants-in-aid for urban arteries, thus enabling many more states and cities to undertake this type of construction, with its heavy but necessary costs, than was possible when federal aid was restricted to highways outside city limits. It will be recalled, as a direct parallel, that many states did not traditionally contribute to the cost of highways within incorporated municipal jurisdictions. The change of state and federal financial policy now makes it possible to construct the highest type of traffic routes progressively outward from the urban center. Previously they generally had to be built inward from open country, with the center itself (where traffic is most congested) too often left with no arteries of modern free-flowing design. As the author has stated, traffic load diminishes rapidly with distance from principal cities, so that the policy of building outward rather than inward is manifestly correct from a technical standpoint.

The proposed central artery through downtown Boston, Mass., is a case in point. It will receive the heavy streams of entering surface traffic, converging from the northwest and south toward its extremities, and lead them to, or through, the heart of the city. This project is sponsored by the city planning board, and the 1946 session of the state legislature authorized the Post-War

[19] Executive Director, Greater Boston Development Committee, Inc., Boston, Mass.

Highway Commission to draw upon the highway fund (gasoline tax revenue) for preliminary surveys and engineering. It is planned to provide express connections with the Sumner vehicular tunnel leading to East Boston, and with the twin tube of this tunnel when constructed. Extension of the Central Artery outward beyond its currently planned termini might be a matter for future consideration, but is by no means as urgent as the construction of the downtown section.

The proposed Boston Central Artery also furnishes an excellent example of selecting right of way through a blighted "fringe area," as defined by the author, which is only a few blocks from principal central destinations.

The writer wishes to stress the importance of careful traffic counts and estimates for peak 15-min and 30-min periods, as a necessary basis for the sound determination of the correct number of vehicle lanes to provide for express highways. General, 24-hr counts are important in estimating total flow, particularly for toll facilities; but they do not answer the question of critical traffic loads that may result in congestion.

When serving as executive director of the Chicago (Ill.) Plan Commission in 1941 and 1942, the writer was one of the exponents of an "inner belt" expressway to distribute traffic from all radials. This inner belt utilized the existing Wacker Drive and Outer Drive and provided for completing the circuit. "The Preliminary Comprehensive Master Plan"[20] retains this important feature of the over-all future highway pattern.

Downtown off-street parking facilities for passenger cars are coming to be recognized as intrinsic parts, not only of comprehensive city planning, but of specific actual highway planning, design, and construction. When an express artery skirts close to the business center, parking spaces or garages should be close to the artery. Sometimes, they may be physically connected with it, so that cars can leave the highway and enter a garage without utilizing local surface streets. This arrangement is possible in cases where an elevated expressway (rather than the preferable depressed expressway) is required for compelling reasons.

With the inevitable traffic increases that every city must provide for, over the next 10 to 20 years, it is self-evident that maximum utilization must be made of the existing investment in surface streets, whether or not free-flowing arteries are constructed. Thus, city roadways must be free of parked cars to release curb-side lanes for moving cars; and in the daytime trucks must eventually be loaded and unloaded within building lines.

The writer considers that the great cost of express highways in downtown areas is better justified if these modern arteries are made available for commercial traffic, than if they are reserved exclusively for passenger cars. Commercial traffic includes both trucks and public transportation buses. It is argued sometimes that placing passenger cars on the new expressway will eliminate congestion on the old major surface street and make it entirely adequate for trucks. This argument neglects consideration of the delays at traffic lights and the fact that, to the truck operator, time lost is actually money "out-of-

[20] "The Preliminary Comprehensive Master Plan," Chicago Plan Comm., Chicago, Ill., January, 1946.

pocket"; whereas to the passenger-car driver, it is a case of time saved possibly being money "in-the-pocket."

A cogent reason for permitting buses on urban expressways is that no city (to the writer's knowledge, at least) has enough high-speed public transportation. A new expressway should thus be conceived as an addition to the public transportation network, and not as a competing facility that will encourage car owners to engage in needless driving, in lieu of utilizing the more economical mass transportation system. In appropriate cases the right of way should also include rapid-transit tracks.

If, for local reasons, an interim decision is made prohibiting commercial traffic on a planned express highway, there should nevertheless be no feature of the design that will later preclude a change of policy. Thus grades, curvature, clearances, and structural strength should all be designed on the basis of eventual use by heavy trucks and buses.

Because of the high capital cost of free-flowing express highways, even under favorable conditions of low land price, careful consideration should be given the policy of defraying at least a part of the debt service by tolls. In downtown districts where trips are short and ramps occur frequently, this will not generally be feasible from an operating standpoint. As the average trip lengthens, and with the wider spacing of ramps that is indicated for the outskirts of metropolitan areas, the feasibility of tolls increases. On highways, the driver who objects to a toll will not be required to pay it. He can always penalize himself, if he so desires, by using the slower local thoroughfare.

The author has stressed the great value of economic analysis as justification for proposed projects. Time saved, multiplied by traffic load, multiplied by value of time gives dollars saved. For the majority of passenger-car users, it is believed that the simple saving of time is what will determine their views—or vote—on a particular planned facility. In 1940, the New York City (N. Y.) Planning Commission prepared a city-wide plan of express highways, so located that no important origin or destination center was more than 1½ miles from one of these express routes. At that time Mr. Barnett made many valuable and constructive suggestions. The writer calculated that a trip of 12 miles would mean 1½ miles at each end on surface streets, and 9 miles by express highway. The 3 miles on local streets would take 15 min at an average speed of 12 miles per hr; and the 9 miles would take 15 min at an average speed of 36 miles per hr. Without express highways, one would have to go the entire distance on local streets at about 12 miles per hr—requiring 60 min. With the express highways, the same trip would take only 30 min, thus saving half of the previous running time.

The author has made a noteworthy contribution to the literature of urban highway planning. The translation into construction of the principles he has stated will go far to relieve the critical traffic congestion that faces every major American metropolitan region.

SPENCER A. SNOOK,[21] M. ASCE.—It is an opportune time to emphasize the need of arterial highways in cities. The detailed requirements of existing

[21] Asst. Engr., N.Y.C.R.R., Cleveland, Ohio.

data have been stated in papers by Fred Lavis, M. ASCE, and others,[22] and have been in use for a number of years, especially in New Jersey and within the New York metropolitan area. Nevertheless, it seems that arterial highways in most cities have been deliberately avoided, primarily because of cost; and so, by-passes have been built. These served the purpose for the through travel but totally neglected, in most cases, transportation in larger cities of urban commercial and commuter traffic. This problem should be concentrated upon, as usually the cities cannot afford to handle it. Most of the motor taxes come from these areas although the least money has been spent there.

Obviously, congestion of traffic is the lack of free-flowing traffic; and arterial highways, with access at frequent points, will reduce the cost and time for this urban traffic. There are still plenty of useless, time-consuming traffic lights that could be of the actuated type for cross streets.

Elevated highways with proper side roadways do not make a bad appearance, if architecturally treated. They compare favorably in costs with the depressed highway depending upon local conditions. The traffic noise is not as great and the elevation assists the driver in knowing where he is going.

It is always of utmost importance to have the controls of the structural features definitely set, before the detailed plans and designs are started. Frequently plans that have been started are discarded because some controls are changed, and hence the total cost is increased.

The number of public planning agencies, by whatever name, having jurisdiction in one city should be as few as possible as too many cause "jams" in progress because of inability to agree.

Lawrence S. Waterbury,[23] M. ASCE.—As Mr. Barnett has stated, in the rural areas there is a fairly good system of highways which, despite certain inadequacies, has served enormous traffic movements. However, it has been impossible, in many instances, to maintain these highways properly during the war period, and many of them have been quite heavily overloaded. As a result, it will be necessary to rebuild some of these, to construct additional links in the rural system of highways, and to improve many of them in accordance with modern design standards.

Between most of the large centers of population there are not too many serious delays encountered by traffic traveling over these highways. The cities, however, present quite a different situation. Traffic congestion and suggestions for its relief are in the minds of many people in the urban areas. Everyone is affected by congested traffic conditions—either as pedestrian, driver of a motor vehicle, or as a passenger using the mass-transportation facilities. Traffic congestion is something the average person encounters, in one way or another, causing him delay or inconvenience. He is naturally thinking of improvements and may have suggestions for relief of any intolerable conditions. He brings pressure on various civic groups, with the result that traffic

[22] "Highway Economics," by S. Johannesson, McGraw-Hill Book Co., Inc., New York, N. Y., 1931.

[23] Associate Engr., Parsons, Brinckerhoff, Hogan & Macdonald, New York, N. Y.

committees in many of these civic organizations do some very constructive and helpful work in preparing plans for the relief of congestion.

As has been stated, congested traffic conditions probably have been a factor in the deterioration of parts of the cities in the United States.

The need for relief in the urban areas has been recognized in the Federal Highway Act of 1944, which earmarked certain funds for use by the state highway departments in the development of modern highway facilities in the urban areas.

A free-flowing artery in the thickly settled city areas costs a considerable sum of money to construct, and the property damage costs are high. Naturally, it is impossible to construct these needed facilities overnight; it is necessary to construct them in stages, spreading the cost over a period of years. The sections that require the greatest relief should have first priority, and in the majority of cases these seem to be the most expensive in cost per mile of highway. In any business in which vast sums of money are to be invested, the investor would first investigate the economic justification before embarking on the venture. Since it is important for highway planners to be certain that they are proceeding in the right direction, they must collect and analyze, carefully, all the data bearing on the problem, and test all the possible solutions.

Mr. Barnett has emphasized the usefulness of a preliminary engineering report for testing these solutions and for the purpose of uniting all interested agencies in the consummation and approval of a plan for an expressway. This certainly should be the first step in express highway planning, since certain general principles of location and design would be covered in such a report.

Prior to any consideration of expressway location, a thorough study should be made of traffic characteristics of the urban areas. This will include not only a determination of the volume of traffic using the present facilities, but also a complete analysis of the origin and destination of this traffic. It will also be necessary to predict what the future pattern of traffic may be; and, when the most suitable location is decided upon, the volume of traffic that may be expected to use the new facility, must be estimated.

The existing land use of the urban area must be studied, and consideration given to future changes that may be expected as a matter of natural development, or desired as a part of the city improvement plans. These changes are certain to affect the future traffic pattern. A thorough analysis of land use in its relation to traffic is required, so that expressway locations will aid in the future favorable development of the urban area and serve the traffic needs adequately. Population studies, present and future, must be made at the same time as land uses are analyzed, as this too will be reflected in the future traffic pattern.

Mr. Barnett has reminded his readers that the factual data regarding the movement and the origin and destination of motor vehicles leave much to be desired and give the highway planner few clues regarding intracity traffic patterns. However, he must utilize whatever data are available, then supplement these with additional traffic surveys and research. The author has mentioned one method of securing these data, by home interviews, which is being

given some rather severe tests for adequacy and accuracy. There are other methods of making urban traffic surveys which will also yield sufficient data to make forecasts.

It is impossible to suggest a standard method of treatment in the location of expressways which will have a common application in all cities. Each city constitutes a special problem which must be analyzed individually. However, there are certain general characteristics common to most cities. For the most part, cities have grown with no planned development. The street patterns were not laid out or designed for the large volumes of motor vehicle traffic that wish to use them and traffic congestion has been the result.

The nucleus of the city is the central business district. Extending from this area the city has expanded, and people have moved farther and farther out as transportation facilities of various types have been provided. As congestion increased in the central business district and on the various routes leading to it, decentralization of the city began, resulting in smaller business areas being scattered in the outlying regions. This has caused serious reductions in real estate values in the central business district and has resulted in physical deterioration of many properties.

Development of the expressway provides a facility for safe and rapid movement of a larger number of motor vehicles in and out of the business district, and over the routes leading to it. It has the same function as the development of rapid-transit systems in the solution of mass-transportation problems. The location of the expressway should be coordinated with the service provided by the mass-transportation system of the city and in this way will provide rapid transit for those persons using the mass-transportation facilities.

The traffic pattern of the average city generally consists of a flow of vehicles over several routes converging on the central business district. As they approach the center of the city, the traffic volume is increased by the influx of vehicles from the suburban areas along the routes. Congestion is generally at a maximum in the central district but there may be, and usually are, critical points as highways merge, or as cross traffic is encountered.

The expressway should be so located as to serve not only traffic from outside the city but also traffic originating within the city limits. In this way, the maximum benefit may be obtained from the improvement through provision of express service for local residents of the city. An analysis of traffic destination on main arteries approaching most cities shows that a relatively small proportion is through traffic. The expressway, therefore, should be located to provide service for the greatest number of users—namely, those destined for the central districts of the city and originating in near-by surburban and fringe areas. As the expressway passes through the outer regions of the city, it should be located so that the residents of those areas may have convenient access to enable them to use this new facility for express service from points reasonably close to their homes to the central business district.

By so locating the expressway in these outlying residential areas, buses can also use the expressway, and this will result in an improved mass-transportation service. This is an important factor, since mass-transportation facilities oper-

ating in urban and suburban areas provide a sizable share (especially in the larger cities) of the daily travel needs of persons to and from work, schools, stores, and places of worship or recreation.

The ratio of daily transit riders to the urban population shows the extensive use of mass transit by persons in the urban areas in the United States. In the population class of from 100,000 to 250,000, in the years prior to 1940, this ratio was 38%. In 1943 it was 105%, or more than doubled. In the population class of 500,000 to 1,000,000, the ratio was 72% for 1940, and for 1943 it was 145%.

In some cities, the expressway may be parallel to a rapid-transit or streetcar line; it may then be desirable to develop the expressway and improve the mass-transportation facilities as a joint project.

The expressway should penetrate the downtown or the central business district close enough to enable easy distribution to all parts of the area. Naturally, the location through, or adjoining, the central district will require a detailed study of property damage and construction costs. It will also involve an analysis of the effect on the business and property values in the area. Consideration must be given as well to the problem of providing parking space within short distances of the interchange locations on the expressway. Stopping areas will also be required to accommodate the buses using the expressway.

This is a general policy which will apply to most cities. There are certain instances, however, particularly in the case of some of the smaller cities located between two large cities, where the proportion of traffic passing through and beyond the city is far greater than that destined for the center of the city. In such cases, the expressway should skirt the more congested area or possibly by-pass the city completely.

In cities that have rivers flowing through or alongside the central business district, the expressway may be located advantageously along the river. This will usually result in lower construction cost and will simplify the intersection problem. Where such routes can be developed, full advantage should be taken of these natural barriers to cross-traffic movement but, of course, other things being equal, the most direct route is preferable to a circuitous one.

Although Mr. Barnett did not attempt to discuss structural features of the expressway, a few words regarding the location with reference to existing street patterns may be in order. The width of right of way for an express highway will generally require a full city block. In such cases, the present streets on both sides of the city blocks will remain as service roads. The center section will be used for the expressway and any land, not otherwise required, may be used for parking spaces or appropriate landscaping. In the outlying sections, it is preferable to follow the natural ground level as closely as possible. In the event that there are frequent cross streets to be "grade separated," it will often be desirable to introduce a rolling grade, with the expressway successively passing over and under the existing streets to provide grade separation. As the expressway route approaches the more developed sections of the city, it will frequently be necessary to carry the expressway continuously at a separate grade from the existing streets. In any case, elevated structures should be avoided where possible; however, it is a matter for individual treatment in each

city. Although, in industrial sections, particularly where there are a series of railroad tracks at the street surface, it may be preferable to elevate the expressway.

At appropriate points along the expressway, provisions must be made for vehicles to enter or leave. To locate these interchange points properly, a thorough analysis of traffic movement is again essential. In outlying regions, it is not necessary or desirable to provide access at every crossroad. If possible, they should not be closer than from one half to one mile apart, depending on the location of the intersecting main arteries and their relative importance as feeder routes to the expressway.

As the expressway penetrates the central business district, the spacing of interchanges will probably be less frequent than in the outlying regions; they should be provided to give access to the most important streets in the central district.

Interchanges should be designed with adequate deceleration and acceleration lanes so that there is no interference with the main traffic stream by vehicles leaving or entering the expressway. The most satisfactory type of interchange is one in which the vehicles leave or enter the expressway by a ramp running as nearly parallel to the expressway as practicable. These ramps should connect with the service drive rather than make direct contact with a main cross street. In this way, there will be ample opportunity for the speed of the vehicle to be materially reduced from the speed at which it was traveling on the expressway. As a general policy, vehicles would leave the expressway at the interchange nearest their destination; thus, the motorist would drive a minimum distance on city streets to reach his destination after leaving the expressway. If the vehicle is to be parked in or near the central business district, the motorist should be encouraged to select a parking space that is nearest the point at which he leaves the expressway. The parking space preferably should be within reasonable walking distance or about 1,000 ft from the motorist's ultimate destination.

When the expressway location is properly chosen, it will serve bus and truck traffic as well as private motor vehicle traffic. It will provide a route that may be convenient for local city buses and also one which will serve intercity buses. Upon leaving the expressway, the bus should proceed to a terminal located, in so far as is practicable, at a point most convenient for the majority of the patrons. This terminal should be reached by a minimum of travel on the city streets after the bus leaves the expressway.

Consideration should be given to the possibility of developing bus stops along those expressways that are to serve local mass transportation. Under certain conditions, these may be located safely at the interchanges by providing a separate bus-stop lane, but this arrangement must not interfere with the exit or entrance to the expressway or the main traffic stream. By locating these bus stops along the expressway, it would not be necessary for the buses to leave the vicinity of the expressway until they approached the terminal, and much better local service would be provided.

Street and highway systems are public ways, and, as such, should be planned with a view to the accommodation of all types of highway travel or vehicles.

New facilities should be planned to incorporate, to the maximum extent practicable, provision for public transit facilities whenever warranted in the over-all plan based on population and land-use studies. In this way mass transportation will be made more safe, convenient, speedy, and economical for all the public.

The expressway, located so as to serve the freight distribution and industrial areas, should have interchanges at places where trucks may leave the expressway close to the truck terminals, requiring a minimum of travel on the surface streets.

Parking space, including parkway lots and garages for motor vehicles, should be located so as to be most convenient to the final destinations. Consideration should be given to providing parking space that is essentially a part of the expressway, with entrance and exit directly to it, but not so as to interfere with the through stream of traffic. Parking spaces so located would be reached without any travel on the surface streets of the central district.

The location of the expressway is intended primarily to serve the needs of high-speed traffic originating outside the city and passing to and through the congested central business district. In addition, it will serve the traffic originating in the outlying areas within the city limits and provide this traffic with a high-speed facility. Important consideration should be given to circulation within the central district and it is desirable to provide a facility that will assist in good circulation but not at the expense of retarding the expressway movement to and through the district. Careful consideration must be given to the development of the service drives and surface streets of the central business districts which are to serve as the distributors of the traffic after it leaves the expressway.

As stated, it is not possible to prescribe a standard method of treatment for the location of expressways which will provide a solution for all cities. However, the general principles outlined herein should provide sufficient guidance for the proper location and treatment of expressways as the characteristics of each city are analyzed. The facility can then be designed to serve the particular urban area under consideration best.

These principles would be the guide to be used in the preparation of the preliminary engineering report as recommended by Mr. Barnett. As a result of the various investigations to put into practice these general principles, planners would be in a position to make the recommendations for highway facilities which will adequately serve the present and future traffic needs and aid in the favorable development of urban area and region.

Bernard L. Weiner,[24] M. ASCE.—A rather complete general description of express highway planning is given in this paper. Considering the purely technical aspects of the problem, there is very little to be added. The paper is timely; one need be only a casual reader of the newspapers to known that the traffic problem has once more reached extremely serious proportions. It can scarcely be claimed, however, that any really courageous effort is being

[24] With Feld and Timoney, Cons. Engrs., New York, N. Y.

made toward its solution. Although the responsibility for this lack of effort lies in many quarters, the highway engineer cannot escape his share of the blame.

The fact that the automobile designer has advanced beyond the highway engineer is not surprising; and, as is usual in such cases, chaos is the result. The automobile industry has indeed made great progress. Changes in fundamental concepts take place exceedingly slowly and it only required thirty years for the manufacturers to realize that they had something which needed a new approach. Real progress in automobile design began when the industry realized that the concept of the "horseless carriage" was obsolete and led only to trouble. At that moment, an entirely new vehicle was born—the present-day automobile—which has changed very little except for "differences in the shape of the tin." Apparently, planners of highways and of other facilities still do not take into account the probability that the motor vehicle is here to stay.

Mr. Barnett writes (under the heading, "Terminal Facilities") that the truck-loading problem will be solved only by a bold approach. It might be added with equal justification that the "bold approach" is needed for all the problems that plague the world. Wherever mankind has made progress, it is a certainty that bold thinking has been done by someone or other; wherever mankind has failed, it is equally certain that bold thinking was lacking. Even worse, it has often been to someone's real or imagined interest to prevent such thinking—history is full of examples.

At that moment, the newspaper editors are "yelling their heads off" that the traffic congestion problem must be solved. They write "Something must be done"; yet, at the same time, they "point with horror" to the rising cost of local and national government and call for a reduction in "normal" expenditures. The problem can be solved, of course, but it will require more than the mere waving of a wand or the passing of a punitive law. It will not be a "costless" solution, but no investment is expensive if it insures adequate dividends. In cities of all sizes, the losses resulting from traffic congestion are so large and so apparent that there is very little doubt that large expenditures are justified to eliminate it.

It would be easy to show that no real attempt has ever been made to solve most problems of any importance that have been insoluble over long periods of time and have reached an acute stage. Characteristically, there has been nothing but tinkering; there has been little effort to reduce the problem to basic fundamentals. In attacking any problem, nothing should be considered so obvious that it is accepted without question.

Admittedly, large costs would be involved if all buildings were required to provide off-street loading areas, but it is also costly to provide elevator and other services. The street floor, however, need not necessarily be used for loading; the lower levels could be utilized. It is not at all beyond the range of possibility to provide elevators large enough to lower and raise entire trucks 10 ft or 20 ft below the street level, at locations where ramps are not possible for lack of space.

There has been altogether too much tendency to think of the express highway as a "study in motion," almost as if it were built for mere aimless motion.

There are three parts to a trip taken by a vehicle: The trip begins with the vehicle at rest at the starting point where it loads; it then proceeds to its destination over local streets and over highways; and it finally comes to rest again at its destination, where it unloads. Unless provision is made for the two end conditions, the express highways may just as well not be built. It is of little value to move a truck or passenger vehicle speedily from one point to another if all the time saved, and more, is lost because it cannot come to a stop quickly.

Traffic control—as distinct from mere law enforcement—is now largely in the hands of the police. It just happened that way. This control is so complete that the various police forces of the United States virtually have legislative powers. The police's point of view is punitive and only in rare instances is it constructive. "Hounding" the motorist and fining him, as much as fifteen dollars for parking in New York, N. Y., may achieve the result of keeping cars out of the congested areas; but it is no solution (see heading, "Radial Highway Arteries Are the Greatest Need: (3) Relief of Congestion"). The people do not receive the benefit of the use of their cars and, in a city like New York, the curse of centralization has made the public transportation system unfit for human occupation.

Better results could possibly be obtained if the police were restricted entirely to the enforcement of the law as interpreted and amplified (by the necessary administrative regulations) by an entirely independent body. Such a body should be made up of representatives of the various interests involved and should be under the general supervision of competent traffic and highway design engineers. It should be well financed, and the personnel should give its full time to the job of traffic control.

The purpose of this body would be to study ways and means of facilitating the movement of traffic in all its phases. Such studies would include major improvements, but comparatively minor changes would not be neglected either. Most important of all, since such a body would be made up of civilians, it would be more likely to keep in mind that the purpose of all regulations is not the punishment of violators but keeping traffic moving smoothly—and to permit it to stop where it legitimately should stop.

As stated, the police's point of view is rarely constructive. When the costly approach to a major bridge in New York City was opened to traffic, it was found that a combination exit to, and entrance from, a service road created a traffic hazard. As it happened, the exit was important, for it permitted traffic from a main thoroughfare to reach an existing bridge across the Harlem River, directly and quickly. The police "solved" the problem by closing the exit, thus vitiating an important part of a costly improvement. As it happens, a rather inexpensive piece of reconstruction would have eliminated the hazard and also saved the exit. Although it is quite a few years since the exit was closed, nothing has been done about it. This example is typical, however, of the police methods of controlling traffic.

Many traffic lights could well be eliminated; others can and should be synchronized. Also, more traffic controlled lights at minor intersections could be used to good advantage. The motorist is also too familiar with police signs reading, "No Parking Between Signs." It is a common experience to find such

signs around a bank or main post office in a large city. Common sense would indicate that a reasonable parking period—from ten to fifteen minutes—be permitted to allow for the average business transactions at such places. Although this is done in small towns, the contrary is true in large cities—even in residential districts. The motorist would be more inclined to cooperate if it were evident to him that an attempt was being made to give him every possible "break." As it is now, rules and regulations are ignored and those who have legitimate and necessary business in restricted areas charge parking tickets to operating expense—when they are caught.

In his discussion of the deteriorated areas along the approaches to cities, Mr. Barnett decries the fact that obsolete laws and pressure groups prevent the protection of traffic facilities—a condition which, he states, is not the fault of the highway engineer. Issue might be taken with the last part of this statement. Not only in this particular case but also in the more general social-political-economic problems of the nation, the engineer is altogether too prone to consider his professional responsibilities from too narrow a point of view—that of a mere technician. It seems to the writer that it is as much the job of the engineer to educate the public, study the financial aspects of public improvements, etc., as it is his job to perform the actual technical duties.

The civil engineer has too long considered himself, and has also allowed others to think of him, as a spender rather than as a producer. It would be a good idea, in fact, to adopt or invent a new word for "taxes" as applied to public works—for the word "tax" originated in the days when people paid tribute for mere physical protection. In the matter of highways, the taxpayer should be made to realize that, just as he pays for his car and its maintenance, he must also pay for the highways, which are essential parts of his motor vehicle transportation system. Industry is becoming more and more dependent on public relations; why should not the professions likewise become dependent?

In passing, it should also be stated (see heading, "Radial Highway Arteries Are the Greatest Need: (2) Shelf of Plans") that the sooner the idea of using public works "to provide jobs" is abandoned, the better for the profession and for the nation. Public works should be built only because there is a need for them in their own right. Public works cannot cure unemployment, and any attempt to make them do so leads, sooner or later, to "make work" projects at starvation wages—which does no one any good.

Like Mr. Barnett, the writer does not wish to raise the subject of financing; but one observation may be made. Although the author expresses the "orthodox" and accepted "financial habits" in use today, the present method of financing by borrowing is an anachronism. The bold approach might well be applied to the financing phase of all projects—public works and other construction. It is well known that public works financed by borrowing cost eventually two and one-half dollars for every dollar originally borrowed. With a bold approach to this problem, this excessive cost could be largely eliminated.

It is an accepted truism that a bridge destroys the value of property whereas a tunnel improves it. This maxim could well be applied to the express highway. The viaduct should never be used except as a last resort. Furthermore, sound engineering takes all factors into account—including human nature. Man—in

spite of his vaunted civilization—still likes the good earth, and being forced to ride above it is not pleasant. Also, from a more practical point of view, viaducts are never wide enough to provide for the inevitable disabled car. A single accident can, and does, block traffic for a mile and more back. From these and other points of view, the viaduct is undesirable.

Finally, in relation to expressways and parkways in general, there is another item to be mentioned. The landscaped and separated expressway tends to approach perfection—and, oddly enough, for this very reason tends to become monotonous even for comparatively short distances. For long distances—50 miles or 100 miles or more—the "perfect" highway does become deadly monotonous. The answer to this problem is difficult to define; but, nevertheless, highway engineers should give it their attention. The customer, after all, must be pleased.

George H. Herrold,[25] M. ASCE.—The difference between rural and urban routes and their capacity to serve the traffic using them is caused by the difference in population density in rural and urban areas, and by the fact that the states have large sums of money to expend freely in rural areas whereas such funds have not been available to the cities. As an example, the ninth Federal Reserve District (comprising Minnesota, North Dakota, South Dakota, and part of Wisconsin and Montana) has an average density of population of 13.5 persons per sq mile, compared with the cities of St. Paul and Minneapolis, Minn., which have an average density of 8,000 people per sq mile.

Before World War II, the United States was greatly exercised over traffic congestion and the decentralization of business districts. This decentralization or disintegration was caused by hazards created in the central business district by motor vehicles, by high speeds, and by poor law enforcement. Careful and timid people gradually stopped coming to the central business district unless they could not avoid it. Instead of being an attractive place to visit, the central business district became an undesirable place, with a corresponding reduction of business income and a lowering of taxable values.

During the war period people discovered that the transit industry was geared to handle the people who had to move from one place to another. Motor vehicle transportation decreased because of cars that broke down and because of restrictions in their use; and mass transportation increased by leaps and bounds. However, to a large extent, the congestion problem—the congestion that occurs at regular times and definite places—was solved. In St. Paul the number of people that used automobiles to take them to work decreased 47% whereas the number of people traveling on street cars and buses, with the aid of staggered working hours, increased accordingly.

When state trunk highways were first designated, the routes selected were existing highways leading to the city and its business district. These routes were chosen because they best represented the travel habits of farmers going to market or people from small towns going to the city. As a rule, the highways were improved only to the city limits, leaving to the city the problem of

[25] Planning Engr., City Planning Board, St. Paul, Minn.

handling this traffic, which was augmented by the traffic generated in the city. Traffic from these trunk highways used the city street system to reach destinations—various "points" in many areas including the central business district.

A city is laid out in blocks bounded by streets designed to make the blocks accessible and usable. On these blocks are buildings and people, and each block has its quota of motor vehicles. Traffic finds its way on cross streets to a trunk or arterial highway, and there it merges with the traffic from outside the city and proceeds toward destination areas and the central business district. As the traffic from outside the city moves toward the city's center, it merges with the traffic from the city's cross streets which are predominately for serving property owners.

Under the heading, "Radial Highway Arteries Are the Greatest Need," the author states:

> "It has become clear, also, that traffic congestion in cities will be solved to the greatest extent feasible by the construction of facilities that permit the uninterrupted flow of traffic into and through the cities."

Mr. Barnett cites three types of expressways: The expressway at grade—that is, built on the surface of the ground; a depressed expressway, and an elevated expressway. No matter which type is adopted, the expressway will be used by the same or increased volume of traffic, and the traffic will reach the central business district at the same time that it now arrives there. Instead of the city-generated traffic entering the expressway at every street intersection, a number of streets would be closed off and the traffic would enter the expressway every mile or so. Instead of one vehicle per minute entering the expressway at each street intersection there would be, say, sixteen vehicles per minute entering at designated access points. On an expressway these vehicles could travel at greater speed than on other routes. The driver could leave home 5 min or 7 min later, but would arrive at the central business district at the same time he arrives there now. Although an expressway does not solve any congestion problem, it increases speed and removes some frictions; and it moves people faster to the areas of congestion.

Fig. 12 shows the origin and destination study made by the Minnesota Highway Planning Survey in the St. Paul-Minneapolis metropolitan area. It shows the traffic flow in cities of St. Paul. (hatched) and Minneapolis (stippled) that originates in the satellite areas of the two cities. Each city has its distinct following and the flow from one to the other is negligible. The cordon where the interviews with motorists took place is about 1.5 miles outside the twin-city limits. In Fig. 12, the numbers within the hatched and stippled areas represent the average daily traffic observed between 6:00 a.m. and 10:00 p.m. in July and August, 1941. A traffic flow of less than 400 vehicles per day is shown by a single line and a number.

It is extremely important that "trading behavior"—the social habits and the economic reasons behind them—be studied in determining the location of an expressway and its access connections and exchanges. The intracity traffic flow presents a different picture. In St. Paul the wide traffic flow bands run

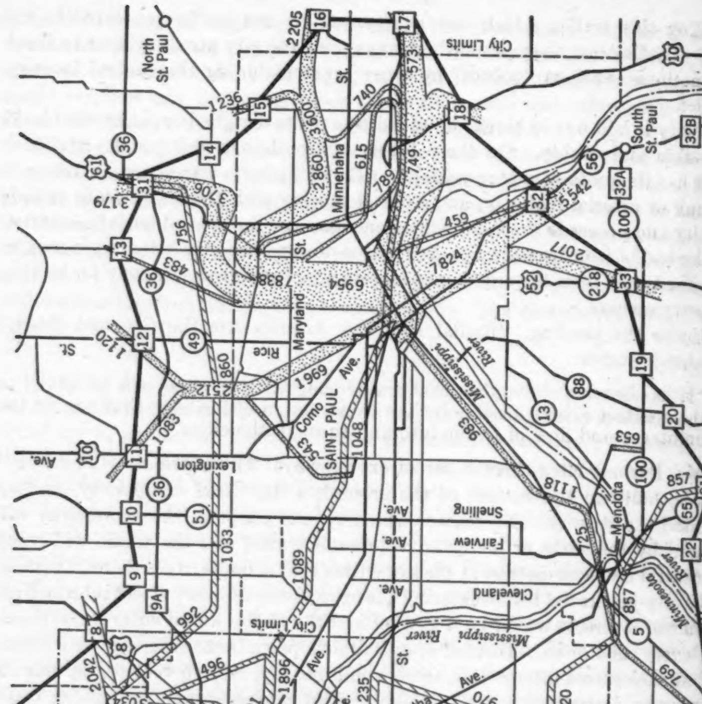

FIG. 12.—FLOW PATHS OF TRAFFIC THAT ORIGINATES IN THE SATELLITE AREAS OF ST. PAUL AND MINNEAPOLIS, MINN.

east and west. In Minneapolis they run north, south, and southwest, illustrating that the intracity motor traffic is predominantly for going from home to work (or vice versa), distributing commodities, shopping, and visiting—either for business or for pleasure. The wider bands on certain streets indicate a traffic excitor—people moving two, three, or ten blocks to contact one another. There is only an occasional through movement. The buildings along the streets and the people in them cause these motor vehicle movements.

The writer is apprehensive as to the effect of arguments or inferences that expressways solve congestion problems. The true problem that confronts all cities is one of mass transportation—to devise a well-balancēd movement of people and goods.

It makes no difference (except as to the cost) whether the traffic is taken to congested areas on a limited-access surface street, a depressed limited-access highway, or an elevated expressway. Where a block of land plus two streets is to be acquired for construction, there are great advantages in the elevated highway—economies as to construction, economies as to the use of the land, economies in utilities, and economies in maintenance.

Mr. Barnett is correct in stressing the advantages of a close-in circumferential route and also (see "Use of Existing Streets") in stating that a complete plan is much more than "bulling" through a free-flowing type of highway. Fig. 3, showing the moving of an arterial road from the central business district to the riverbank, illustrates good location. In a number of places the author makes use of expressions such as "a flexible system of expressways," "flexible routes for the driver to choose from," etc. In a city things are fixed—buildings are erected, utilities constructed, and street systems are fixed in relation to permanent transit systems. The wealth of a city has been built up around these fixed things. The word "flexible" is extremely misleading.

Mr. Barnett writes (under the heading, "Planning Agencies") of "* * * a spectacle of so much planning that what should have been a healthy rivalry resulted in a jam which prevented progress." Possibly some one was stubborn or had a limited technique. However, cities are full of things called "progress" that were put there before all the facts were known. There are many activities in a city other than moving around in an automobile.

In the "Introduction," the author states that "As yet there have been few instances in which the desirable separate provision for arterial traffic has been attempted." The business transacted in a city, the visiting, and the contacts made are not from arterial traffic comparatively speaking. The converging people from 5,000 blocks of 50 sq miles of city make business; and, if these people come by automobile, congestion results.

It seems confusing to state (see "Use of Existing Streets") that:

> "One fallacy in such reasoning lies in the fact, just mentioned, that an individual vehicle is destined for a point in a district and use of surface streets should be reduced to a minimum."

Each vehicle is destined to a point and every point is a different location that can be reached only by surface streets. The existing major streets must accommodate the bulk of the movement of people and goods.

An express highway through a city requires land, approximately 400 ft wide, with ramps, service roads, roadways, and accelerating and decelerating lanes. Except where stragetically located, such a structure introduces a disrupting force to all the factors of good living. If a school building is on one side of this expressway, the children who live on the other side must go to one of the arterial crossings and backtrack to their school building instead of going the usual route directly from home to school; or there must be a new arrangement of school districts and new school buildings. Because they must carry all transportation of the closed streets in between, these arterial crossings become greater hazard factors than before. People going to church are subjected to the same inconvenience, and neighbors cannot visit neighbors as before. They cannot shop at their favorite neighborhood store or use their favorite neighborhood service station. For the city as a whole—school districts, church districts, social districts, and neighborhoods that may be cut in two by an express highway—the effect on the city tax structure may be an injury that cannot be compensated.

Mr. Barnett's paper concerns the Interregional or Interstate Highway System as extolled in *House Document No. 379* (2d session, 78th Congress). This system is a network of highways connecting the main cities of the nation, apparently designed for military routes. However, it is to be used in peacetime for all-purpose traffic, trucks, trailers, semitrailers, buses, and passenger automobiles. The standards of construction are to be the highest standards used in highway construction. The highways are to be designed for a speed as great as 70 miles per hr and will be expected to care for all motor traffic that is likely to be developed in the succeeding 20 years. The system will enable buses and trucks to compete effectively with railroads. It will bring these buses and trucks directly to the heart of the city, through the city, and beyond the city. As compensation to a city, it is stated that these express routes running through the business center, and through the city, will serve the population of the city between home and business. This conclusion is extremely doubtful.

The writers of *House Document No. 379* maintain that the shortest route may not always be desirable and that the most direct route should give way to locations which would not be disrupting—riverbanks, waterways, and railroad rights of way (where the street system has already been broken and where all development of the city in past years has been based on this situation). An express highway, if one is needed through a city, should be located where it will disrupt the cross street system the least. Surface streets are a necessary part of any comprehensive system of transportation. The traffic picture in a city is changed continually by the location of new buildings, new factories, new manufacturing districts, and new residential districts. Therefore, a plan must be adopted in which the express highway does not cut across streets that have been developed, to the fullest extent through the years, to serve the abutting property. In this case, location is far more important than engineering design, and it must not be thought that, if the location destroyed a few old buildings, it is necessarily a good location.

The problem confronting all cities is one of transporting people. An express highway is built for the use of passenger automobiles and all other motor vehicles—motor buses, motor trucks, and tractor-trailer and semitrailer com-

binations. It is not for the much needed segregation of passenger automobiles and the rapidly growing truck traffic.

The great spread of destinations of passengers from all parts of the city through the entire central commercial area, the manufacturing area, the wholesale area, the railroad terminal area, and the waterfront area requires further exploration. A check on where people alight from street cars and buses furnishes a good sample of this phenomenon. The people's habits and behavior, as they move from place to place, involve a surprising number of tangible and intangible factors, all of a variable but interrelated nature.

To expend from three to five million dollars per mile for an express highway into and through a city is a major operation, and location is all important. Large cities are prohibiting parking of cars in the central business district, establishing one-way streets, and exploring methods of "steady flow traffic" to make greater use of their existing street system. All these studies and experiments are valuable. Possibly the "close-in circumferential route" should be located and built first. The traffic flow into it would help locate radials and interchanges.

No passenger cars should be allowed inside the circumferential route. People would transfer from automobile to shuttle buses and taxicabs, or they would walk to their destination. From an economic standpoint it would be far better to improve mass transportation to the highest standards possible, and then later to follow up with motor vehicle express routes. Building express routes first will increase congestion to a self-limiting status. Building up mass transportation will move the people where they need to go and may stop disintegration of central districts.

Ralph R. Leffler,[26] Esq.—Pavement-minded engineers, paving bureaus, and paving and earth-moving interests have derived much profit and power from the decentralizing of the big city. These interests have almost complete control (officially and otherwise) of planning for recentralizing (rehabilitating) the big city for the "general welfare of all." It is not surprising that puny planning, thin thinking, and verbose vaporings characterize the offerings of such of these interests as are typically selfish and bureaucratic. Mr. Barnett's paper makes determined and fairly successful efforts to avoid the selfish and bureaucratic.

Nevertheless, Mr. Barnett's paper is unintentionally quite "pavement minded." It lacks sufficient "structural mindedness"—giving scant consideration to the merits of elevated highways (on columns) and none at all to the overwhelming advantages of two-deck elevated highways (on columns) in big cities. Elevated highways, particularly two-deck elevated highways, are the product of structurally-minded as distinguished from pavement-minded engineers.

The paper treats "Parking in the Central Business District" quite cautiously, briefly, and very inconclusively under the heading, "Terminal Facilities." Extended exploration of the merits of elevated highways, especially of two-deck elevated highways (on columns), would probably have led Mr. Barnett to much more conclusive and structurally-minded ideas on "Parking in the Central Business District" on the second, third, fourth, and fifth floors of existing and future buildings and on the "setback" roof of future buildings.

[26] Engr. of Structural Design, The San. Dist. of Chicago, Chicago, Ill.

The features and merits of two-deck elevated highways (on columns) have been discussed by the writer elsewhere.[27,28] Thorough study will convince almost anyone, except a paving bureaucrat, that the structurally-minded engineer can be very helpful in recentralizing the decadent big city—if given the opportunity.

M. HIRSCHTHAL,[29] M. ASCE.—The profession is greatly indebted to Mr. Barnett for his timely and substantial contribution, which focuses attention on a great need—a thorough discussion of means of coordinating express highway traffic through cities and suburbs of a metropolis so as to produce a free flow throughout.

Development of the highway and its design have naturally followed closely upon the development of the automobile. When the automobile first made its appearance, a 16-ft width of roadway constituted a two-lane highway. This was shortly increased to 18 ft with an allowance of 9 ft for a width of lane; a four-lane highway was made 36 ft wide. At that time the general practice was to use 60% of the street width or right of way as roadway, thus providing a 36-ft road width for a 60-ft city street or highway. Most city streets have been laid out on this ratio basis, even to the 100-ft-wide express streets in which the roadway has a width of 60 ft. Lane widths in state highway design specifications were set at 9 ft as standard, and remained so until about 1941.

In recent years this lane width has been gradually increased to 12 ft (particularly on express highways), with a provision of 5 ft or 6 ft (in some instances, as much as 12 ft) for a "parkway" separation between the two sets of lanes for traffic in opposite directions, and with additional provisions for gutters and shoulders on either side. (Incidentally, in all this express highway planning, including New York and New Jersey state highways, nowhere has the writer seen any provision for the pedestrian—he is the forgotten man.)

Despite the widening of the lanes, perhaps because of such widening, it is not at all unusual to find cars straddling two lanes. Accidents continue to increase by reason of cars moving from one lane to another, or by passing another car and miscalculating the space available for that purpose, especially if a bus or a truck is one of the vehicles involved. The only way to avoid these all too frequent occurrences is to provide barriers between the lanes of traffic in the same direction; to prevent such crossovers except at definite locations, say, at one-half mile (or perhaps one-quarter mile) intervals, with proper safeguards similar to those for the many points of merging traffic from roads entering into the express highway. The writer anticipates electronic control in the future.

Such barriers could be provided, without the necessity of additional right of way, by making 9 ft the clear lane width, the actual requirement for a vehicle. The remaining 3 ft of the 12-ft lane widths could be used for barriers or curbs of sufficient height (15 in. minimum) to eliminate the possibility of vehicles mounting these curbs and at the same time to discourage the motorist from driving too close to them. Furthermore, this would simplify the assignment of a definite lane for trucks and other slow moving vehicles if desired. Hazards

[29] Concrete Engr., D. L. & W. R. R., Hoboken, N. J.

of sideswiping and similar accidents would be reduced to a minimum. Another advantage is attained in the economy of the cost of grade eliminations across the highway, both for railroads and other highway overcrossings and undercrossings, which would more than compensate for the extra cost of the barriers and the provision of drainage.

Provision of the 3-ft-wide barrier between the traffic lanes in the same direction permits locating in that space the columns or piers required for a bridge in the event of grade crossing elimination over the express highway (a railroad overcrossing) and eliminates the necessity of long-span construction, which is evidently far more costly than that for short spans. Also, where soil conditions are poor, it may obviate the necessity of expensive foundations by the substitution of a spread footing. This may be all that is required to carry the light reactions resulting from short-span design, while heavy foundations are likely to be required for piers and abutments that carry the loads from long spans. Moreover, the great majority of crossings between highways and railroads are at angles other than right angles, resulting in skew bridge structures of increased span length, thus accentuating the foregoing condition.

To cite an actual example: At Fox Hill, Mountain Lakes, N. J., state highway route No. 6 crosses the tracks of the Delaware, Lackawanna and Western Railroad (D.L. and W.R.R.) at an angle of 26° 19′ (a skew of 63° 41′), requiring a center-to-center span length of girder of 103 ft to span the required lanes in one direction; whereas each lane would require only one quarter of such span length had it been possible to provide these barriers and hence space for the location of columns or piers between each lane. It is quite evident that 103 lin ft of girders for four 26-ft spans would weigh a fraction of that for one 103-ft span, particularly for railroad loading, and that the sum of the reactions of the small spans would be similarly reduced for the footing design.

Where the express highway is the overcrossing in a grade elimination, the provision of this space for barriers will make available shallower floor depths because the floor system need span only the width of one lane with girders located in the barrier space, and the 15-in. or more available depth above the road surface may prove sufficient for a depth of girder of moderate span length, so that the girder itself (or a pair of girders) may act as the required barriers.

Similarly there can be cited an example of this case: New Jersey State Highway route No. S3 crosses the D.L. and W.R.R. tracks at Clifton, N. J., on a proposed bridge over the four railroad tracks. The plans provide for the girders to be 54 ft apart on each side of the 16-ft center "parkway" or "island" to accommodate the lanes in each direction. For this condition a 4½-ft floor depth is required. It is evident that a drastic reduction in this floor depth would result if the girders spanning the tracks were only 12 ft apart (in the barrier space) with additional resulting economy in the length of approaches required for this reduced floor depth. Numerous cases could be cited, but these have been selected because of their emphasis.

Approximately 25 years ago the writer proposed[30] to the New York City (N. Y.) authorities a remedy for the traffic congestion on the avenues running north and south, in the form of elevated sidewalks providing two additional

[30] "Elevated Sidewalks of Reinforced Concrete for New York City," by M. Hirschthal, *Engineering News-Record*, May 31, 1923, p. 974.

traffic lanes, instead of the 25-ft sidewalk space, in each direction for local traffic, with pre-cast bridges spanning the intersecting street roadway openings. It was then emphasized that the shops would benefit thereby in having two stories of display to advertise their merchandise. A a matter of fact, this remedy could be applied as well to all the crosstown streets now so congested in midtown Manhattan.

The writer hopes these comments will receive the attention of express highway planners in metropolitan as well as other areas.

JOSEPH BARNETT,[31] M. ASCE.—Although the sixteen discussions are chiefly confirmations of the principles of express highway planning as given in the paper, some are critical. Mr. Lavis suggests that the profession would derive more benefit if the paper were more specific. It is agreed that each city and each project in a city needs detailed study; yet the solutions of specific problems show a definite sameness that leads to a set of principles. This is time-honored engineering procedure. The paper is intended to show these principles.

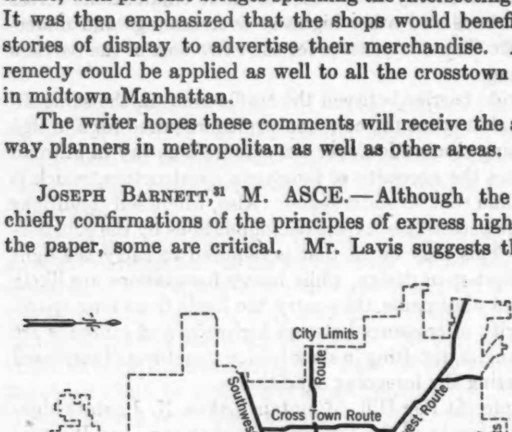

FIG. 13.—COMPREHENSIVE SUPERHIGHWAY SYSTEM FOR CITY OF CHICAGO, ILL.

As a matter of fact Figs. 1, 2, and 3, showing patterns of arterials, are actual cases although the names of the cities are not given. Figs. 4, 5, and 6 illustrate types of expressways which have been in operation for some years. An excellent example of the pattern of arterials described in the paper (namely, radial routes and an inner circumferential, with an intermediate or outer circumferential for the larger cities) is presented in Fig. 13, which shows the arterials for Chicago, Ill. The locations were determined over a period of years after factual origin-destination data were obtained and analyzed and the other factors outlined in the paper had been given serious consideration. A few of the arterials, such as the Lake Shore Drive, are in operation and the West Expressway is under construction.

The fact that this pattern is ideal in most respects is confirmed by the discussions of Messrs. Baker and Van London, who cite specific cases in which a large percentage of the traffic traversing the central business district is destined beyond it. An analysis of seven cities from this standpoint is shown in Fig. 14. By carrying the large portion of traffic destined beyond the central business district on free-flowing arteries, congestion of the downtown streets will be relieved and traffic necessarily using them will be better accommodated. On this factual basis Mr. Herrold's criticism is invalid. When par-

[31] Chf., Urban Road Div., Public Roads Administration, Federal Works Agency, Washington, D. C.

alleled by solutions to other problems, such as the terminal problem, there can be little doubt that relief of downtown traffic congestion will result. These facts are overwhelming arguments against the policy of carrying free-flowing arteries to the edges of central business districts and expecting existing streets to act both as distributors and as arteries for through traffic. These streets generally already are used to capacity and superimposing upon them the traffic induced by improving radial routes will further congest the downtown streets.

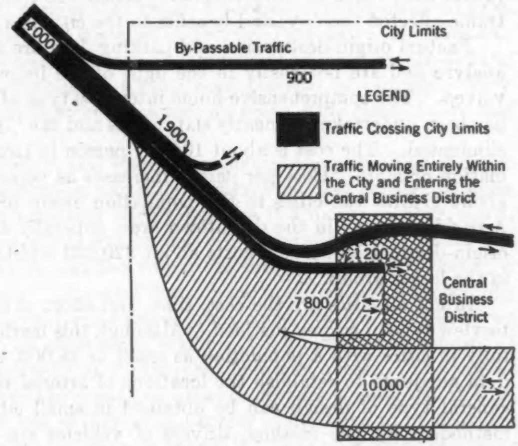

FIG. 14.—ORIGINS AND DESTINATIONS OF TRAFFIC ON AN INTERSTATE ROUTE THROUGH A TYPICAL CITY WITH A POPULATION OF FROM 50,000 TO 100,000, AS BASED ON DATA FROM SEVEN CITIES

A careful examination of the effects of a proposed solution on the downtown streets was discussed by Messrs. Baldock and Lewis and more attention to the terminal problem was suggested by Messrs. Baldock and Weiner. Both problems are related. No analysis of a city motor transport problem is complete without an analysis of the effects of heavily traveled free-flowing arteries on existing streets, an analysis of the terminal problem, and what should and can be done about both. Without such analyses a city may well find that, as Mr. Herrold stated, although the arteries will enable drivers to reach the central business district sooner, greater congestion may well occur. However, the opposite will result if a properly coordinated plan, based on factual data and not just on opinions, is carried through. In Atlanta, Ga., for example, the parking desires and the prospective parking facilities had a profound effect on the choice to locate an important arterial on one, rather than on the opposite, edge of the central business district. The latter location would have resulted in vehicles destined for the parking areas using streets through the central business district whereas with the former location vehicles destined for parking areas will travel short distances on existing streets not used as much as the downtown streets.

Proper locations of arterials, traffic and parking desires, and effects of proposed solutions on existing streets cannot be safely determined by measurements of volumes on existing thoroughfares and the judgment of planners, even when backed by the customary data collected by city planners. These are valuable assets but they cannot be relied upon without factual data regarding origin and destination, parking and loading, and the many important needs revealed by the obtainment and analysis of such data. Expenditures for improvements of arterial routes in cities are large. Not only are initial expend-

itures high, but a location once accepted and agreed upon commits public officials to a long-range program of improvement involving comparatively large sums of money. The foundation for such a program should be sound justification based upon factual data; benefits to traffic, both arterial and other traffic affected thereby; and benefits to the city as a whole.

Factual origin-destination and parking data are not difficult to obtain and analyze and are not costly in the light of the improvement expenditures involved. The comprehensive home interview type of origin-destination survey has been undertaken in nearly sixty cities and the "bugs" have nearly all been eliminated. The cost is about 10¢ per person in large cities of 1,000,000 population or more. Cost per person increases as population decreases, reaching about 17¢ for the cities in the population group of from 50,000 to 100,000. A parking survey in the downtown area, generally needed to supplement the origin-destination survey, costs about $20,000 additional when made in cities in the larger group.

In not all cities are the cost, time, and effort of a comprehensive home interview type of survey justified. Although this method has been used successfully in cities with a population as small as 15,000, reliable origin-destination data adequate to establish the locations of arterial routes and to indicate the general type of design can be obtained in small cities at less cost by other methods. By one method, drivers of vehicles are interviewed as they are parked. Data are thus obtained not only as to parking habits and desires but also as to the origin and destination of the trip and the purpose thereof. Such surveys cost from $4,000 to $8,000. In another method origin-destination data are obtained from vehicles passing two or more cordons of survey stations. One cordon generally is placed around the edges of the urban area and another, around the central business district. The data are best procured by interviews, although postcard questionnaires are sometimes used. This method is successful if knowledge regarding trips between different sections of the city outside the central business district does not have an important bearing on the problem.

The value of adequate and reasonably accurate traffic data lies beyond the determination of desirable locations of arterial expressways. In many cases locations of arterials can be determined with very meager traffic data; but an analysis of the effects upon the existing street system, previously discussed, and a determination of the accesses and the traffic loads for which they should be designed cannot be made properly without such data.

The matter of terminals, both for passenger vehicles and trucks, is a vast subject and the statement of principles in the paper is condensed indeed. The problem has been excellently restated by Nathan Cherniack, M.ASCE, and by discussers of his paper.[32]

In regard to design types, Messrs. Hadley and Leffler bring up the matter of elevated structures, a two-level structure being one type suggested. It may be of interest that the elevated highway shown in Fig. 6 (which was designed many years ago) provides a second level, but this idea has been abandoned. The two-level elevated has the advantage of narrowness and economy as com-

[32] "A Statement of the Parking Problem," by Nathan Cherniack, *Proceedings*, Highway Research Board, National Research Council, Vol. 25, 1945, p. 250.

pared with a one-level elevated, but the ramps leading to the upper level present added problems and damage to adjacent land may be great. The advantages and disadvantages of elevateds as given in the paper are valid regardless of the number of levels. Several designs that began by considering the elevated type as obviously superior finally were designed as depressed expressways. This was not because the engineers were "pavement minded" as accused by Mr. Leffler. If they were, the elevated would not have been thought of initially. Very few elevated highways have been constructed; on these, wide right of way was available or was acquired.

Messrs. McCrosky, Hadley, and Waterbury suggest the possibility of direct connections between expressways, particularly elevateds, and parking garages. This possibility has been discussed widely because it appears to have merit. Traffic using such garages would not be delayed at terminals and would not use existing streets, thus reducing the volume of traffic thereon. However, a word of caution is in order. Assuming that all the practical and financial difficulties of such a development can be overcome, consideration must be given to the effect of operation on expressway traffic. The fundamental concept of an expressway is free movement and infrequent points of access. The rate at which vehicles can be moved into parking areas or garages is not great at best, so that numerous such points of ingress and egress would have to be provided unless an extremely large storage plaza is available. The plan does not appear to have the flexibility of operation that is desirable to insure against interference with traffic on the expressway. A more flexible plan, and one which appears readily attainable, is one in which the parking facilities are near the expressway but are not a part of it.

Mr. Lewis and Mr. McCrosky discuss the desirability of expressways for segregated traffic. It is agreed that there is fallacy in the theory that the construction of expressways or parkways for the exclusive use of passenger vehicles will benefit commercial vehicles sufficiently by releasing the existing streets to them; yet the segregation of traffic is desirable because of the smooth operation, high capacity, and great benefits to passenger vehicles and occupants including passengers in buses (where use by buses is feasible). In the larger cities separate expressways for passenger vehicles and for mixed traffic appear to be justified.

Several discussers take up the matter of transit. Improvement of transit is one of the important items in the broad attack necessary to relieve congestion in the cities. It is unrealistic to expect most of the home-to-work, home-to-shop, and home-to-business trips to be made in private vehicles, particularly in the larger cities. When properly designed, operated, and controlled, mass transportation can do much to relieve traffic congestion simply by reducing the number of vehicles on the streets and in the parking places. However, the position of express highways in relation to transit is not as simple as the discussers indicate.

In the larger cities rail transit might be included in the same right of way with expressways with some economy resulting to both—but such a case is certain to be exceptional. Use of expressways by buses is the more likely pattern into which transit will fit, particularly for rush hour express type of transit operation between outlying sections and downtown areas. Bus operation with frequent stops does not appear practical on expressways. Such stops would

have to be designed with separate stopping areas and speed change lanes for entering and leaving without interfering with through movements. They logically should be at important cross streets where transfers to crossing transit lines would be desirable. Provisions for separate stops at such locations are costly since they involve widening or lengthening grade separation structures, and the speed change lanes hamper the design and operation of ramps if interchange is also to be provided. In addition, a poor service is rendered patrons when they are required to climb stairs or ramps.

Where interchange ramps are provided, bus operation and stopping problems are solved economically and superior service is given patrons, if the buses use the interchange ramps, stop at turnouts at the level of the cross streets, then use ramps again for returning to the expressway. Where cross traffic is not heavy, buses can cross the intersecting street. Good designs have been made in which buses U-turn on to ramps leading back to the expressway after loading passengers, thus avoiding the crossing of the intersecting street. This is not possible, of course, where single one-way ramps are provided in each quadrant of an intersection. Most bus companies are not partial to operation on expressways where stops necessarily are few and far between, since bus operation is profitable and patrons are served best where bus stops are frequent and near the destinations of patrons.

Mr. Weiner cites the need for better use of existing facilities. This need is obvious for such existing facilities as streets, intersections, and control devices, but the need also exists for better operation of expressways. In large metropolitan areas existing expressways frequently become clogged during peak load hours when freedom of movement is needed most. Sometimes, because of inadequacies of design, such as lack of a shoulder, a stopped vehicle on a through lane can jam traffic in the same direction on all lanes. Sometimes congestion is due to simple overload. Whatever the cause, slowing down of traffic to 25 miles per hr or less results in use of the expensive facility for volumes less than capacity. For example, an expressway loaded bumper to bumper, with all vehicles stopped, is carrying no traffic in an operational sense. At such times all vehicles would benefit by denying the expressway to vehicles to the amount of the overload. Where jamming occurs regularly, it can be anticipated and police controls arranged for at the critical entering ramps.

Mr. Feld rightly suggests that it is not feasible to design expressways for peak loads. However, his submission of a photograph of the Hendrick Hudson Parkway in New York, N. Y., on Navy Day, although interesting, is academic only. No one would be expected to design for such an extraordinary peak. The American Association of State Highway Officials considers the thirtieth highest hour of the year to be the appropriate hourly volume for use in design, the year to be that for which the facility is being designed. For certain locations the thirtieth highest hour is as little as 8% and for other locations as much as 20% of the average daily traffic.

The writer has not attempted to give closing statements on all matters taken up in the discussions. For some, comments can be found in the paper; others, although worthwhile, are not related to the principles of express highway planning in metropolitan areas. All the discussions, however, have added much to the worth of the paper and evoke the appreciation of the writer.

Paper No. 2310

FUTURE COSTS AND THEIR EFFECTS ON ENGINEERING BUDGETS (PRESENTED BEFORE THE SANITARY ENGINEERING DIVISION OF THE ASCE ON JANUARY 17, 1946)

By Louis R. Howson,[1] M. ASCE

With Discussion by Messrs. Isador W. Mendelsohn, and Louis R. Howson.

Synopsis

In periods of rapidly changing construction costs many essential projects fail to go ahead because budgets are insufficient to cover the cost. This is particularly applicable to the postwar period. Appropriations made in 1940, after which other than war-related construction was practically suspended, are totally inadequate to cover costs in 1946 when restrictions were lifted and work could proceed. Budgets prepared in 1946 will likewise be inadequate unless they are made after consideration of the impact of wage adjustments, increased material costs, and government policies.

This paper presents a study of the effect of other wars upon construction costs, indicates some of the factors inherent in the present situation not experienced earlier, and forecasts the level of general construction costs until 1956 in relation to costs experienced in 1940.

1. Introduction

More briefly, perhaps, the subject of this paper may be stated as "What's Ahead for the Construction Industry?" The studies here considered were prompted by considerations of developments in sanitary engineering; to a very large extent, however, the future costs of sanitary engineering works are affected by the same fundamental conditions as the cost of the construction industry in general. The effect of such increased costs on budgets and financing of what are essentially public works offers some complications which are not inherent in private work.

Note.—Published in March, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Cons. Engr., Alvord, Burdick and Howson, Chicago, Ill.

The spring of 1946 is a difficult time in which to prepare a discussion on this subject. V-E and V-J Days are so recent, and there is so much turmoil in labor relations, such delays in reconversion, and such serious maladjustments arising from the war, that accurate forecasting is impossible. As is well known it is the universal experience that there is a price "spree" after all wars. The picture in the present instance, however, is somewhat further obscured by the fact the psychological "spree" started nearly ten years before the war, and by the simultaneous adoption by the federal government of the conflicting economic policies during the war, consisting of price curbs or ceilings on commodities, combined with incentive payments to war workers.

With the war over, there is a vast reservoir of construction available. If it proceeds normally it will provide direct employment for at least 3,000,000 men, and indirectly affect many more. However, if costs rise too high, the public will refuse to pay the prevailing prices and construction will come to a dead stop. It matters little what the hourly wage of labor may be if none is employed.

Even with the critical shortage of housing, the most optimistic forecast is for the completion of 400,000 units in 1946, a figure 200,000 less than the number completed in 1940, and 300,000 less than the 10-yr average from 1921 to 1930, inclusive. The conflicting economic policies of price controls for materials and finished structures, and of higher hourly rates for labor, are found to prove difficult to reconcile.

That the volume of construction will be influenced by its cost is illustrated by a survey made for *Architectural Forum* by Crossley, Inc., which concluded "Prospects are thinking realistically and precisely about what they can afford with relation to savings and income—sizable proportions of people are inclined to postpone building or buying if the house they want is going to cost more than the price they now have in mind."

That statement is equally applicable to sanitary engineering works. It is therefore important to consider the conditions likely to affect costs and volume of sanitary works in the postwar years.

In starting consideration of this subject, reference may be made to a well-known member of the legal profession who in addressing a group of engineers stated that he always liked to be associated with engineers, for in all of his experience: "The engineers and lawyers stood back to back with the engineer facing forward." That is a brief but picturesque statement of one essential difference between the two professions. The legal profession relies almost wholly upon precedent. The engineering profession, being a creative one, necessarily makes its designs for the future. While the lessons and experience of the past are valuable guides to the engineer, construction and the period in which that construction must serve necessarily lie in the future. Every engineering undertaking is a forecast—even the appraisal of utilities already constructed and in service—for value itself is a measure of future usefulness.

Someone has defined a forecast as the art of drawing a mathematically precise line from an unwarranted assumption to a foregone conclusion. The forecast of this paper will not be of that type, for an engineer certainly ap-

preciates that any sound opinion must be built upon a foundation of information about the forces with which that opinion is concerned.

2. Necessity for Appraisal of Future Conditions

Two major elements affecting construction projects are those of time and cost. Construction projects cannot be created and put into service without incurring expenditures of money and without the lapse of time. The more extensive the project the more important becomes the factor of time.

From a long experience with municipal projects, it has become almost axiomatic that ten years ahead is the "present" and any municipal utility that is not kept that far ahead of its projected requirements is almost habitually unable to meet them as they mature. Public projects such as water supply, sewerage, and sewage treatment, therefore, are peculiarly dependent for their success upon adequate future financing as well as the development of sound engineering design and execution. In periods of rapidly rising prices scores of sound public projects fall by the wayside because the funds appropriated for their execution have proved insufficient to cover the cost of construction at the time bids are taken. This invariably results in delay, misunderstandings, criticism, and, frequently, either restricting the project to a serious extent, or abandoning it for another decade or more. Adequate consideration of the factors affecting future costs and provision for them in estimates, even in such difficult times, will serve to avert some of these disappointments.

3. Construction Volume and Costs

The two important factors of construction volume and costs are closely interrelated. Construction volume is peculiarly sensitive to economic influences, the volume maxima usually occurring during periods of normal prosperity or that induced by war, and the minima normally being undertaken in times of depression when materials and labor prices are usually most favorable.

In diagrammatic form Fig. 1 shows new construction activity in the continental United States as reported in the industry report, construction and construction materials, of the Department of Commerce for the years 1929 to 1944, inclusive. Referring to the upper graph, Fig. 1, the points for 1945 and as forecasted for 1946 are from an address on "What's Ahead for 1946?" by William H. Shaw, chief of the construction statistics unit, of the construction division, Bureau of Foreign and Domestic Commerce, Washington, D. C. The figure of $15,000,000,000 for 1950 is taken from various government forecasts and construction industry goals; it will be noted that this is nearly 50% higher than the boom year of 1929, and a billion and a half dollars higher than construction expenditures during the peak war year of 1942 when new industrial plants, cantonments, and other war-related construction were under way. This is indeed an ambitious goal when expressed in terms of dollars and compared to past performance.

It is believed, however, that this upper curve by itself may be misleading, representing as it does dollars expenditure rather than the physical construction which results from that expenditure. With that thought in mind the dollars expenditure has been adjusted (lower graph of Fig. 1) to reflect the changes in

construction costs, by dividing these costs by the *Engineering News-Record* construction cost index (1913 = 100) for that year. The last four years are based upon the writer's prediction as to construction cost indexes during that period.

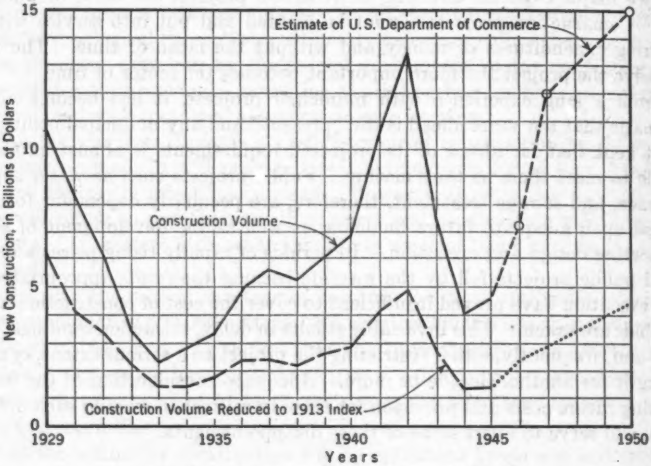

FIG. 1.—TOTAL NEW CONSTRUCTION IN UNITED STATES

It will be noticed from this lower line, which reflects costs in terms of structures built rather than of dollars spent, that even the war peak year of 1942 failed by approximately 20% to reach the construction volume of 1929; and that the forecast of 1950 will be approximately 30% below the construction of 1929 and approximately 10% below the construction of 1942. In other words, although the billions of dollars which it is hoped will flow into the construction industry in 1950 will be approximately 50% greater than those of the boom year of 1929, the actual construction resulting from that huge expenditure will be about 30% less.

Public Vs. Private. Construction.—During periods of normal prosperity private construction in the United States usually leads public construction in the proportion of three or four to one.

The relation between public and private construction for the seventeen years from 1929 to 1945, inclusive, is shown in Fig. 2 together with the forecast made by Mr. Shaw, for 1946. It will be noticed that in only two years, other than during the war, did expenditures for public works exceed those made by private owners—and then by only a very small amount during the worst depression years, 1932 and 1933. The forecast of the construction division of the U. S. Department of Commerce for 1946 is that 70% of the construction will be privately financed and 30% financed by the public.

In his discussion, Mr. Shaw predicted that by the end of 1946 "we can and should be building at an annual rate of better than $9,000,000,000 with

a goal of at least $12,000,000,000 in 1947." He continues with the statement, "Our forecast assumes reasonable costs—close to present levels." In appraising the possibilities therefore, it becomes pertinent to inquire as to whether costs will be maintained "close to present (1945) levels."

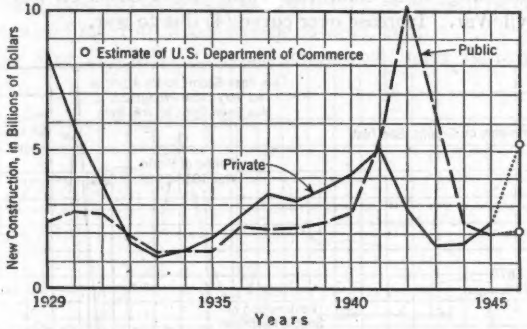

FIG. 2.—PUBLIC VS. PRIVATE EXPENDITURES FOR NEW CONSTRUCTION

4. EFFECT OF WARS ON PRICE LEVELS

Every war of lengthy duration has exerted a marked immediate effect on price levels but it has had a lasting effect as well. This is borne out by a study of recent wars and those within a period of centuries. The more nearly the present time is approached, the more accurate are the bases for the study.

The close of World War I left engineers confronted with the same type of problem that is being discussed here. At that time the late John W. Alvord, Hon. M. ASCE, was engaged on a number of public utility appraisals, one of which, the Bluefield Water Works and Improvement case, eventually found its way to the U. S. Supreme Court. The Bluefield decision was one of the two first decisions of that court holding that regulatory bodies must recognize the change in price levels resulting from the war.

A study by Mr. Alvord in 1921 at a time when construction costs of both labor and materials were at the all time peaks up to that date gave the data plotted in Fig. 3, showing the experience before, during, and after the Civil War as reflected in wages; and before, during, and up to that date as affected by World War I. Referring to the corresponding numbers on the diagram, the following notations apply:

(1) Wage statistics for period from 1840 to 1891 obtained from the Aldrich Report (Report of Committee on Finance of the U. S. Senate on Wholesale Prices, Wages and Transportation, 52d Congress, 2d Session). For period from 1892 to 1907 from the reports of the United States Bureau of Labor (*Bulletins Nos. 77 and 259*). From 1908 to 1920 from monthly *Labor Review*, March, 1921.

(2) Wage trend based on conditions preceding Civil War, ignoring effect of war.

(3) Average wage trend from 1879 to 1899; increase between curves (3) and (2) probably all due to effect of war.

(4) Wage trend based on conditions preceding World War I, ignoring effect of war.

(5) Actual wage conditions for twelve years after Civil War applied to present (1921) conditions to show probable wage curve after the war.

(6) Probable wage trend following World War I based on wage conditions following Civil War. Increase over curve (4) due to war.

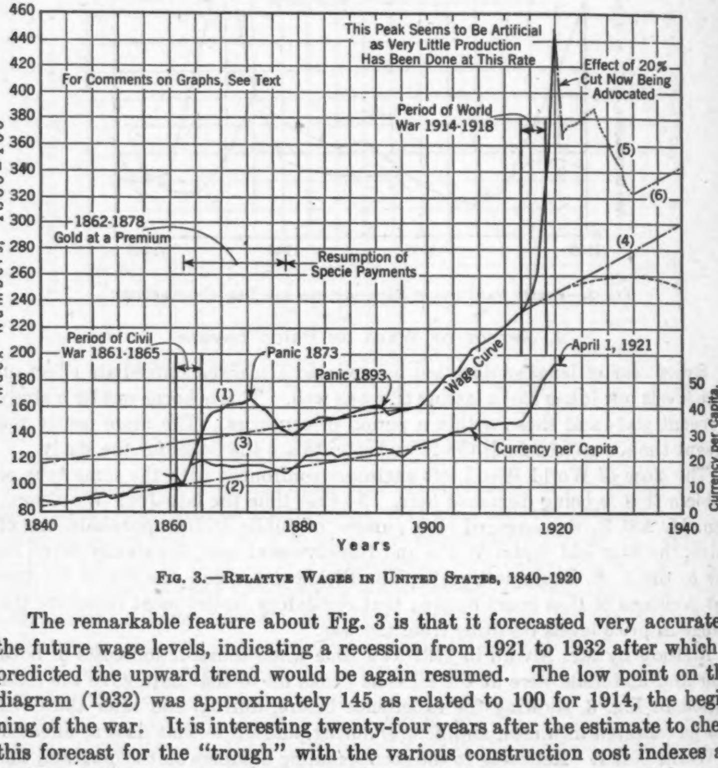

FIG. 3.—RELATIVE WAGES IN UNITED STATES, 1840–1920

The remarkable feature about Fig. 3 is that it forecasted very accurately the future wage levels, indicating a recession from 1921 to 1932 after which it predicted the upward trend would be again resumed. The low point on this diagram (1932) was approximately 145 as related to 100 for 1914, the beginning of the war. It is interesting twenty-four years after the estimate to check this forecast for the "trough" with the various construction cost indexes actually recorded for that same date. By way of comparison, some of the more important indexes for 1932 to the same base were as follows:

Engineering News-Record (E.N.-R.) construction cost index......	157
American Appraisal Company................................	155
Associated General Contractors..............................	171

In view of its historical significance, this exhibit (Fig. 3) is included herein just as it was presented with testimony.

In Fig. 4 there are three diagrams, each starting with the beginning of an important war in which the United States was engaged. The ordinates repre-

gent indexes with the first year of the war in each case being assumed as 100, as follows:

(*A*) World War I—E.N.-R. construction cost index (1913 = 100).
(*B*) Wages before, during, and after the Civil War (1840–1891) from Aldrich Report and from 1890 to 1919 from U. S. Bureau *Bulletins Nos. 77 and 259* and monthly *Labor Review*, March, 1921.
(*C*) World War II—E.N.-R. construction cost index (adjusted to 1939 = 100).

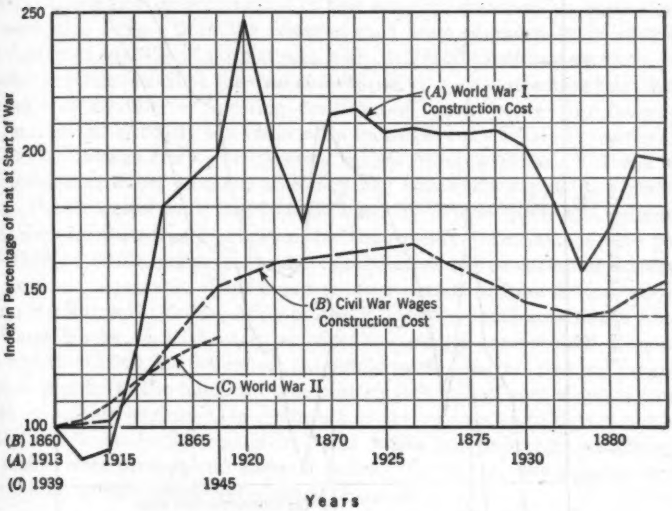

FIG. 4.—EFFECT OF WAR ON CONSTRUCTION COST AND WAGE INDEXES

The relationship and similarity during the three periods is apparent. In the Civil War and World War I aside from the extreme peak in 1920, the indexes continued to rise or maintain their level until nearly ten years after the close of the war. If it is logical to predict the future from the past, the E.N.-R. construction cost index, which as of January, 1946, was approximately 310 (1913 = 100), will rise to the 350 to 360 range by 1951 with nothing more than short time reactions in the interim.

To show the relation between wage rates and construction costs, Fig. 5 contains two diagrams, one (*A*) showing the union hourly wage rate of all building trades as reported by the U. S. Department of Labor and the other (*B*), E.N.-R. construction cost index. Just a casual glance at these diagrams, both platted with respect to the same time and index scales, will serve to show their close relationship. Construction costs have been somewhat more volatile and there would appear to be a lag in wage rates reflecting changing economic conditions, but aside from this minor difference, the relationship is remarkably close. This is as would be expected, for in the ordinary construction project

40% more or less of the total cost of project is spent for labor on the site, and a very substantial part of the remainder is expended for labor in manufacturing materials entering into the construction.

It should be noted that Fig. 5 does not reflect the result of post World War II strikes, wage increases, and cost increases. These might well raise graph (*B*)

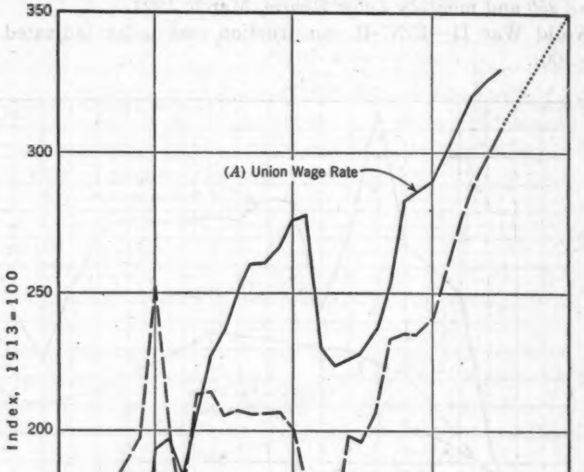

FIG. 5.—RELATION BETWEEN WAGE RATES AND CONSTRUCTION COST

to 350 or 360, as compared to its 1945 figure of 310, instead of requiring until 1950 for prices to reach that level under a continuation of the average rate of increase on construction costs since 1932.

5. CONSTRUCTION COST INDEX OF PAST AND FUTURE

In Fig. 5 there has also been platted the projection of E.N.-R. construction cost index to 1950. This graph discloses that:

(*a*) The only time since 1913 that the United States has had a substantially level construction cost index was during the period of prosperity extending through the twenties.

(b) The inclination of the construction cost index from 1932 to 1940, which is generally considered to have been a period of depression, was substantially as steep as during World War I, and World War II. This is believed to be a reflection of many factors, including general deterioration in labor output and efficiency; the growing effort of some labor union executives to discourage production incentives and piecework; the demoralizing effect of certain types of made work upon labor efficiency and morale; and various governmental efforts to keep prices up rather than permit them to react to ordinary economic laws.

It seems incongruous that, during the period covered by one of the worst depression periods ever experienced in this country, construction costs should rise more than 50%. With the prices of such basic commodities as corn and hogs depressed to 20% of normal and with 10,000,000 men out of work, construction costs increased at the rate of 10% per year. Contractors went out of business and sanitary engineering construction work was so revolutionized that for a period of nearly ten years not a foot of sewer was laid by contract in the City of Chicago (Ill.) The Work Projects Administration, (W.P.A.) with its demoralizing effect on labor efficiency had effectively supplanted contract work. Public works were largely subsidized by federal funds and minimum wages were instituted as a condition for the subsidy. During the nine years from 1932 to 1940, inclusive, public expenditures for construction averaged 75% as much as private. This compares to a normal of from 30% to 40%.

In 1945 Harry E. Jordan, Affiliate ASCE, executive secretary of the American Water Works Association, in an effort to secure a cross section of opinion as to why the $2,000,000,000 municipal public works program was not progressing more rapidly to the blueprint and construction stages, sent a questionnaire to 150 consulting engineers, to engineers of the various state departments of health, and to others interested in water works and sewerage construction. The replies were prompt and comprehensive. In general, the reasons for the delay fell into three rather well-defined channels:

1. Rising costs of construction.
2. Uncertainty as to whether there would be federal participation in public works after the war.
3. Congestion in designing engineers' offices.

The first reason, that of rising costs, is fully discussed herein. The second reason, resulting from the uncertainty as to federal policies, can only be removed by prompt action in Washington and of that there seems to be little likelihood. The third reason, congestion in designing engineers' offices, is gradually ironing itself out.

Uncertainties Affect Contract Costs.—It was almost the universal experience during 1945 that such sanitary engineering work as went out to contractors for bids attracted few bidders and their prices were materially higher relative to prewar amounts than would be indicated by the increase in the E.N.-R. construction cost index. This reflects the uncertainty and fear inherent in the present picture. Uncertainty costs money. Contractors have their four fears: (1) Rising material prices; (2) inability to get materials when needed; (3) rising labor wage rates; and (4) decreased efficiency of labor.

Availability and efficiency of labor will probably improve somewhat after the unemployment benefits to war industry workers are stopped. It is believed that the only important recession from present high construction contract costs will be brought about by stabilizing wages and thus stabilizing prices of materials but that the general construction cost tendency thereafter will be upward for the next few years.

6. Conclusions

From the foregoing discussion it is believed certain general conclusions may be drawn:

1. It is apparent that hesitancy and uncertainty, particularly in the labor picture, both as to cost and efficiency, justify the reluctance of contractors to bid on work of any magnitude requiring any considerable length of time, unless a very liberal "contingency" factor is included. Washington's "no policy" labor attitude is believed to be largely responsible.

2. It is believed that clarifying the labor picture will greatly improve the possibility of securing fair bids on construction work; that wage stabilization even at a higher level will affect contractors' bids less than the previous uncertainty.

3. Engineers should be realistic. Postwar construction costs are bound to be materially higher than prewar. In most lines of general construction the increase above 1940 will probably approximate 50% by 1950, and in certain classes of construction such as pipe lines and sewers involving a large proportion of common labor, the increase will be materially higher.

4. Aside from the removal of the contingent item by the clarification of the labor situation, there is nothing in the picture of prospects for 1946–1956 to indicate that construction costs will be materially lowered. There will probably be a continued rise, possibly accelerated by the further rise in labor wage scales.

5. Rising construction costs particularly to an extent in excess of 50% above 1940 will materially retard construction and many public works will be deferred or abandoned.

6. One of the important deterrents toward normal procedure in public works construction is the failure of Washington to declare itself with respect to federal aid. Aside from a few of the very large cities most American cities do not want federal aid for their projects. However, many public works will be deferred awaiting a definite position relative to federal aid for public projects. Public officials do not want to be in the position of having their city proceed on its own when had it waited a few months it could have had a government subsidy which would either have reduced that city's cost or enabled it to do more work.

7. So far as sanitary engineering works are concerned, about $2,000,000,000 worth of water works and sewerage construction was in the development stage as of January 1, 1946, of which something less than 10% was in the blueprint stage. Cash was in hand for much of the water works improvements. Sewerage, however, was not so fortunate; much of this work was bound to be delayed as it was projected on the basis of 1940 costs which had already been exceeded by from 30% to 60%.

DISCUSSION

Isador W. Mendelsohn,[2] M. ASCE.—The subject of this timely paper concerns every engineer intimately. Construction costs are rising and are in a stage of unpredictable flux. As to the phenomena responsible for increasing construction costs, it is necessary to study the entire construction industry critically and to evaluate the numerous factors and their interplay. Anything short of such analysis will provide only an unbalanced judgment. When, in four of his seven conclusions, Mr. Howson stresses the relationship of wage rates to high construction costs and in none of the conclusions specifies definitely any other influences contributing to such high costs, it is a moot question as to whether his analysis of factors of construction costs is complete.

Characteristics of the Construction Industry.—The construction program in the United States for the period from 1915 to 1944 comprises new, work relief, and maintenance construction. In past years the cost of new work has varied from \$2,350,000,000 in 1933 to \$13,498,000,000 in 1942,[3] averaging \$6,700,000,000 annually. Maintenance construction has averaged \$3,000,000,000 annually, whereas work relief construction for the period from 1933 to 1943 has averaged \$636,000,000. New construction includes private and public residential and nonresidential buildings, farms, public utilities, military and naval work, pipe lines, highways, sewage disposal, water supply, conservation, and development. In hearings before the Temporary National Economic Committee on Investigation of Concentration of Economic Power, Isador Lubin testified[4] that the construction industry employed 5.5% of nonagricultural workers in 1929 and consumed about 15% of the commodities produced in the United States for the period from 1919 to 1935. Willard Thorp stated[4] the construction industry has certain definite characteristics: (1) It produces a product which is not uniform in type, design, size, and location, and operates on a made-to-order basis; (2) the products are far from simple, requiring thousands of materials and a variety of skills; and (3) the demand is irregular, essentially local, and highly seasonal. Considering the third point, Beardsley Ruml has aptly stated that the circumstances which result in a profitable outlook for the building of a factory by one company will simultaneously affect thousands of companies.[5]

According to the Social Security Board, there were, in 1938, 22,000 general building contractors, 8,000 other general contractors, and nearly 67,000 special trade contractors, involving a total of more than 825,000 employees. To these should be added about 50,000[4] who operate "on their own" in the construction industry.

[5] "Public Works and Construction After the War," by Beardsley Ruml, address before New York Building Cong., New York, N. Y., April 24, 1945.

In comparison with other industries, Mr. Ruml finds that the construction industry is costly and wasteful.[5] Pertinent factors[4] are: (1) Difficulty of organizing and planning an efficient work program, bringing many parts together in varying ways, places, and on various types of operations; (2) expensive purchasing, in small lots; (3) expensive selling practices; (4) uneven flow of work and employment; (5) little research, and resistance to new methods and materials; (6) inadequate and unstable financing; (7) bitter competitive practices leading to agreements, collusions, price controls, use of building codes, and union restrictions; (8) a tendency for each part of the construction industry to increase its own charges rather than to reduce them; (9) high transportation costs of construction materials (in 1936, 57% of the value of gravel and sand at destination, 28% of that of common brick, and 21% of that of lumber, shingles, and laths, being absorbed by freight charges); and (10) high degree of concentration of construction material production, showing relatively few producers for many important items, four leading companies[4] cutting 22.8% of the Douglas fir; 7% of the southern pine; and 49.3% of the structural steel shapes.

According to Mr. Ruml:[5]

> "Architects, building contractors, building supply companies, labor, finance and mortgage companies, all found it necessary—each in its own way—to establish and to hold a price structure high enough so that the days and hours of activity would pay for the time when there was little or nothing to do."

Unreasonable Restraints of Trade in the Construction Industry.—In the opinion of Thurman Arnold,[4] unreasonable restraints of trade are the most conspicuous reasons for high construction costs. Restraint practices developed in government proceedings involve producers and distributors of building materials, contractors, and labor. Producers of building materials have fixed prices by private arrangement.

Distributors of building materials try to raise the price of their services by establishing a fixed markup between the price they pay the manufacturer and the price at which they sell. Many groups of contractors set up little closed markets from which they exclude outside contractors or new types of services.

The building-trades unions have frequently been used as the "strong-arm squads" for collusive agreements among contractors, refusing to supply labor where the contractors' ring wishes labor withheld. In other cases the unions themselves have refused to permit the use of new products or new processes.

Restraints of trade in building have: (*a*) Harassed, boycotted, and eliminated competitors able and willing to reduce prices; (*b*) handicapped the use of prefabricated materials and thwarted the development of methods of mass production in the industry; and (*c*) prevented experiment in housing design, materials, and methods of construction.[4]

United States Department of Justice Action Against Restraints of Trade.—Since the passage of the Clayton Act in 1914, the Department of Justice has

instituted approximately 674 cases,[6] of which 160 have involved some parts of the construction industry. In 1939 the Anti-Trust Division of the Department launched a broad attack on restraints in the building industry. Preliminary surveys were made in twenty-six cities. Grand juries were assembled in eleven cities. By September, 1940, ninety-eight indictments involving 1,281 defendants had been returned. Among the defendants were associations of manufacturers, distributors, contractors, and labor; and individual officers of trade associations, business enterprises, and labor unions. In addition to the criminal cases, nineteen equity proceedings were instituted, involving a total of 367 defendants (as stated by Thurman Arnold in an unpublished address before the Illinois Association of Real Estate Boards at Chicago, Ill., on September 20, 1940).

From this campaign economic results appeared more quickly than did legal results. In May, 1939, the Pittsburgh city engineer[7] drew up an estimate of the cost of the electrical work in a new municipal hospital being built with funds of the Public Works Administration (P.W.A.). His estimate was $105,000; the city advertised for bids, opened them, and found that the lowest was $154,000. Specifications were revised and the city re-advertised. The lowest bid was then $148,000, which was rejected. The third set of bids brought a low offer of $152,000.

About that time a team of eight men from the United States Department of Justice reached Pittsburgh and began its investigation. This team advised rejection of the latest bids. On November 3, a federal jury indicted twelve electrical contractors, a trade association, and forty-five individuals, charging a conspiracy to defraud through collusive bidding. A few days later the city received a new set of bids for this hospital electrical work—with a low, this time, of $117,000.

A little later the city[7] opened bids for the purchase of sand and gravel. For the first time in years, the sand and gravel bids received were not identical, and the quoted prices dropped from the prevailing level of $2.25 a ton to from $1.65 to $1.80 a ton—a saving of $17,000 on sand and gravel for the first quarter of 1940.

In another case a low-cost housing project in Pittsburgh was planned in two units, bids on the first being opened before the Anti-Trust Division began investigating and those on the second after the federal grand jury had been sitting about three months. The investigation resulted in bids lowering the electrical contract by 23.5%, the heating contract 27%, the plumbing contract 26%, and the general contract 12%. The over-all reduction in the cost per family on the second unit was $148 per room, or 17% of the total cost.

A federal grand jury in New Orleans returned an indictment on February 21, 1940, against three organizations representing lumber interests. These groups were charged with conspiracy to fix prices, to curtail output, to enforce an

[6] "Anti-Trust Cases in the Construction Industry," U. S. Dept. of Justice, Washington, D. C., July 1, 1946.

[7] "War and Prices," Temporary National Economic Committee, Pt. 21 of "Investigation of Concentration of Economic Power," December 4–8, 1939 (*No. Y4.T.24:Ec. 7/Pt. 21*, Supt. of Public Documents, Washington, D. C.).

agreed policy of distribution, and to restrain trade by abuse of grading, grade marking, and inspection. All these practices were subsequently enjoined.

Federal Trade Commission (F.T.C.) Action Against Restraints of Trade.—Illustrative of many unlawful monopolistic cases in restraint of trade concerning construction activity processed by the F.T.C. are the following:

1. Approximately thirty-one corporations engaged in the business of manufacturing water gate valves, hydrants, fittings, and similar products,[8] and in the sale of such products to cities and state and federal governments, comprised substantially all the manufacturers of such products used for water supply systems. They were located in seventeen different states. The monopolistic practices in this case consisted of agreements by these corporations to fix and maintain prices. The commission found that these practices had actually hindered price competition and had created in the members of this group a monopoly unlawfully restraining interstate commerce.

2. In 1937[8] the commission issued findings and an order against an organization of building material dealers with a membership of more than 150. The materials in which the organization dealt included cement, brick, tile, clay products, sewer pipe, sand, gravel, stone, lime, lumber, roofing, and other materials ordinarily used in the construction industry. The main objective of these associations and their members was to confine retail distribution in building materials and supplies to recognized dealers and to prevent the direct sale by manufacturers to all others.

In 1935 the United States, through the Procurement Division for the Relief Administration,[8] sent to manufacturers in one state an invitation for bids on 100,000 bbl of cement. As a result of action by the state association of builders' supplies, no cement company would quote prices. When the same invitation was mailed to manufacturers outside of that state, again no direct bids were received.

The commission found that interstate commerce in the sale and distribution of building materials was thus restrained because the organized collusion eliminated the so-called irregular dealers and manufacturers and producers selling to such dealers. Competition in the sale of all building materials was substantially lessened. Competitors of members were unable to obtain interstate shipments of their requirements. Costs to the consuming public were increased.

Identical Delivered Price Systems in the Construction Industry.—A paramount economic factor in unfair pricing in the construction industry is the identical delivered price systems, such as the basing-point, the freight-equalization, and the zone systems. According to the Procurement Division of the United States Treasury Department, during the period from December, 1937, to November, 1938, 76,000 bid openings, or 24.1% of 332,000 bid openings during that period, involved the receipt of identical bids from different sellers.

---

[8] "Federal Trade Commission Report on Monopolistic Practices in Industries," Temporary National Economic Committee, Pt. 5-A of "Investigation of Concentration of Economic Power," March 2, 1939 (*No. Y4.T.24:Ec. 7/Pt. 5-A*, Supt. of Public Documents, Washington, D. C.).

This covered industries including all the major categories from which the government makes purchases.[9]

Concerning the basing-point system,[8] the federal government was in need of steel sheet piling for public jobs at Morehead City, N. C., at Miami, Fla., and for the Triborough Bridge in New York, N. Y., in 1933. The government received bids from only the four companies in the United States making this sheet piling, and those bids were alike for each one of the three jobs delivered at the three sites. The bids were determined by the basing-point system—for example, on the Miami project, freight from Pittsburgh to Miami plus the base price of the Pittsburgh manufacturer. Whichever one of these freight-plus-base price arrangements to Miami was lowest—that was the price charged by all four companies.

The price was identical for the unwelded piling per 100 lb, for piling corners, piling T-sections, fabrication, the extra in welding in pairs, copper content, and all-rail freight factor.

The president of a large corporation testified[8] regarding steel:

> "We generally make the prices.* * * If anyone in the industry makes a lower base price, then that price is taken * * * and becomes a part of the basing-point formula, and all delivered prices are identical again."

Among the industries[8] with basing-point systems are basic industries—steel, pig iron, cement, and lumber—and other industries—builders' supplies, road machinery, vitrified clay sewer pipe, construction machinery, reinforcing materials, valves and fittings, and cast-iron pressure pipe.

Identical delivered prices undermine incentives to economical production and distribution and enable obsolete mills to continue long after they would have gone out of business if price competition had prevailed. Above all, they deprive the public of the benefit of price competition.

In testimony on the basing-point procedure, Harold L. Ickes stated that[8] in purchases by the federal government between June, 1935, and March, 1936, under his administration as Secretary of the Interior, identical bids occurred at least 257 times involving a gross expenditure of $2,866,252.97. Identical bids were received for structural steel, steel tanks, valve boxes, well drilling, fire hydrants, pumps, plumbing and heating specialties, aerators (sewage), cast-iron pipe, water meters, and filter equipment.

Building Codes.—Another of the numerous aspects of the construction industry are the building codes. Such codes[10] are important and necessary in construction, primarily to protect safety and health and next to allow for all the efficiency that industry and enterprise can provide. A survey of the National Bureau of Standards indicates that 25% of the codes have not had a thorough overhauling for more than 20 years, whereas another 23% have not had one for from 16 to 20 years. An extensive survey[11] of building legislation

[9] "Cartels," Temporary National Economic Committee, Pt. 25 of "Investigation of Concentration of Economic Power," January 15–19, 1940, p. 13,330 (*No. Y4.T.24:Ec. 7/Pt. 25*, Supt. of Public Documents, Washington, D. C.).

[10] "Your Building Code," by Miles L. Colean, National Committee on Housing, New York, N. Y., February, 1946.

[11] *Engineering News-Record*, April 18, 1946, pp. 84–87, 108, and 113.

by the John B. Pierce Foundation indicates that a complete revision of the Chicago code is desirable because of its obsolescence, restrictiveness of requirements, and too much variation from generally recognized material standards.

Wide divergence of building code requirements among cities increases costs. Allowable working stresses in concrete, for instance, vary from 500 lb per sq in. to 1,000 lb per sq in.; minimum thicknesses of brick basement walls vary from 8 in. to 16 in. for the same height and load; live-load requirements for dwellings vary from 25 lb per sq ft to 80 lb per sq ft; minimum permitted floor areas for the same type of room vary from 60 sq ft to 120 sq ft; and minimum ceiling heights vary from 7 ft to 9 ft.

Analysis of a random selection of codes showed that the city requiring the lowest amount of pipe (by size and weight) in a one-story house saved 30% of the total amount of cast iron required by the city with maximum requirements. The costs under the minimum code were 80% of the costs under the maximum code for metals other than cast iron[10]—a saving of 20%.

Construction Cost Index, Engineering News-Record (E.N.-R.).—It is noted that the E.N.-R. construction cost index is referred to especially by Mr. Howson in developing his thesis of close relationship between wage rates and construction costs. It has been stated[11] that the E.N.-R. construction cost index:

> "* * * measures wage rate and material price trends. It is not adjusted for labor efficiency, competitive conditions, management, mechanization or other intangibles affecting construction costs."

—nor does it reflect quality of materials. It is well to note that none of the indexes listed[11] by the E.N.-R. construction cost index contain most of the mentioned factors and but one includes productivity of labor and efficiency of plant and management.

According to a letter dated June 28, 1946, the components for the original E.N.-R. construction cost index were chosen by selecting an imaginary cube of construction that would be composed of 2,500 lb of structural steel, 6 bbl of cement, 600 fbm of 12-in. by 12-in. long-leaf yellow pine, and 200 hours of common labor. This formula produced a value of 100 for 1913. Now the index has four components[12]—(1) structural steel shapes, Pittsburgh base price, multiplied by 25 cwt; (2) cement price at Chicago, exclusive of bags, multiplied by 6 bbl; (3) lumber (which until 1935 was 12-in. by 12-in. long-leaf yellow pine wholesale at New York and since 1935 2-in. by 4-in. S4S pine and fir in carload lots), E.N.-R. twenty-city average price, multiplied by 1,088 fbm; and (4) common labor, E.N.-R. twenty-city average of wage rates in force, multiplied by 200 hours. Analysis indicates that, as a reliable measure of construction cost trends (magnitude involved or competitive prices), the four components are representative neither of construction materials nor of labor.

Before 1921, the labor component represented less than 50% of the total material and labor weight,[11] whereas since 1921 with the exception of 1923, the

[12] "Survey of Current Business," U. S. Dept. of Commerce, 1942 Supplement, p. 183.

labor component has been more than 50% and is now (1946) approximately 60% (see Table 1). Actually, labor on nonbuilding construction (see Table 2) approximates from 20% to 45% of labor and material costs.[13] According to a tabulation of labor and material estimates for various types of federal construction projects during 1945 prepared by the Bureau of Labor Statistics (B.L.S.),[11] the percentage of on-site labor varied from 40.0% to 47.6% for building and nonbuilding construction. Furthermore (see Table 3), common labor on nonbuilding construction approximates 40% of the total labor used (data supplied to the writer by Edward M. Gordon from the records of the B.L.S.). The common labor component of the E.N.-R. construction cost index does not truly reflect the skilled, semiskilled, and supervisory labor comprising the larger part of such construction.

TABLE 1.—FOUR-COMPONENT PERCENTAGES OF E.N.-R. CONSTRUCTION COST INDEX (1913–1945)

Year	Index	Weighted Percentages of Construction Cost Index			
		Labor	Cement	Lumber	Steel
1913.....	100	38.0	7.1	17.4	37.5
1917.....	181.24	31.0	5.8	13.2	50.0
1919.....	198.42	47.0	8.0	13.3	31.7
1921.....	201.81	53.6	8.4	13.2	24.8
1929.....	207.02	52.8	6.5	17.6	23.1
1932.....	156.97	54.4	6.2	14.6	24.8
1935.....	196.44	53.7	6.6	16.8	22.9
1939.....	235.51	58.0	5.6	14.1	22.3
1940.....	241.96	57.7	5.5	15.1	21.7
1945.....	307.74	59.2	4.8	18.9	17.1

Table 2 indicates that the three material components of the E.N.-R. construction cost index represent generally minor portions of the total materials incorporated in the projects.

"Structural Steel Shapes" Component.—The classification, "structural steel shapes," is not representative, in quantity and price, of various forms of steel used in nonbuilding construction. From an extensive study[14] of consumers' prices of steel products made by the B.L.S. in 1943 for the period from January, 1939, to April, 1942, the following conclusions are presented:

a. Actual delivered prices paid by steel consumers deviate frequently from published delivered prices. By published price is meant the sum of published base price at the basing point nearest the consumer, plus published extras applicable to the given specification, plus rail freight from the basing point to the consumer's plant.

b. The relative importance of the three components of the delivered price is approximately: Base price, 79%; extras, 14%; and freight, 7%.

c. Base prices alone are neither good measures of the level of prices of steel nor adequate indicators of the comparative prices of different steel products.

d. The delivered price of steel was increased as much as 50% in some instances, because of higher freight costs resulting from changes in basing points.

e. Actual prices varied from 50% to 135% of the April, 1942, published delivered prices during the period covered, whereas published prices remained stable.

[13] "Construction Studies of Public Works Administration Projects," by George D. Babcock, Director, Eng. Management, Federal Works Agency, Washington, D. C., 1943.

[14] "Labor Department Examines Consumers' Prices of Steel Products," *Iron Age*, April 25, 1946.

f. For many products a very small proportion of purchases is made at the base price.

g. Extras applicable to structural shapes include size and section, special cutting, length, United States Navy and American Society for Testing Mate-

[a] Two hundred Public Works Administration and other federal projects. [b] Three projects at Greece, N. Y., totaling $327,000. [c] Overhead—that is, superintendents, foremen, and clerks. [d] Skilled and semiskilled labor. [e] Common and other classes of unskilled labor.

rials specifications, cambering, chemical requirement, milling, splitting beams, painting, special marking, protected shipment, surface finish, federal specifications, quantity, test requirement, and restricted physical test.

Lumber Component.—Lumber used as one of the four components of the E.N.-R. construction cost index does not portray competitive price trends. According to the Federal Trade Commission (F.T.C.),[15] of the total lumber cut in the United States (24,975,000,000 fbm) in 1939, nearly 83% was produced in four Pacific states and eleven southern states. About 58% of the total cut in 1935 was for building construction. A statement of the Interstate Commerce Commission for 1939 shows that out of each dollar at destination the cost of transportation amounted to 20.16¢ for lumber, shingles, and laths and 27.79¢ for cement.

In 1940 the B.L.S. index of lumber prices rose steadily from August 3 to September 7, for a total of more than six points. There was no shortage of lumber, actual or prospective.

The rise in lumber prices was used to justify an increase in the price of low-cost houses of more than 7%. Complaints reaching the Department of Justice suggested that some of these price increases were due to collusive price fixing and restriction of output. Accordingly, federal grand juries investigated the production and distribution of construction lumber. In February and April, 1941, consent decrees were entered in two cases which enjoined lumber associations against restraint in trade practices.[6]

According to the E.N.-R.,[16] current prices for 2-in. by 4-in. lumber delivered in the New York area have reached a new high of from $85 to $95 for southern pine and from $91 to $121 for Douglas fir. The price structure per 1,000 fbm of Douglas fir consists of: Mill price, $37; freight to New York, $25; dealer handling, $5; 30% markup, $20; and a truck delivery charge of from $3.55 to $32.

Another news announcement in the E.N.-R.[17] states that, in federal courts in California, Washington, Oregon, and Arizona, the Office of Price Administration (O.P.A.) filed forty suits against lumber firms, seeking a total of about $9,000,000 in treble damages on charges of illegal activities involved in handling 65,000,000 ft of lumber. The O.P.A. charged that shippers had diverted lumber by sending it to themselves at dummy addresses and holding it there for bargaining; and that mills were producing out-size timbers in order to charge premium prices.

Another aspect of the lumber trade that deserves attention is quality of product delivered. The E.N.-R.[18] carries the news item that the St. Louis (Mo.) area is being flooded with black market lumber, some of it so green that the "* * * sap practically is running out of it * * *." As one O.P.A. official stated:

> "The great tragedy of this 'racket' is not so much the inflated cost of this housing material, but the loss of investment that will come when this green wood starts to buckle * * *."

Cement Component.—There were 154 active cement manufacturing mills in the United States in 1941 with an estimated annual capacity of about 247,000,000

[18] *Ibid.*, June 6, 1946, p. 1.

bbl. About 55% of the total United States Portland cement producing capacity is concentrated in ten companies.[15]

Since about 1916, the delivered prices of cement have been identical at any particular destination in the United States.[6] For example, the United States Navy Department opened bids for cement on November 17, 1943, for eighteen delivery points along the seaboard from Portland, Me., to New Orleans, La. At Boston, Mass., sixteen companies bid an identical price of $2.52 per bbl. At Philadelphia, Pa., fifteen companies bid identically at $1.98 per bbl. The price in Washington, D. C., for sixteen companies was $2.11.

The F.T.C. has had a pending case against the basing-point system in the cement industry for a number of years and the Department of Justice brought a suit against a leading trade organization with about ninety member cement companies in June, 1945. The F.T.C. reported to the United States Senate in 1933 that, through the use of the basing-point system, many commercial and private purchasers have been forced to pay higher prices for cement. The basing-point system has encouraged crosshauling with resultant aggregate increases in freight.[8] On the basis of available data, the F.T.C. estimated that in 1927 there was an average unnecessary burden of 24.3¢ per bbl which, applied to the entire production of that year, made a total of about $42,000,000.

Labor Productivity.—Although the B.L.S. has been making studies on labor productivity since before 1898, it has not as yet developed an adequate measure based upon fundamental concepts in construction activity. Of productivity of labor in industry, W. D. Evans of B.L.S. has stated that,[19] in the period between the wars, most industries achieved large increases in man-hour output. Better processes, machines, handling of materials, organization of jobs—all contributed to improvement of productive efficiency. During World War II, unit labor requirements for liberty ship construction decreased almost 60% from the date the first ship was delivered in December, 1941, to December, 1943.[20] The decline in unit labor requirements reflects the economies of mass-production methods.

Apropos of labor productivity in building construction are some news items that appeared in 1946.[21,22] An Ohio contractor, charged by the Wage Stabilization Board with paying workmen illegal (too high) wages in constructing homes for war veterans, told how he "trimmed" construction costs so that he was able to sell five-room homes with an O.P.A. ceiling price of $7,250 for $5,850 and make money. By using his own superintendents and the best men obtainable, together with labor-saving equipment, and eliminating all subcontractors, this contractor reduced the cost of excavation from $75 to $14 per house; reduced the brickwork cost from $325 to $130 per house; sewer digging and pipe laying costs $100; cement basement floors and steps costs from $220 to $90; rough-in carpentry costs from $300 to $120; plumbing costs from $650 to $350; painting costs $250; electrical work from $140 to $60; and grading costs from $200 to $20 per unit.

[22] *Ibid.,* July 4, 1946, p. 2.

Efficiency of Management in Construction Activity.—Lives there an engineer who in the course of his professional practice has not witnessed examples of construction abandoned after little or no use which could have been forestalled by proper planning and management?

In the initial stages of P.W.A. several water distribution systems were installed before suitable water supplies were developed. Some of these supplies did not prove adequate. In the case of a sewage treatment plant, a garbage grinding unit was built but was only tested and has never been operated, because the city street department (which collects the garbage and is not under the authority of the sewage treatment plant) never changed the routes of the garbage collection and now disposes of the garbage by sanitary fill.

According to the E.N.-R.[23] an agreement was reached in 1946 between the District of Columbia and the Washington Suburban Sanitary Commission whereby the sewage from Montgomery and Prince Georges counties, Maryland, will be discharged into the Washington sewerage system for treatment at the District of Columbia plant at Blue Plains. It was learned that the Maryland sanitary commission will abandon the use of its 7.5-mgd primary treatment plant when the connecting sewers are built. This plant, costing about $800,000, was first put in operation in November, 1940.

In the opinion of Miles L. Colean[24] the excessive street and sanitary improvements in the outlying areas of many large cities during the economic boom of the 1920's are unwarranted public improvements due to political pressure.

Even in these days of high construction costs, low prices can be obtained by good planning. The previously mentioned case of the Ohio contractor is one example. In another, a low unit cost of $2.09[25] per sq ft was achieved for a one-story frame factory building of 27,000 sq ft erected in Los Angeles County, California, as a result of attention given to economy in preliminary studies of five schemes considered by the consulting engineers and architects.

As to the dependability of E.N.-R. construction cost index for measuring labor and material price trends, it is noted Mr. Howson reported elsewhere,[26] in 1946, that it is practically the universal experience of those attempting to let work by contract that the prices bid exceed greatly those estimated by adjusting prior construction costs according to the construction cost indexes, including E.N.-R.

Furthermore, E.N.-R. also considers that[27] uncertainties about material and labor supply, spotty conditions on labor efficiencies, and low productivity on some jobs provide the "invisible" costs that push many bids up higher than would be indicated by the cost indexes that measure material prices and labor wage trends.

In his paper Mr. Howson states that the steep rise of the E.N.-R. construction cost index from 1932 to 1940 is a reflection of many factors, including

[23] "District Will Treat Maryland Sewage," *Engineering News-Record*, June 27, 1946, p. 54.

[26] "Construction Costs and Water Rates," by Louis R. Howson, *Journal*, A.W.W.A., June, 1946 p. 747.

[27] "Highlights of Construction Costs—1946," *Engineering News-Record*, April 18, 1946, p. 107.

general deterioration in labor output and efficiency. In this view Mr. Howson seems to be at variance with the E.N.-R. which states[28] that the weighted indexes (including E.N.-R. construction cost index) measure only hourly wage rate and material price trends, whereas contractor indexes such as the Turner index reflect low labor productivity and attendant factors.

An interesting comparison can be made of Mr. Howson's statement with that of Thurman Arnold on the cause of high construction costs in the period from 1932 to 1940. The latter states:

> "Building costs soared in 1937 and were largely responsible for reversing the upward trend of business throughout the country, not only in construction, but in all industries. A major factor in high building costs has been a series of concerted efforts to fix prices and to perpetuate antiquated methods."

LOUIS R. HOWSON,[29] M. ASCE.—The author is in agreement with the first premise of Mr. Mendelsohn's discussion, namely, that construction costs are rising. He cannot agree with the second statement that they are in a "stage of unpredictable flux." All engineering construction costs are necessarily a matter of prediction. Nothing can be built in the past and therefore the engineer is directly concerned with future construction costs. The past serves only as a basis for his estimate of the costs and conditions under which work must be executed in the future.

That it is practicable to predict with reasonable accuracy the effect of wars upon construction costs is well indicated by the forecast made by the late John W. Alvord, Hon. M. ASCE, reproduced as Fig. 3. In this forecast, made in 1920, Mr. Alvord predicted not only the lowest level which prices would reach following World War I, but also predicted that the low point would be reached 12 years after the date of his forecast, or in 1932.

Mr. Mendelsohn indicates that the author's analysis of factors of construction cost is inadequate in that the relationship of wage rates to high construction costs is believed unduly stressed. Reply to this suggestion is offered by reference to Fig. 5, which shows the relation between wage rates and construction cost from 1913 through 1945. The fact that Fig. 5 discloses the generally close relationship cannot be disputed either during a period of rising or a period of declining costs. For illustration, in the 33-yr period from 1913 to January, 1946, the *Engineering News-Record* (E.N.-R.) construction cost index increased from 100 to 316, while the average hourly wage rate of skilled and common construction labor increased from 100 to 353 in the same period.

In the shorter upswing during World War II—that is, from 1939 to April, 1946—the E.N.-R. construction cost index increased 42%, whereas the average of common and skilled labor increased $34\frac{1}{2}$%. During 1946, as reported in *Engineering News-Record* for February 20, 1947, the E.N.-R.construction cost index rose 12.3% while skilled construction labor wages rose 10.8% and common labor wages rose 15.7%.

Similarly, at the beginning of the depression from 1930 to 1932, the E.N.-R. construction cost index decreased 23.1% while during the same period the aver-

[28] "Construction Trends," *Engineering News-Record,* August 8, 1946, p. 63.

[29] Cons. Engr. (Alvord, Burdick and Howson), Chicago, Ill.

age reduction in common and skilled labor rates was 25.2%. On the long upswing from 1932 to April, 1946, the E.N.-R. construction cost index rose 114.5% as compared to the average increase in common and skilled labor hourly wage rates of 103.5%.

In this connection it was stated in the paper under the heading, "4. Effect of Wars on Price Levels:"

> "It should be noted that Fig. 5 [relation between wage rates and construction cost] does not reflect the result of post World War II strikes, wage increases, and cost increases. These might well raise graph B [E.N.-R. construction cost index] to 350 or 360 as compared to its 1945 figure of 310 * * *."

It is significant that as of January 1, 1947, one year after the paper was presented to the Society, the E.N.-R. construction cost index was 381. This short term prediction of the effect of strikes, wage increases, and cost increases also indicates that construction costs are not wholly in a stage of "unpredictable flux."

Mr. Mendelsohn quotes from Beardsley Ruml, Thurman Arnold, Harold L. Ickes, and others not experienced in engineering construction to develop what is apparently his premise that there are vested interests among contractors and materials' suppliers operating in restraint of trade and that the result is higher costs in the building industry than would otherwise be necessary. The author would call attention to the fact that not the least of the "vested interests" is organized labor under the control of some labor leaders.

Since Mr. Mendelsohn has based much of his discussion upon statements of those not in the construction industry, the author presumes to reply in kind from an editorial from the *Chicago Daily News* entitled "No Building." The following is quoted:

> "In the face of these demands, Northwestern University [Evanston, Ill.] has been forced to abandon a $3,000,000 building program—including dormitories, classrooms and hospital facilites—because building costs have increased 75% during the last year. Loyola University [Chicago, Ill.] is considering a two year moratorium on building. The University of Illinois [Urbana] is in process of curtailing a huge building program to the irreducible minimum.
>
> "There is another example of how high material prices and high wages in the building trades, and monopolistic control by union labor works against the public interest. The 75% increase in building costs is due in part to the increase in building wages; in part to the increased cost of materials. The increased cost of materials, in turn, is largely due to the increased cost of the labor that goes into their production.
>
> "Because the building trades unions have a tight monopoly over all building operations, new materials and new construction methods that could save time and money are banned. Because organized labor has a monopoly, it is able to keep the number of building tradesmen far below the demand, thus maintaining an artificial scarcity of labor.
>
> "Because of those conditions, construction necessary to the public welfare cannot go ahead. Monopolies in restraint of trade are forbidden by law; union labor operates in restraint of essential building. But union labor is exempt from regulation as a monopoly."

Mr. Mendelsohn calls attention to the effect of building codes upon construction costs. Certainly there is much room for improvement through the modernization of building codes.

Mr. Mendelsohn discusses the E.N.-R. construction cost index at considerable length. This index obviously does not attempt to reflect the prices resulting from the iniquitous black market practices in the sale of construction materials which are referred to by Mr. Mendelsohn as existing during the period of the late Office of Price Administration.

From Mr. Mendelsohn's statement with respect to the dependability of the E.N.-R. construction cost index in which he refers to a paper by the author reported elsewhere[26] it might be inferred that the author does not consider the E.N.-R. index reliable. That is far from the fact. To clarify the author's position the entire paragraph referred to by Mr. Mendelsohn is reproduced as follows:

"Construction Costs vs. Construction Cost Indexes

"In normal times, the *Engineering News-Record* Construction Cost Index is a valuable and reliable aid in translating costs of one period into estimates for another. However, 1946 is not a normal year. The construction industry is beset by fear—fear of strikes, uncertainty about labor rates and efficiency, inability to secure materials when needed and to contract for materials at a fixed price before bidding, and fear of government- and union-imposed restrictions affecting performance and costs. These all operate to restrict bidding and increase the allowance for contingencies and the total cost. These hazards are not reflected in construction cost indexes. Accordingly, in 1946 it is practically the universal experience of those attempting to let work by contract that the prices bid much exceed those estimated by adjusting prior construction costs according to the construction cost indexes."

Comparison of labor performance in building construction and in mass production industries cannot be fairly made. Buildings are, and to a major extent always will be, individual units built at scattered locations and each is essentially "custom built." There is no production line in general building construction. Production line methods do not apply to building construction and, particularly with respect to dwellings, standardization appears not to be desired by those who need living accommodations.

The author agrees with Mr. Mendelsohn that good planning results in lower costs but good planning is essential at all times and cannot balance increased labor wage rates and material costs. In studying construction cost trends it must be presumed that every engineering project has had the benefit of economic study and development.

The author appreciates the analysis of construction cost factors and their development in Mr. Mendelsohn's discussion.

DESIGN LIVE LOADS IN BUILDINGS

By John W. Dunham,[1] M. ASCE

With Discussion by Messrs. D. Lee Narver, N. N. Freeman, and John W. Dunham.

Synopsis

Based upon surveys of the actual live loads in office buildings and warehouses, and upon a consideration of probable actual live loads in apartment buildings and places of assembly, this paper develops and proposes a system for the reduction of basic live loads in the design of building members.

1. Introduction

General.—It is common practice to reduce basic live loads for use in the design of a particular member depending in some fashion on the size of the area supported. For columns this reduction has commonly been a function of the number of floors carried. For beams, when permitted, the reduction has been a function of the tributary area. Thus the general principle is well recognized.

Quantitative information that defines the relation between the probable average live load and the size of the loaded area in the various occupancies is difficult to find. Some pertinent information for office buildings has been published in the form of live-load surveys.[2] Such data are valuable but cover only limited parts of buildings. They do suggest, however, that larger reductions of live load than those ordinarily used may be permissible.

In order to obtain factual information bearing upon this relationship, the U. S. Public Buildings Administration surveyed the live loads in the southeast quarter of the Internal Revenue Building and the main portion of the Veterans Administration Building, both in Washington, D. C., and in eight private warehouses. The surveys were made under the general direction of the writer.

This paper is based upon a report, "Live Loads in Office Buildings and Warehouses," prepared by the writer in the structural engineering division of the U. S. Public Buildings Administration. In addition, it treats the question of live-load reduction in apartment buildings and assembly occupancies and proposes a general system of live-load reduction.

Note.—Published in April, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Asst. Chf. Structural Engr., Public Bldgs. Administration, Washington, D. C.

[2] *Engineering News-Record*, March 29, 1923, p. 584.

Definitions.—For the purposes of this paper the following terms will be assumed to have the meanings indicated:

Basic Live Load.—The live load per square foot of floor area for which the floor is designed or may be posted.

Unreduced Live Load.—The product of the loaded area under consideration and the basic live load.

Actual Live Load.—The total of all the live load found in a given area.

Average Actual Live Load.—The total live load found in a given area divided by that area.

Design Live Load.—The product of the area under consideration and the basic live load for that area reduced as permitted by a design specification. This is the load that a member of a structure is designed to carry.

2. Design Live Loads in Office Buildings

Method of Conducting Surveys.—The average live load for each panel of floor including that in the corridors was obtained and recorded on a set of plans. The live load included furniture and its contents, movable property generally, and the people found in each space at the time it was surveyed. Weights were determined as follows: (*a*) Representative pieces of furniture, and their normal contents, were weighed with spring scales—the weights thus determined being used for all corresponding items found in the survey of the building; (*b*) persons found in a given panel at the time it was surveyed were counted and assumed to weigh 150 lb each; (*c*) special furniture and equipment not corresponding to the typical items were weighed with spring scales in the space in which they were found. In some cases the pieces were too large to weigh in their entirety and in these instances parts of the equipment, such as separate drawers, were weighed and the weight of the entire unit computed; and (*d*) weights of miscellaneous items such as rugs, pictures, and papers on top of filing cabinets were estimated.

Internal Revenue Building.—A survey was made of the live loads in the southeast section of the Internal Revenue Building (identified herein as I R Building), Washington, D. C. This part of the building is approximately 226 ft by 210 ft in plan and seven stories high, plus an unfinished attic story which is omitted from this analysis. There is a central court about 135 ft by 110 ft in plan extending through all stories. The average usable area of each floor in this portion of the building is approximately 26,000 sq ft. There are seventy columns in this area. The basic live load used in the design of the building is 100 lb per sq ft. No reduction was used for the floor slabs or beams. The design live load on the columns was obtained by considering the seventh floor to be the top and using the following percentages of the basic live load: 100% on the seventh floor; 90% on the sixth floor; 80% on the fifth floor; 70% on the fourth floor; 60% on the third floor; and 50% on each of the remaining floors.

Veterans Administration Building.—A survey was made of the live loads in the main part of this building (V A Building), which is L-shaped, 60 ft wide, and approximately 462 ft in developed length. There is also an attached wing 44 ft by 51 ft. It is eleven stories high above grade and there are 144 columns ex-

tending through all stories. The area of each floor in this part of the building including the wing is about 29,000 sq ft.

This building was not designed by the federal government but was purchased for governmental use. There is some doubt regarding the design live loads; however, for purposes of comparison, a basic live load of 70 lb per sq ft has been assumed. An assumed design live load on the columns was obtained by using the following percentages of the basic live load: 100% on the eleventh floor; 90% on the tenth floor; 80% on the ninth floor; 70% on the eighth floor; 60% on the seventh floor; and 50% on the remaining floors.

Statistical Distribution of Live Load.—The total areas occupied by average, actual live loads of various ranges are given in Table 1, both for individual floors

*The percentages opposite each floor refer to the indicated total area of that floor. Those in parentheses, opposite to "Total" line, refer to the total area of the building.

and for each building as a whole. For instance, on the first floor of the I R Building 5,229 sq ft are occupied by average, actual live loads varying from 20 lb per sq ft to 40 lb per sq ft. For the building as a whole, 32,709 sq ft are occupied by actual live loads in this range. Of the total floor area of the building 88% supported an average, actual live load of 40 lb per sq ft, or less. Of the total floor area of the V A Building 99.5% supported an actual, average live load of 60 lb per sq ft or less, and 97.75% supported an actual, average live load of 40 lb per sq ft or less.

Variation of Live Load on Floors.—The maximum, average, actual, unit live load found in the I R Building occurred on 825 sq ft of the second floor (in the V A Building, 1,176 sq ft of the tenth floor) and amounted to 106 lb per sq ft (90 lb per sq ft in the V A Building). To show how the average, actual live

load varied with respect to area in the most heavily loaded regions, the continuous areas of 800, 1,000, 1,200, and 1,400 sq ft carrying the greatest average, actual live load were determined for each floor. The results have been plotted for each building in Fig. 1.

Variation of Live Load on Columns.—To show how the actual column live loads in the I R Building varied in relation to accumulated tributary area, the twelve columns (nineteen columns in the V A Building) which, from inspection, seemed to be the most heavily loaded were selected (see Fig. 2). These columns

constitute more than one sixth of the columns in the part of the I R Building involved. The actual live load supported by each of these columns at each floor and its accumulation in each story were computed. The results for the critical columns in both buildings are given in Cols. 8 and 9 of Table 2. The

three columns of the I R Building that supported the highest, average, actual live loads (each for part of its length) are reported in Tables 2(*a*), 2(*b*), and 2(*c*). Table 2(*d*) includes the corresponding data for that column of the V A Building of the nineteen investigated, which supported the greatest, average, actual live load. Using a basic live load of 100 lb per sq ft (70 ft per sq ft in the V A Building), the unreduced live loads for each of these columns were computed and are recorded in Cols. 4 and 5. The actual live loads expressed as percentages of the corresponding unreduced live loads are given in Cols. 6 and 7.

In order to show, graphically, the relation between the average, actual live load supported by each story of the column and the accumulated area supported by that story the corresponding values for several representative columns of both buildings were plotted in Fig. 3. It will be noted in the I R Building that

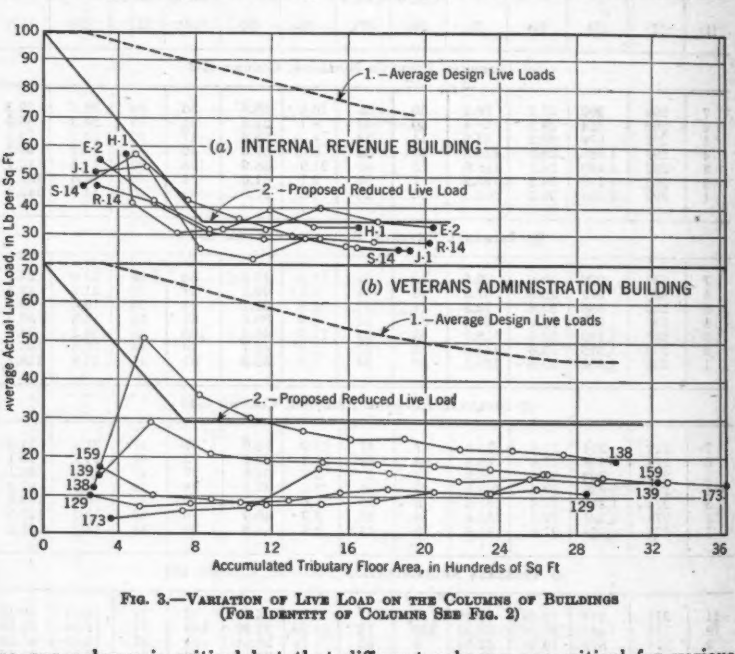

FIG. 3.—VARIATION OF LIVE LOAD ON THE COLUMNS OF BUILDINGS (FOR IDENTITY OF COLUMNS SEE FIG. 2)

no one column is critical but that different columns are critical for various areas. It appears that the intensity of live load diminishes faster on columns as the area increases than it does on floors.

Significance of Survey Data.—A consideration of the loadings found in these surveys and their comparison with those previously reported[2] indicates that the I R Building is representative of a rather heavy occupancy and that the V A Building is representative of an average occupancy, although the maximum load found in the latter is higher than appears usual.

The surveys show clearly that, as the tributary area of a member increases, the chances of its being fully loaded decrease. The decrease in actual live load

was more marked in the case of columns than in that of floors. It appears to be a fact that the probability of several contiguous floor panels being fully loaded is much greater than that several successive stories of a column will be fully loaded.

One of the common ways of reducing the live loads on columns heretofore has been to use the following percentages of the basic live load: 100% on the top floor; 90% on the first floor below the top; 80% on the second floor below the top; 70% on the third floor below the top; 60% on the fourth floor below the top; and 50% on the other floors.

In order to compare the results obtained by this method with the loads that actually occurred in the buildings surveyed, the heavy dotted lines (curves 1, Fig. 3) were plotted in Figs. 3(*a*) and 3(*b*) to show the average design loads with respect to area, using the foregoing method of reduction, as applied to columns carrying 275 sq ft of floor. For this purpose basic live loads of 100 lb per sq ft and 70 lb per sq ft for the I R Building and the V A Building, respectively, have been used. It is clear from a comparison of the heavy dotted lines and the loads actually found that the correspondence is not good and that the shape of the line is not that of the actual loading.

It is noteworthy that the maximum live loads found in each case occurred in only one part of the building and that this part was less than 1% of the floor area of the building.

There is an obvious advantage, as regards flexibility of use, to design the building so that these maximum loads can be permitted anywhere. There is just as obviously a lack of economy in providing strength throughout the structure that will not be used in 99% of the building.

Therefore, it seems logical, if possible, to design an office building in accordance with a calculated risk of occasional overstress in the members, limited so as to insure against the possibility of serious overstress. If this can be done the building can be posted for its basic live load with the assurance that, even if any member is fully loaded, disaster is impossible.

Basic Live Loads and Design Live Loads.—Such a system of basic and design live loads is possible. It should conform to the following essentials: (*a*) A basic live load equal to the maximum to be allowed on any panel; (*b*) a rapid reduction to a minimum load based upon the relation of live and dead loads in such a manner that overstress on any member, due to full basic load throughout the structure, cannot exceed a predetermined value; and (*c*) the system should be such that only a very small portion of the structure will be overstressed by the probable actual live loads.

It is proposed that: (1) The basic live load shall be the maximum average live load that it is intended to allow on any panel; (2) the basic live load may be reduced for the design of any member at the rate of $\Delta w_L = 0.08\%$ per sq ft of tributary area; and (3) the maximum reduction shall not exceed Δw_L as determined by the following formula:

$$\Delta w_L = \frac{w_D + w_L}{4.33\, w_L} \qquad (1)$$

in which w_D is the dead load per square foot of tributary area; and w_L is the basic live load. To express the reduction as a percentage, Eq. 1 is multiplied

by 100. The maximum reduction Δw_L is such that, if a member has a tributary area large enough to allow the maximum reduction, and if the member is loaded with the full basic live load, the overstress will not exceed 30%. In other words,

$$w_L + w_D = 1.30\,[w_D + (1 - \Delta w_L)\, w_L] = 1.3\, w_D + 1.3\, w_L - 1.3\, w_L\, \Delta w_L \quad (2)$$

Simplifying and solving for Δw_L in Eq. 2 yields Eq. 1 as a proportion; multiplying by 100 expresses the reduction as a percentage.

The proposed system, then, conforms to two of the aforementioned essentials. The question as to whether it conforms to the third, "that only a very small portion of the structure will be overstressed by the probable actual live loads," can be best determined by comparison with the loads found in the surveys. The proposed rule is illustrated graphically by the heavy, solid line curve 2, in Fig. 3(*a*).

As an example, the rule can be applied to the design of the I R Building. The typical floor beam in this building has a tributary area of 335 sq ft. The live load reduction will be (335 × 0.08% = 26.80%), say, 27%. The design live load then is 73 lb per sq ft (plus 180 lb per sq ft dead load). Reference to Table 1(*a*) shows that not more than 3.5% of all the beams in the building would be overstressed when designed for this load. The most severe load reported was 106 lb per sq ft on an area of 825 sq ft. The most severely loaded beam, therefore, would be supporting (106 + 180 =) 286 lb per sq ft of tributary area. Since it has been assumed to be designed for (73 + 180 =) 253 lb per sq ft, the overstress will be about 13%.

So far as the beams in the I R Building are concerned, from 1% to 3½% of the beams would be overstressed in some degree. Only ½% would have the maximum overstress of 13%.

An inspection of Fig. 3(*a*) indicates that the columns would be overstressed in four locations. Since there are seventy columns and since there are seven stories of each column under consideration, this represents less than 1% of the column shafts in the building, considering each story length separately. The greatest overstress will occur in Col. E-2, Fig. 2(*a*). Considering the actual live loads and dead loads on the floors, this story of the column will be required to carry (40 + 180 =) 220 lb per sq ft although designed for (35 + 180 =) 215 lb per sq ft. The overstress obviously cannot be greater than 2.4%.

The proposed system is also illustrated graphically by the heavy, solid line, curve 2, in Fig. 3(*b*). The typical floor beam in the V A Building has a tributary area of 300 sq ft. The live-load reduction will be (300 × 0.08% =) 24%. The design live load then is (0.76 × 70 =) 53.2 lb per sq ft. The maximum live load found in the survey was 90 lb per sq ft (dead load 110 lb per sq ft). The most severely loaded beam would be supporting (90 + 110 =) 200 lb per sq ft. Since it has been assumed to be designed for (53.2 + 110 =) 163.2 lb per sq ft, the overstress would be about 22½%.

The live load of 90 lb per sq ft occurred on 1,176 sq ft. Since this is less than ½% of the area of the building as a whole it is apparent that less than ½% of the floor beams would be overstressed this amount. Table 1(*b*) indicates that the remainder of the beams would have no overstress.

Curve 2, Fig. 3(*b*), indicates that the maximum overstress on any story of any column would amount to about 6% in the ninth and tenth stories of column 138, Fig. 2(*b*). Since eleven stories of 144 columns are under consideration this means that only two of the story lengths out of 1,584 would be overstressed. It appears that the proposed system conforms to the third essential required of it for office occupancies.

The proposed system of basic live loads and design live loads will permit office buildings to be posted and policed for their basic live loads without: (*a*) The incorporation of so much unused strength as heretofore; (*b*) significant overstress in members from probable loadings; and (*c*) danger of structural failure in the remote contingency of full basic live loading on the entire tributary area of any member.

Proposed System Versus Lower Basic Live Loads.—It seems apparent that the questions of proper basic live loads and of proper reductions are inseparable. Another approach to the problem of obtaining as much economy as is justified is to lower the basic live loads and to allow smaller reductions than those proposed herein. For instance the report of the Building Code Committee of the U. S. Department of Commerce[3] recommended a minimum live load on floors, for office purposes, of 50 lb per sq ft. It also recommended that a percentage reduction in total column live loads be permitted as follows:

Floors supported	%
One	0
Two	10
Three	20
Four	30
Five	40
Six	45
Seven or more	50

It is pertinent, therefore, to compare these two general recommendations to determine their relative merits. The loads found in the survey of the V A Building, which averaged 11.6 lb per sq ft for the entire structure, are of the same order as those found in the surveys referred to in Section 1 under the heading "general." It will be enlightening therefore to compare the writer's proposal as it applies to that building, with the system of loads recommended by the Building Code Committee.

In Fig. 4(*a*), the heavy line represents the design loads according to the proposed system, assuming a basic live load of 70 lb per sq ft and a dead load of 110 lb per sq ft. The dotted lines represent the design loads according to the recommendations of the Building Code Committee, assuming a basic live load of 50 lb per sq ft and that the columns each carry an area of 275 sq ft per floor.

Here are two buildings, one designed for a 70-lb live load under the proposed system, and the other designed for a 50-lb live load under recommendation 2.

The slabs of the first will be designed for a higher live load. The beams of both will be designed for practically the same live loads. The upper story and

[3] "Minimum Live Loads Allowable for Use in Design of Buildings, Report of Building Code Committee," U. S. Dept. of Commerce, November 1, 1924.

the fourth, third, second, and first story columns in the first building will be designed for a pound or two more of live load per square foot than those in the second building. The ninth, eighth, seventh, and sixth story columns will be

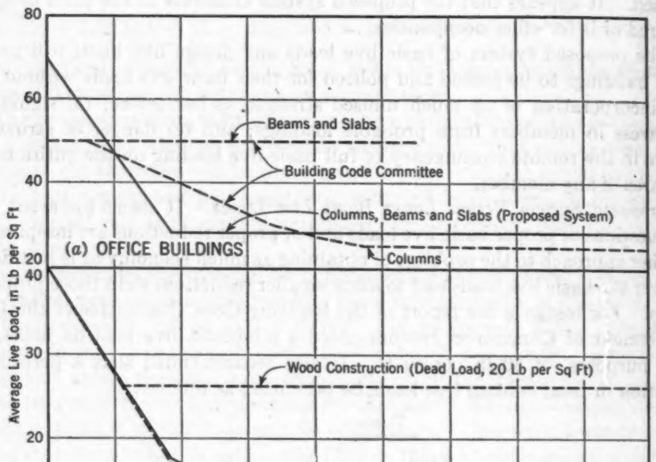

FIG. 4.—COMPARISON OF LIVE-LOAD REDUCTIONS

designed for a somewhat lower live load in the first building than in the second. The slabs in the first building will cost approximately 1½¢ more per sq ft than those of the second. The beams and columns will cost about the same in both buildings.

However, although the difference in cost is slight, the difference in usability is significant. The first building may be posted for 70 lb per sq ft of live load. The second should be posted for 50 lb per sq ft of live load if both are to fulfil the requirement that the members should not be substantially overstressed by the probable maximum live loads. The first building will be much more flexible in its use without sacrifice of safety.

It appears from the foregoing comparison that a system having a high basic live load but permitting quick reductions relative to tributary area is preferable to one using lower live loads and permitting only nominal reductions.

3. Design Live Loads in Apartment Buildings

Probable Live Loads.—The live load in apartments is made up of movable property such as furniture and furnishings, and persons. The live load created by furniture and furnishings varies from 0 to 10 lb per sq ft, with an average of about 4 lb per sq ft.[3,4] The live load attributable to persons will vary from 0 to 30 or 40 lb per sq ft.[3] These loads will be very small except in the case of special gatherings such as parties, club meetings, and funerals. A living room containing one person for every 6 sq ft is crowded, and, although denser crowds are possible, they are very unlikely because of considerations of comfort and ventilation. A crowd with one person to every 6 sq ft will average about 20 to 25 lb per sq ft. Such a crowd is very unlikely to fill more than the living room, or living room and dining room together, at any one time. It is also probable that such a crowd will occur simultaneously in comparatively few of the apartments in a building.

It will be instructive to consider an average apartment building and to discuss how the average live load may be expected to vary in relation to the area of the building under consideration.

The Bureau of Standards report cited previously[4] contains a survey made of thirteen representative apartments ranging in area from 431 sq ft to 796 sq ft. The average area was 628 sq ft. The areas of the dining room and living room in these apartments averaged about 40% of the areas of the entire apartment in each case.

To consider an example, assume that: (1) Each apartment in an apartment building has an area of 650 sq ft; (2) for each apartment there are 75 sq ft of corridor; (3) the area in each apartment subject to crowding at any one time is 260 sq ft; (4) one apartment in five will contain a crowd at the same time; (5) the crowded spaces will be loaded with 40 lb per sq ft; and (6) the remaining spaces will be loaded with 5 lb per sq ft.

TABLE 3.—Examples of Probable Live Load

Area	w_L	One Apartment		Two Apartments		Five Apartments	
		Area (sq ft)	Load (lb)	Area (sq ft)	Load (lb)	Area (sq ft)	Load (lb)
1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)
Area subject to crowding..	40	260	10,400	260	10,400	520	20,800
Remaining areas.........	5	650+75−260	2,325	1,300+150−260	5,950	3,250+375−520	15,525
Total...............	..	725	12,725	1,450	16,350	3,625	36,325

In a single apartment and its proportionate amount of corridor, the total load will be 12,725 lb (see Table 3, Col. 4). Since the total area under consideration is 725 sq ft, the average live load is $\dfrac{12,725}{725} = 17.6$ lb per sq ft.

[4] "Fire Resistance Classifications of Building Construction, BMS92," Bureau of Standards Rept, 1942.

In two apartments and their 150 sq ft of corridor, the total load will be 16,350 lb (Table 3, Col. 6). The average live load will be 11.3 lb per sq ft. Similarly for four apartments and the adjoining corridor, the total load will be 23,600 lb; the area, 2,900 sq ft; and the average live load, 8.1 lb per sq ft. In five apartments there will be 520 sq ft heavily loaded so that the total load will be (Table 3, Cols. 7 and 8) 36,325 lb. The area is 3,625 sq ft and the average live load is 10.0 lb per sq ft.

Basic Live Loads and Design Live Loads.—The foregoing average live loads are plotted against the corresponding areas in Fig. 4(*b*). The line connecting the points rises slightly (as would be expected at the area representing five apartments) and if continued would fall again until an area representing ten apartments were reached.

In order to test the validity of the proposal for reducing live loads in office buildings to this type of loading, the dotted lines were drawn to show the design live loads obtained by that proposal for wood construction and fireproof construction. The relationship of the average live load to the design live load obtained by applying the proposed reduction formula to a basic live load of 40 lb per sq ft is good.

There would be no overstress in the case of the wood construction, whereas in the case of the fireproof construction the maximum probable overstress indicated is 6%. Since the maximum possible overstress with full basic live load is limited to 30% by the method it is believed that the proposed method of live-load reduction is applicable also to this type of occupancy.

4. Design Live Loads in Assembly Occupancies

Spaces in buildings to be used for assembly purposes are definitely intended to be occupied fully at times. Moreover, there is a distinct probability of impact because occasionally the people present will move simultaneously; for example, they will rise at the playing of the national anthem. It is logical, therefore, that the basic live loads for such spaces should not be reduced for the design of supporting members.

5. Design Live Loads in Warehouses

General.—Most codes do not permit the use of reduced live loads for either the columns or the beams in warehouses. As far as floor members are concerned this practice seems sound. The tributary areas are not likely to be large and it is well-known that several adjacent floor panels are frequently fully loaded.

Accordingly, the investigation of variation in live-load intensities in warehouses was limited to column loads. The investigation was conducted to obtain data bearing on the relation of average, actual live loads on columns to the accumulated tributary areas carried by the columns. Surveys were made by the Public Buildings Administration, under the writer's direction, of eight representative, general-purpose warehouses in New York, N. Y., Philadelphia, Pa., Baltimore, Md., and Washington, D. C. Two buildings were surveyed in each city. The buildings varied in height between six and eleven stories.

Method of Conducting Surveys.—An engineer visited each building and selected from among the columns the one that, for its full height, had the largest percentage of its entire tributary area most heavily loaded. The rated or official live load, the actual live load on each floor, and the tributary area were obtained.

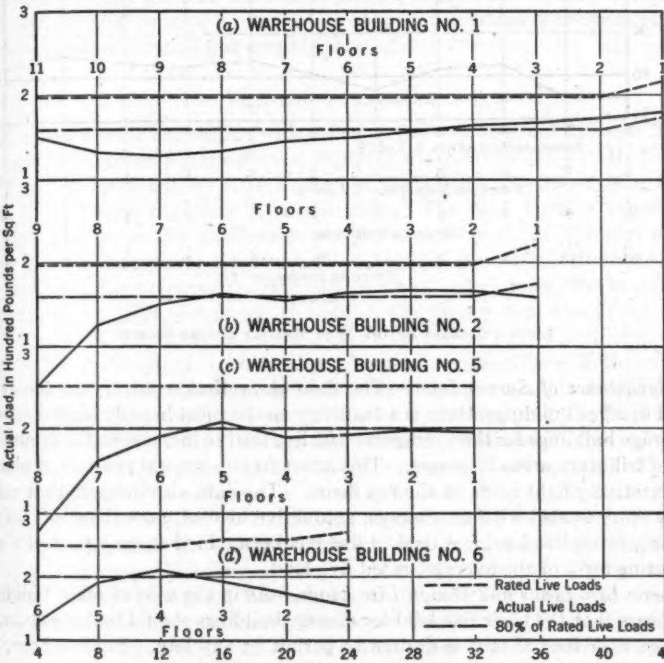

FIG. 5.—LIVE LOADS ON WAREHOUSE COLUMNS

This information for the four cases in which the actual live load was highest relative to the rated live load has been plotted in Fig. 5. The abscissas are cumulative tributary areas by floors. The average, actual live loads corresponding to each accumulation of area are indicated in each case by the full lines. The average, rated live loads corresponding to each accumulation of area are indicated by the dotted lines. For instance, the sixth story of the column in building No. 2, Fig. 5(*b*), was carrying a tributary area of 1,200 sq ft. The average, actual live load upon it was 150 lb per sq ft and the average, rated live load for that area is 200 lb per sq ft.

The most heavily loaded stories measured from the top down are summarized in Fig. 6. The heavy line in this figure indicates for each story the heaviest average, actual live load expressed as a percentage of the average,

rated live load. For instance, the maximum ratio of average, actual live load to average, rated live load on the story below the top floor in any of the buildings was 0.75 and occurred on the column surveyed in warehouse building No. 1 (Fig. 5(*a*)).

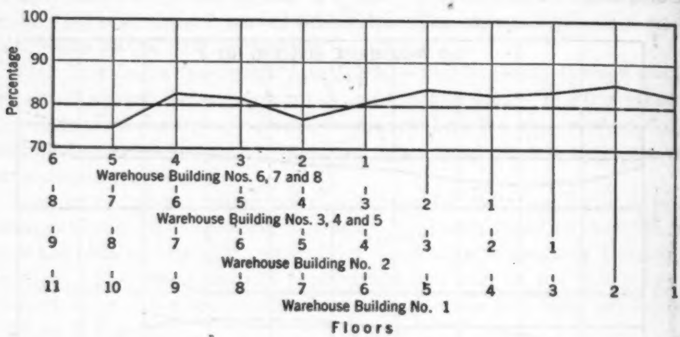

FIG. 6.—SUMMARY OF THE MOST HEAVILY LOADED STORIES

Significance of Survey Data.—The data show that, contrary to the trend found in office buildings, there is a tendency on the most heavily loaded column of storage buildings for the average, actual live load to increase as the accumulation of tributary areas increases. This arises from a general practice of placing comparatively light loads on the top floors. The data also indicate that rarely is any story loaded with an average, actual live load of more than 80% of the average, rated live load. A dashed line has been added to each part of Fig. 5 indicating 80% of the average, rated live load.

Basic Live Loads and Design Live Loads.—As in the case of office buildings it appears that the basic live load for storage buildings should be the maximum average floor load that it is desired to permit in any bay. Furthermore, the basic live load should be used unreduced for the floor and beam design. In the light of the data presented herein the basic live load for storage buildings should be reduced for storage buildings as for office buildings with a maximum reduction of 20% for the design of columns. In the columns surveyed, such a reduction would result in a maximum excess of average, actual live load over design live load of $6\frac{1}{4}$%. The percentage overstress resulting from this condition would be less than $6\frac{1}{4}$% depending upon the weight of the construction.

6. CONCLUSIONS

The foregoing facts and reasoning seem to the writer to justify the conclusion that it is sound to derive design live loads from basic live loads as follows:

A. The basic live load shall be the maximum average live load which it is intended shall be allowed on any panel of a floor of a building.

B. When the basic live load is 100 lb per sq ft or less, for any occupancy except assembly occupancy, the basic live load may be reduced for the design of

any member at the rate of 0.08% per sq ft of tributary area; but the maximum reduction shall not exceed Δw_L as determined by Eq. 1.

C. In assembly occupancies the basic live load shall not be reduced for the design of any member.

D. When the basic live load is more than 100 lb per sq ft, it shall not be reduced for the design of floors, beams, girders, or trusses. It may be reduced at the rate of 0.08% per sq ft of tributary area for the design of columns but the maximum reduction shall not exceed 20%.

7. Acknowledgment

The field work in connection with the surveys of the Internal Revenue Building and the Veterans Administration Building was performed by P. H. Heimer and J. W. McLure, and by J. H. Feehan of the Office of the Supervising Engineer, U. S. Public Buildings Administration. The field work in connection with the surveys of the warehouses was performed by H. R. Williams of the Office of the Supervising Architect, U. S. Public Buildings Administration. Mr. Williams also prepared the figures and tables and reviewed the text of the original report. For permission to publish the survey data the writer is indebted to W. E. Reynolds, M. ASCE, Commissioner of Public Buildings.

For their cooperation and helpful suggestions in connection with the surveys of warehouses, thanks are also due to Warren T. Justice, president, The Pennsylvania Warehouse and Safe Deposit Company, Philadelphia, Pa., and to the following members of the Merchandise Division, American Warehousemen's Association: Charles E. Nichols, M. ASCE, manager, Washington, D. C.; F. T. Leahy, executive vice-president, Port of New York, New York, N. Y.; L. E. Naumann, president, and F. L. Malsey, vice-president, Baker and Williams, New York; Thomas E. Witters, president and general manager, Baltimore Fidelity Warehouse Company, Baltimore, Md.; W. E. Edgar, superintendent, Terminal Storage Company, Washington, D. C.; and J. P. Johnson, vice-president, Terminal Refrigeration and Warehouse Corporation, Washington, D. C.

The original manuscript from which this paper was prepared, containing unpublished tabular data, has been placed on file for reference at the Engineering Societies Library.

DISCUSSION

D. LEE NARVER,[5] M. ASCE.—It should be of interest to know that a live-load reduction formula for the design of buildings, developed to accomplish the results described by the author, was proposed to the Committee on Live Loads of the American Standards Association in October, 1939. The proposal went through the "crucible" of criticism of that committee and, after changes, was adopted in the form presented by the author. The proposal was first published in pamphlet form—"Minimum Design Loads in Buildings and Other Structures"—on May 22, 1945, by the American Standards Association (ASA—58.1—1945) and sponsored by the National Bureau of Standards. On October 19, 1945, the material was issued by the U. S. Department of Commerce in pamphlet form.[6]

The object of that committee's work, together with that of committees on other phases of building construction, was to formulate principles that can be used by cities throughout the United States in the development of uniformity of building codes.

In the sentence preceding Eq. 2, the author states that the formula limiting the "design live load" is so developed that, even if the "basic live load" is attained over large areas, design stresses will not be exceeded by more than 30% of their value. It is the writer's thought that this does not tell the full story. Consider the load values given for the Internal Revenue Building (I R Building): Since the maximum $\Delta W_L = \frac{100 + 180}{4.33 \times 100} = 0.645$, the minimum "design live load" is 35.5 lb per sq ft, and the minimum total design load = 180 + 35.5 = 215.5 lb per sq ft. This loading will develop the full design stress. The "basic live load" plus dead load equals 100 + 180 = 280 lb per sq ft, which will produce 130% of the design stress.

If steel is the structural material being used, either as rolled shapes or in reinforced concrete, specifications A-7 of the American Society for Testing Materials establish a minimum yield point of 33,000 lb per sq in., or 165% of the allowable design stress of 20,000 lb per sq in. The net effect is 165% − 130% = 35% of the design load of 215.5 lb per sq ft, or 75 lb per sq ft, as the load that must be added to the "basic live load" to develop the minimum assumed yield point. This means an overload capacity of the structure of $\frac{75}{100}$ or 75% of the "basic live load."

The I R Building is an example of office building loading on the heavy side of average; but consider an office building on the light side, whose dead load is 130 lb per sq ft and whose "basic live load" is 50 lb per sq ft.

By the proposed formula (Eq. 1): Maximum $\Delta W_L = 0.83$, or a minimum "design live load" equals 8.5 lb per sq ft. The design load equals 130 + 8.5 = 138.5 lb per sq ft.

[5] (Holmes & Narver), Los Angeles, Calif.

[6] "American Standards Building Code Requirements for Minimum Design Loads in Buildings and Other Structures," *Miscellaneous Publication No. M-179*, U. S. Bureau of Standards, U. S. Dept. of Commerce, 1945.

Under the same stress assumptions as before, there is 35% of the design load, or 48.5 lb per sq ft that must be added to the "basic live load" to develop the minimum assumed yield point. In this case, the overload capacity of the structure amounts to $\frac{48.5}{50} = 97\%$ of the "basic live load."

Both of these examples show a substantial overload capacity. The yield point of steel used in the foregoing calculations is a required minimum. For several years job tests have been showing the yield point of structural steel to be greater than 40,000 in tension; and in bending it is still higher. Assuming in practice that the yield point will not be less than 40,000 lb per sq in., Eq. 1 will result in an overload capacity of the structure of 150% over the "basic live load" for the I R Building and one of 194% for the example of a building having a dead load of 130 lb per sq ft and a "basic live load" of 50 lb per sq ft.

It is to be noticed that a limitation has been placed on the proposed live-load reduction formulas. It is recommended that assembly occupancies have no live-load reduction. This is a sign of warning that there may be other classes, or particular cases, of loading for which the formulas should not be followed. It is difficult to set up terms of a building code that will always be applicable, and the engineer using the proposed system of reduction should consider carefully whether or not his particular problem falls within the usable limits of the formulas. For example, a specialized storage building, in which full "basic live load" capacity will be attained during known seasonal periods, should have no reduction of live loads.

It appears that the proposed system of arriving at loads for design purposes is closer to giving a true result for the normal run of buildings than the systems now in common use. However, as in the case of all design, the closer the design approaches true conditions, the more important good engineering judgment becomes. It is a step in the right direction toward economic design, and economy is as much a consideration for the engineer as is a safe design.

The proposed system may involve more engineering work than the present methods, but this is a business problem and should not be an obstacle in the way of adoption if the system improves engineering practice and results in economies of construction.

N. N. Freeman,[7] Esq.—In bringing this important subject to the renewed interest of the engineering profession, this admirable, clearly written paper marks a forward step.

The surveys conducted under the author's supervision seem to have been limited in scope, however, and were not quite correct in procedure. The number of observations was obviously small; and the recurrent use of the expression "* * * at the time it was surveyed * * *"—indicates that most of the data are the result of only one observation made at a certain time and date. It is agreed that the live loads representing furniture and movable property may be fairly constant during a prolonged observation period. Persons, on the other hand, represent a very active live load, and figures may change considerably. There may be rush hours, queues, or conferences, and it would have been advisable if more extensive observations could have been made to deter-

[7] Civ. Engr., Haifa, Palestine.

mine the maximum actual live loads imposed by people in certain areas of the entire building. Such maximum figures, together with the more constant live loads, would then represent the actual live loads for such a structure.

For the aforementioned reasons, data shown in Tables 1 and 2 represent only actual live loads at a certain time and date, and do not express critical live loads for the buildings in question.

Even if the loads given represent maximum actual live loads, data found in the survey of only two structures cannot be applied as general rules to all office buildings. Only extensive and prolonged investigations into many different types of such structures can supply a basis for an estimate of reasonably correct general design loads which represent actual conditions. Such investigations doubtless require considerable time, but zeal and money invested would be repaid many times over by savings in the design of new structures.

The author's proposal for determining amended design loads rests upon a basic assumption which has not been supported by any experimental evidence. He proposes to allow an occasional overstress in certain parts of the structure. Then he assumes that if this overstress is limited to 30% it is not dangerous and may be ignored in the design.

Whether such an assumption can be accepted without the support of extensive and complete survey data is certainly open to discussion. Such an overstress may reach more than a purely theoretical 30% and could cause a serious reduction in the factor of safety of the entire building. There are certain well-known influences and stresses, however, which only rarely can be included in designs, such as secondary stresses due to stiffness of joints in welded steel frames and in reinforced concrete constructions, uneven settlement of foundations, sudden gusts of wind, and earthquakes. In a proper design such stresses are allowed for by an ample factor of safety, the rate of which is fixed according to local conditions and experience. Even small overstresses at single points may be dangerous, because weakness is introduced into vital construction members and failure may occur in the case of any emergency.

Another obscure point is the assumption of a reduction rate of 0.08% per sq ft of tributary area. No information is given in the paper as to how this value was determined; and there is no clue indicating any special argument in the survey data.

It should be the purpose of further surveys to collect ample actual live-load data in many types of buildings over prolonged periods. Only then will it be possible to conduct a proper statistical investigation that would form the basis of recommendations for a new design system approaching actual conditions.

Before such data are available it seems reasonable to make certain reductions in the basic live loads, however, and the value of 50 lb per sq ft, with a corresponding reduction depending on the number of floors supported, should give safe design values. Especially important, also, is the recommendation by the Building Code Committee of the National Bureau of Standards, U. S. Department of Commerce[8] that a load of 2,000 lb be placed on any 2.5 ft of floor space wherever this load on an otherwise unloaded floor would produce greater stresses than the 50 lb per sq ft of distributed load.

With reference to apartment buildings the author reveals no new informa-

[8] "Steel Construction," A.I.S.C., New York, N. Y., 1930, p. 52.

tion and his computations are based upon assumed values, which may, or may not, approach actual conditions. In the design of apartment buildings, also, it would be advisable to collect proper and ample experimental data before any attempt is made to introduce a new method of analysis.

The chapter on warehouses includes some valuable observations; but a limited survey of only eight buildings cannot form a sufficiently broad basis for any general conclusions to be applicable to all warehouses. Additional information showing types of stores involved, movements of ingoing and outgoing consignments, and loading and transport facilities, is needed for a proper classification of data. Certain reductions in design loads seem to be feasible but further surveys are needed before any such assumptions can be made.

Conclusions.—On the basis of the foregoing, three conclusions are possible in a fair appraisal of this paper:

1. Survey data given are incomplete and insufficient to form a reliable basis for any new proposals to reduce design live loads.
2. Overstresses during design can only be permitted if it is desired to reduce the factor of safety accordingly. It should be proved that a limit of 30% is not dangerous, and the author should explain further how the reduction rate of 0.08% per sq ft of tributary floor area was determined.
3. Further extensive surveys should be made to collect sufficient reliable information as a basis for selecting new reduced live loads which approach actual conditions.

JOHN W. DUNHAM,[9] M. ASCE.—The reasoning of the paper is carried a step forward by Mr. Narver, who compares the resulting overstresses in two cases with the yield point of structural steel. He also adds a note of warning that the proposed reductions must be applied with good judgment. This latter is true of design rules generally.

Mr. Freeman states that the surveys presented in the paper seem to have been limited in scope and that the procedure was not quite correct inasmuch as only one observation was made on any one panel. He questions the source of the maximum overstress of 30% and the reduction rate of 0.08% per sq ft. Mr. Freeman also indicates that the use of a load of 50 lb per sq ft with a corresponding reduction, depending on the number of floors supported, should give safe values. It is assumed that this comment applies to office buildings, and that he has in mind the loads and the reductions recommended by the Building Code Committee.[3,8] These points will be discussed in order.

Any number of surveys will be limited in scope. The writer is not aware of a criterion of sufficiency in this respect, and feels that it is a matter of judgment. More surveys would be helpful but it is doubtful that they would change the picture appreciably.

If the offices in the Equitable Building (surveys of which have been reported[2]) may be assumed to average 500 sq ft in area, the total area surveyed in the five office buildings was 210,290 sq ft. The surveys reported in the paper included over 2,500 panels of office building floors, which had a total area of nearly 430,000 sq ft. There were about 140 columns which appeared to be loaded in such a manner as to be significant.

[9] Asst. Chf. Structural Engr., Public Bldgs. Administration, Washington, D. C.

The arrangement of the load on each of the elements at the time it was surveyed indicates the arrangement that might be found on any of the others at another time. The writer feels that the arrangement of loads in space gave a valid indication of what the distribution on any one element would be in time.

Effort was directed toward determining the actual distributions and combinations in a large number of instances so as to obtain an indication of the probable maximum for a given class of element. It was known in advance that more severe loadings were possible. It was desired to find out what does happen, not what might happen.

The probability of overloading an office building with people is remote. The areas in which the very heavy loads occur represent a small percentage of the total areas surveyed and they are not spaces in which people congregate.

Although the suggested reductions well represent the worst conditions found in the surveys and estimated for the apartments, it was recognized that more severe conditions are possible, however remote their probability. It was this consideration that led to the formula which sets a limit on the proposed reductions. In the writer's opinion the possibility of dangerous overstress is thereby practically eliminated.

The proposed reduction of 0.08% per sq ft is empirical and resulted from the writer's study of the survey data. It gives values that start at no reduction for zero area and correspond well with the average live loads found on the columns carrying the heaviest live load at about 800 sq ft of tributary area (see Fig. 3).

The maximum reduction corresponding to 30% overstress was set to keep the overstress conservatively within the elastic limit of steel and well below the ultimate strengths of concrete and wood. It should be noted that nowhere in the buildings surveyed would the overstress have equaled 30%.

Adoption of the reduction rate and the limiting formula by the American Standards Association seems to indicate that qualified structural engineers concur with the writer's judgment on these two points.

In view of the surveys reported in this paper, and elsewhere,[2] it is contended that the use of 50 lb per sq ft as a live load in office buildings amounts to using an initially reduced live load. The report on the Equitable Building indicated a live load of 87 lb per sq ft in one office. The survey of the Veterans Administration Building, which had about the same average load as the buildings reported on previously,[2] indicated a maximum live load of 90 lb per sq ft. The writer believes that the live load of 50 lb per sq ft was established with the knowledge that a very small part of the building might receive higher loads, as indicated in the surveys, but with the feeling that they would not be enough higher to cause serious overstress.

The comparison indicated in Fig. 4(*a*) and the accompanying text supports the writer's opinion that a higher basic live load, together with the proposed system of reduction, will give a better balanced design for a given building than would result from the use of the recommendations of the Building Code Committee.[3]

In conclusion, the writer wishes to express his gratitude to the discussers of the paper for the additional argument and the new viewpoints they have presented.

SOME THOUGHTS ON ENGINEERING EDUCATION

By Donald M. Baker,[1] M. ASCE

With Discussion by Messrs. E. S. Boalich, Russell C. Brinker, I. Oesterblom, Samuel T. Carpenter, Lynn Perry, L. E. Grinter, Robert O, Thomas, Clement C. Williams, N. W. Dougherty, H. A. Wagner M. E. McIver, Scott B. Lilly, William A. Conwell, A. Amirikian, C. A. Dykstra, Louis Balog, Henry B. Lynch, Alfred R. Golzé, and Donald M. Baker.

Synopsis

The views of a practicing engineer on engineering education as provided by engineering schools and colleges in the prewar period are presented in this paper; and some suggestions are offered for changes and modifications in academic courses for the postwar era. Supported by appropriate data, the paper discusses the organization of the engineering profession, and the general conditions encountered in the practice of engineering. It argues in support of the conclusions that postwar engineering education should emphasize fundamental principles in subjects throughout the broad field of engineering; and that postwar engineering education should also include courses to prepare a graduate for a career involving administrative, executive, and managerial activity, both technical and nontechnical in character. This paper holds that specialization, or the acquisition of knowledge of the advanced theories and their application to design, operation, and processes, should be primarily left to the years after graduation and that engineering schools should provide such positive and formal guidance and assistance to their alumni in this postgraduate period as will encourage and even urge them to pursue systematic studies toward such specialization.

The paper also urges that engineering educational institutions and engineering societies conduct research concerning the engineering profession, the practice of engineering, and the market for engineering services, in the postwar period—in other words, that engineers as well as engineering be given adequate attention.

Note.—Published in April, 1946, *Proceedings*. Positions and titles given are those in effect when the paper or discussion was received for publication.

[1] Partner, Ruscardon Engrs., Los Angeles, Calif.

Introduction

Engineering education, as offered by schools and colleges for the several decades prior to World War II, has kept pace with changes and advances that have occurred in technology, through modification of existing course content and by the addition of new courses to the curriculum. It has not, however, made comparable progress in keeping abreast of changed conditions that have developed during that period in the pattern and structure of the engineering profession, in the practice of engineering, or in the market for engineering services.

Prewar engineering courses (at least in the opinion of graduates, if not from the viewpoint of subject content) tended more and more toward specialization in one of the major branches of engineering, or even in one of the subspecialities of engineering. Emphasis was laid on depth rather than on breadth of instruction, and on imparting skills and knowledge of practice, when experience shows a strong probability that the graduate through changing employment conditions would encounter little opportunity to utilize such skills, or would not have the responsibility for directing such practice, for a long period following his graduation. Little provision was made for furnishing directed guidance, organized assistance, or specific encouragement to those students who, following graduation, desired to continue their studies along specialized lines or in other fields of engineering. The product of formal prewar engineering educational courses presents a picture of a trained rather than of an educated person.

The impact of World War II on the educational system of the United States, and particularly on engineering education, has been such that in many schools prewar engineering courses practically ceased to exist. In many places, short courses in specialized subjects, and accelerated courses of longer duration designed to meet the needs of the armed forces, were substituted. With the end of the war, prewar courses are being reestablished.

Engineering faculties were disrupted during war years, most of their younger members being in uniform, whereas many older ones left, temporarily or permanently, for service to government or industry. Likewise, the source of supply of new instructors, normally drawn from the ranks of recent graduates, disappeared. As a result of the specialized training given many in the armed forces and in industry, however, much has been learned about the technique of instruction, and this knowledge will prove valuable in postwar courses.

It will require considerable time for engineering schools to readjust themselves to normal peacetime functioning. Many students who left prewar courses for the armed services, others who have attended short or accelerated courses, and many young men in service who may have enrolled in courses proposed to be given them during the interval between the end of hostilities and demobilization are seeking to return and secure degrees. These men are more mature and purposeful, and likewise more impatient to secure their degrees, than were the usual prewar upper classmen, and the problem of handling them will be somewhat difficult; but this situation will not last for more than a few years.

On the other hand, there are the usual crop of high school graduates seeking to enrol in normal postwar engineering courses. Once the general pattern and

structure of postwar engineering education has become set, extreme difficulty will be encountered in making changes. If these latter are indicated, it is time to discuss them, and they should be discussed not alone by engineering educators, but by practicing engineers and employers of engineers—laymen and professionals at all levels of responsibility—who constitute the consumers or users of the product in the market for engineering services.

This paper presents the views and opinions, not of an engineering educator, but of a practicing engineer who has been employed by engineers, and also has employed engineers, and who has had a rather unique opportunity to observe the engineering profession and the practice of engineering in an objective manner. The conclusions advanced are not susceptible of definite proof from available data, rather they are primarily matters of opinion based upon observation and contact with large numbers of engineers over a long period of time.

The major purpose of the paper is not so much to argue in support of such conclusions as it is to evoke discussion of the subject of engineering education by the users of its product.

It is not believed that prewar engineering education was a failure. Accomplishments of engineers during the past half century have proved its worth. Rather, it is believed that it has done a creditable job, but that a time has arrived when it should adjust itself to current and future conditions, and should endeavor to educate students not solely to become engineers, but readily to enter engineering or other fields where their education will be of equal value. Four years is too short a time for a student to acquire a knowledge of more than the basic fundamentals of engineering and their simple application. If he so desires, he should be afforded assistance and guidance in his further search for knowledge. Every engineering student must work hard to graduate. This probably was the most valuable single thing that he learned in his course.

Prewar Engineering Education

The general objective of most engineering courses offered during the fifteen to twenty years prior to World War II appeared too often to produce a graduate well versed in the theory of, and with an academic knowledge of, practice in one particular branch, and in many instances in one specialty in the field of engineering, thus equipping the graduate to enter such field or specialty on graduation and encouraging him to do so, irrespective of what the market for services in such field might be in five or ten years.

The standard length of course was four years. Attempts to lengthen it (as had been done in the case of preparatory courses in some of the other professions) have not met with any particular success.

Because of the magnitude and complexity of the field of engineering, and the limited time available for formal professional education, those responsible for the general design and planning of engineering courses have been faced with the following alternatives:

I. To develop a broad general course, in which the student was given a thorough foundation in the basic fundamentals underlying engineering; or

II. To develop a course in which less time was given to the basic fundamentals of alternative I and more time was devoted to advanced applications to, and practices in, a single branch or specialty, with limited instruction in nontechnical subjects.

A course such as alternative I would include mathematics and the physical sciences, with their application to engineering subjects such as simple structures, mechanics of materials, thermodynamics, electrical circuits, electrical machines, and hydraulics. In addition to instruction in these general, basic practices in the field of general engineering, the broad course would include instruction in nontechnical subjects that would be useful to the engineer in his subsequent career, whether that career led to engineering, commerce, or industry. The acquisition of particular knowledge in the various specialities would be left for the period following graduation.

In the prewar period too many engineering courses were the result of a choice of alternative II. During the first two years the student was instructed in mathematics through calculus, and was given one year each of chemistry and physics. He also had a certain amount of work in the shop, field, and drafting room, with possibly a course or so in one or more elemental specialized subjects and a few courses in nontechnical subjects. Beginning in his junior year, at the latest, courses dealt with the application of the subjects studied in lower division courses to the more specialized field that he had been required to select, with further instruction in theory and practice in such specialized field. He analyzed stresses and made designs of large bridges and dams, studied the economics of power plants or systems of high-tension transmission lines, or considered problems of layout or management of industrial plants. He grappled with problems of a character that he would never meet, or at least would not have to solve, on his own responsibility for from at least twenty to twenty-five years after graduation.

Degrees were usually granted in the major branch of engineering represented by the course followed as an undergraduate. If the student returned for postgraduate study, his course too often consisted of more intensive specialization or of research.

The result of this general pattern and structure of engineering education was that the graduate had a good theoretical knowledge of the field or specialty that he had followed, an academic knowledge of practice in this field or specialty, and a slight training in some of the skills that he might need in later years. Although he might be called upon to utilize these skills, in such activities as drafting, computing, use of machines, or use of precise instruments shortly after graduation, not until a very considerable period following that date would he have acquired sufficient maturity and experience to allow him to use independent judgment or to assume any substantial responsibility in the exercise of his knowledge of theory and practice.

As a graduate he seldom had the ability to express himself adequately or a knowledge of how to acquire this ability. He had little knowledge of business or of business principles or practices, of the behavior of people, or of human institutions; and he had little or no information as to where or how to acquire

this knowledge. He was primarily a trained, rather than an educated person. If he happened, through force of circumstances or through choice, to engage in some other branch or speciality of engineering, or if he desired to pursue further the specialty that he followed in his undergraduate years, he was left largely to his own devices and judgment for guidance in pursuing his further education. Few signposts existed to guide him; and there were no goals toward which he could strive in his search for knowledge as he strove for his bachelor's degree.

The prevalent specialization or study of the more advanced applications of basic fundamentals in engineering courses cannot have been due to any single cause or condition, but rather to a considerable number of them. Courses were planned and designed by engineering educators, who were, in most instances, themselves authorities in some specialty. It is a natural tendency for specialists to predominate on engineering faculties. Names of outstanding specialists give prestige and standing. Younger faculty members can best achieve eminence and likewise advancement through acquiring a reputation as an authority in some specialty.

A further cause of this prevalent specialization lies in the popular demand for courses in specialized subjects when a particular specialty has reached a stage which indicates that it might currently offer a considerable amount of employment. For example, interest in irrigation during the early years of the twentieth century developed widespread demand in western schools for courses in irrigation engineering. Rapid development of the petroleum industry during the decade from 1920 to 1930 caused many schools to offer courses in petroleum engineering or geology. At the present time (1946) the increasing development of the aeroplane is causing many schools to offer courses in aeronautical engineering, even though the best informed persons in the industry forecast a postwar reduction in production to from 10% to 20% of present volume. When one school offers courses in a popular specialty, others follow, so as not to be accused of falling behind in the march of progress. The usual result of this practice is that a surplus of men soon develops who were trained in these specialized fields, and many graduates who entered them following commencement are forced to seek other fields or specialities. The specialized courses continue, however, long after the demand for them has subsided, since there is a strong tendency to build curricula around the particular qualifications of individual faculty members.

In considering the progress of engineering education, as it is possible to encompass it within the limited time that the student spends in school, one might liken it to a basic industrial progress in which raw materials are subjected to certain operations and processes, from which an initial product results. This product undergoes subsequent processing of many types, each depending upon the ultimate product desired.

A steel plant, taking iron ore, coke, and limestone, produces first pig iron and then steel billets. From the latter a wide variety of products are made, differing greatly in character, quality, and composition. Seldom if ever does the steel plant attempt to process the billets beyond rolling them into shapes, or to produce the ultimate product, which may range from automobile bodies to

pipe wrenches and watch springs. It produces a basic product which, however, is of such a character, composition, and quality that a more finished product can be made, through further processing, by plants which specialize in further processing for the ultimate markets.

Managers of the steel plants watch the ultimate market closely, forecast demands, and keep abreast of these demands both in volume and character of product. The engineering school that produces graduates who have majored in such specialities as structural engineering, power plant engineering, or design of gas engines may be likened to a steel plant that sought to produce not only steel billets, but also such finished products as automobile bodies or watch springs.

Specialty graduates are sometimes sought by employers to maintain the lower grades of responsibilities on their engineer staffs. In some few instances they are in demand when employers hope to groom a future manager or president; and they are always in demand, of course, when the economic requirements for engineers are greater than the available supply. In such cases, it is but natural for engineering faculties to feel satisfied that the type and character of the courses they offer meet the requirements of the market for engineering services.

Faculties have little contact with the market for engineers with from five to ten years or more of experience. If their members are engaged in outside practice, it is usually as specialists or in a consulting capacity where they have little contact with the rank and file of engineers who constitute the bulk of the profession. Employers seeking to engage older engineers secure them through sources other than alumni rosters and collegiate personnel placement offices.

The Engineering Profession

The engineering profession consists of those persons, almost entirely men (few women are found in engineering), who practice engineering. In general, it may be considered as a heterogeneous rather than a homogeneous profession, with very nebulous boundaries. The field which the practice of engineering

covers is so broad and so diversified, the professional educational background and training of those individuals engaged in it covers such wide extremes, and its members so frequently shift their employment, character of activity, and functions—that very little homogeneity exists. Furthermore, practice of en-

gineering involves activity in so many other lines that it is extremely difficult in many instances to determine whether or not a particular activity falls within or without such practice.

General Traits and Characteristics of Engineers.—In spite of this general heterogeneity of the profession and its more or less nebulous boundaries, engineers as a group of individuals do have certain more or less common traits and characteristics which they have developed as a result of their education and the type and character of their professional experience. For the same causes, they are also lacking in certain attributes.

On the credit side it may be stated that engineers in general are resourceful, hardworking, ingenious, and persistent, and have a great devotion to their work. On the debit side they are extremely narrow in their interests and outlook, and highly individualistic. An engineer is the original "man from Missouri" who "has to be shown" everything.

Engineers cannot express themselves well—too few graduate engineers can write a good report or make out a salesmanlike application for a job, even after they have been out of college from ten to twenty years. Many a graduate, capable of bigger things, never has an opportunity to do them because of his inability to "sell" his capabilities to those who might desire to utilize them. Engineers lack a "dollar" sense, seldom appreciate the relation between the cost, value, or profit. Their habit of basing their work, opinions, and conclusions on factual data, although it is an excellent one, tends to cause them to be too strongly influenced by the details or tangible aspects of a problem and to ignore the intangible phases. They fail to see the broad general features. Engineering educators should recognize the existence of these items on the debit side more than they have done and make a stronger attempt to reduce this general debit balance.

Number of Engineers.—Since the very fundamentals of engineering rest on the systematic collection, analysis, and interpretation of factual data, the paucity of available data pertaining to engineers and to the engineering profession is remarkable. Even data concerning the number of persons practicing

THE FEDERAL CENSUSES OF 1910 TO 1940, INCLUSIVE

engineering are of poor quality. For several decades the Federal Census of Occupations has listed the number of "technical engineers" gainfully employed in the United States, and Table 1 shows these figures for the past four decennial censuses. Line 3, Table 1, listing mechanical engineers "and others" includes

engineers in all categories not otherwise mentioned in the table. The 1940 data include engineers seeking work but not those employed in emergency work. The total number of persons in each category listed (except mining engineers) has increased at a rate greater than the increase of national population, mechanical and other engineers showing the greatest rate of increase. Proportionately, the number of civil engineers and surveyors, listed together until 1940, decreased more than one third and that of mining engineers more than one half. Electrical engineers increased slightly, and mechanical and other engineers increased two and one-half times.

The 270,000 technical engineers listed in the 1940 Census cannot be considered as including all persons embraced in the practice of engineering in the United States. There are large numbers of persons listed under other occupational classifications who, without question, are following the practice of engineering. For example, the 1940 Census lists 9,236 mining engineers. Table 2

TABLE 2.—NUMBER OF PERSONS LISTED IN OCCUPATIONS AMONG WHICH MAY BE FOUND A CERTAIN PROPORTION OF TECHNICAL ENGINEERS (CENSUSES OF 1910 TO 1940, INCLUSIVE)

Item	Description	1910	1920	1930	1940
1	Chemists, assayers, and metallurgists...	16,273	32,941	47,068	59,333
2	Designers, draftsmen, and inventors....	47,449	70,651	102,730	107,286
3	Mine foremen and inspectors..........	23,338	36,931	34,286	33,457
4	Mine operators, officials, and managers..	34,325	25,234	30,896	31,672
5	College presidents and professors.......	15,668	33,407	61,905	65,627
6	Totals........................	137,053	199,164	276,885	297,375

shows that in 1940 there were 297,375 persons employed in occupations either closely, or generally, allied with mining engineering, or with other branches of engineering. Without question there were a considerable number of mining engineers, among these 297,375 persons, and also large numbers of engineers in other classifications. Similarly there are many other occupational groups more or less closely associated with technological activities, such as employees of public agencies, railroads, power companies, contractors, and industrial plants, among whom will be found many engineers. It is quite probable that the actual number of persons who could have been properly enumerated as practicing engineers in 1940 was several times the number listed as technical engineers in the census of that year.

This uncertainty as to the number of engineers in the United States is not in any way the responsibility of the Census Bureau. The enumerators of this bureau are not supposed to be skilled in personnel classification; they must accept the occupational classification given them, and in most instances they secure information as to the working members of a family from the housewife, whose knowledge of the occupation of her menfolk is usually ascertained from the title of the position which they hold, such as foreman, inspector, draftsman, designer, surveyor, or engineer.

An amusing incident illustrative of the difficulty of listing properly the occupational status in the census enumeration came to the writer's attention a few years ago. A friend of his, an engineer, was collecting occupational data in connection with a market survey in a large city, and was surprised to find some two hundred civil engineers listed as residing in a certain area of that city largely occupied by colored persons. Closer investigation disclosed the fact that a large number of colored drivers of garbage collection trucks and their assistants, who lived in the area, had given their occupations to the enumerator as sanitary engineers. They were employed by the Bureau of Sanitary Engineering of the City Engineering Department and, since sanitary engineering was a subclassification of civil engineering, they had been enumerated under the latter heading.

Composition of the Engineering Profession.—The diversity of activities, responsibilities, and functions in engineering practice is great. To describe, properly, the exact place that a person occupies in the practice of engineering, his duties must be classified under each of the following:

A. Horizontal Classification.—The position must be segregated as to the major branch of engineering under which it falls, and then under the particular specialty or subspecialty of the major branch.
B. Vertical Classification.—The relative importance, difficulty, and responsibility of the duties performed, which may range from subprofessional activity upward through the most complicated theory and practice, and the training and experience required to perform them must be determined.
C. Functional Classification.—The type and character of activity followed, such as design, construction, research, operation, sales, consultation, or administration, must be established.

Civil service and personnel administrators have made considerable progress in this type of "job specification," but the resulting number of individual classifications has reached vast proportions.

Seldom does an engineer remain in a given classification for any great length of time. The nature of his activity is one of constant change, such change frequently occurring in each of the three groups of classifications.

The 1940 Federal Census, for the first time, presented certain data relative to education, age, and income (from salaries and wages) for certain occupational groups, including technical engineers. Although there is no way of determining whether the data pertaining to this group are representative of those for the entire engineering profession (including engineers who were listed as following other occupations), as given, they do develop some interesting facts pertaining to a group who compose a substantial segment of the engineering profession. The census data are presented for that purpose, rather than as representative of the entire profession. Data for certain other occupational groups are also presented for purposes of comparison.

Education.—Table 3(*a*) contains data pertaining to educational qualifications of certain categories listed in the 1940 Census report under "Technical

TABLE 3.—PERCENTAGE ANALYSIS OF THE TOTAL NUMBER OF PERSONS IN THE 1940 CENSUS WHO WERE ENGAGED IN CERTAIN TECHNICAL AND OTHER OCCUPATIONS

Item	Description	Technical Engineers					Other Professional and Subprofessional
